Many plans have been proposed for enabling a man to walk beneath the surface of water in such a manner as to assist in the recovery of property from wrecks, by means of waterproof coverings for the head and upper part of the body, or of strong vessels in which every part but the arms should be encased; a supply of air being either transmitted from above by a flexible pipe, or contained in the cavities of the protecting armour. Dr. Halley devised such an apparatus. The diver's head was covered by a heavy leaden cap, supplied with air by a flexible tube extending from the large bell. The diver was to coil this tube round his arm, and unwind it as he left the bell; and to use it as a clue to direct him to the bell in returning. This pipe was formed of leather soaked in oil and hot wax, and was held open by a spiral coil of brass-wire; its internal diameter being about one-sixth of an inch. The front of the helmet was glazed; and the diver, who was clothed in a thick woollen dress fitting close to the body, to diminish the effect of the coldness of the water, was enabled to walk by means of a weighted girdle and weighted clogs. The invention of waterproof India-rubber cloth, which has been applied in various ways to diving-apparatus, affords great facilities for the manufacture of water-tight tubes for such a purpose. Many varieties of diving-dresses have been since employed. Mr. Thornthwaite introduced a few years ago a contrivance for facilitating the descent and ascent of a diver. It consists of a hollow belt of India-rubber cloth, to which is attached a small but strong copper vessel. Into this vessel air is to be forced by a condensing-syringe until it has a pressure of thirty or forty atmospheres. The belt is then put on, in a collapsed state, so that it has no buoyancy, and does not impede the descent of the diver; but when he desires to rise, he opens a valve, by which the condensed air escapes from the copper vessel into the belt. As it expands the belt, it affords sufficient buoyancy to raise the diver immediately to the surface.

A few years ago Dr. Payerne attracted a good deal of public attention by his attempts to dispense with an air-pump to supply air to diving-bells. He made his experiments in 1842, first at Paris, and then at the Polytechnic Institution in London. The ordinary air-tube was removed from the diving bell; and he remained under water three or four hours without any connection with the external air. The experimenter took down with him a small box, containing some chemical agent which will absorb carbonic acid gas as fast as it is generated, and another agent which will evolve pure oxygen gas rapidly; and as he vitiated the air in the bell by his breathing, the one chemical substance absorbed the carbonic acid from it, while the other furnished a fresh supply of oxygen. Many such chemical agents are known; but we believe Dr. Payerne professed to keep his method secret. He made one or two descents at Spithead, near the wreck of the Royal George.

DNIEPER and DNIESTER. These two rivers of European Russia are made the media of conveying much merchandize and produce to the Black Sea. The entire length of the *Dnieper*, with its windings, is about 1000 miles. Its basin comprises fourteen of the finest provinces of Russia, with all of which it has communication by its navigable branches and by canals. The river is navigable almost from its source to its mouth; even the obstructions presented by the cataracts have been removed by the magnificent hydraulic works of the Russian government; several of the ledges of rocks having been entirely removed, and channels formed which are protected from winds by lofty dikes of granite. Produce is generally conveyed down the river to the cities on the Black Sea; but fleets of large barks also pass annually by the canals to Riga and St. Petersburg. The freights consist chiefly of timber, corn, iron, linen, hemp, salt, &c. The *Dniester* which is about 600 miles long, carries cargoes of timber, grain, and other produce to Odessa, on the Black Sea: much of which is brought to England.

DOCKS AND DOCK-YARDS. A dock is a place artificially formed for the reception of ships, the entrance of which is generally closed by gates. There are two kinds of docks, dry-docks and wet-docks. The former are used for receiving ships in order to their being inspected and repaired. For this purpose the dock is so contrived that the water may be admitted or excluded at pleasure, so that a vessel can be floated in when the tide is high, and the water run out with the fall of the tide, or be pumped out, the closing of the gates preventing its return. Wet docks are formed for the purpose of keeping vessels always afloat. Dock yards belonging to the government usually consist of dry docks for repairing ships, and of *slips* on which new vessels are built; besides which they comprise various workshops and storehouses.

The first wet dock for commercial purposes made in this kingdom was formed in the year 1708 at Liverpool. Since that time others have been added at different periods; and at present the margin of the Mersey along the whole extent of the town, for about three miles, is occupied by docks. They comprise the *Northern*, the *Clarence*, the *Victoria*, the *Waterloo*, the *Prince's*, the *George's*, the *Canning*, the *Manchester*, the *Salthouse*, the *Duke's*, the *King's*, the *Queen's*, the *Albert*, the *Union*, the *Brunswick*, the *Herculaneum*, and the *Harrington* docks. They cover more than 100 acres, and have an extent of quay ten or twelve miles in length.

At Birkenhead are docks noticed in a former article [BIRKENHEAD]. Fleetwood, Hull, Bristol, and other commercial towns, have convenient docks.

The first commercial wet dock constructed in the port of London was for the accommodation of vessels employed in the Greenland whale fishery. This dock, which is now known as the *Commercial Dock*, is situated at Rotherhithe; it occupies altogether 49 acres, about four-fifths of which are water: it is now used mainly for the timber and corn trade. Adjoining it is the *East Country Dock*, used for the timber trade.

Up to the end of the last century, nearly all

ships arriving in London discharged their cargoes into lighters in the river. To remedy this inconvenience, a plan was sanctioned in 1799 for constructing wet docks for the reception of ships employed in the West India trade. The *West India Docks* extend across the Isle of Dogs. The import dock is 879 yards long and 166 yards wide; the export dock is of the same length and 135 yards wide; there are besides two basins, one at each entrance, that at Blackwall being 5 acres, and that at Limehouse 2 acres in extent. A canal cut across the Isle of Dogs has been also appropriated as a dock or basin. The *London Docks*, situated in Wapping, and finished in 1805, consist of the western dock of 20 acres, the eastern dock of 7 acres, and the tobacco dock, between the other two, of more than 1 acre. The space included within the dock walls exceeds 71 acres. The warehouses, especially those for tobacco and wine, are of vast extent. The *St. Katharine's Docks*, situated between the London Docks and the Tower, were opened in 1828; the outer wall encloses an area of 24 acres, of which 11 acres are water, the remainder being occupied by quays and warehouses. There are two docks each capable of receiving vessels of 800 tons burden.

The Commercial Dock Company propose, in 1851, to purchase the East Country or Greenland Dock, and to expend 200,000*l.* in enlargements and improvements.

In the half year from June to November 1850, the laden ships which entered the London Docks from foreign countries were 685, measuring 186,517 tons. The stock of goods in the warehouses, on Nov. 30 in that year, amounted to 124,825 tons. A new stack of warehouses has just been constructed by the company on the West Quay.

At the St. Katharine's Docks the goods received during the year 1850 amounted to 119,149 tons. The ships which entered with cargoes were 703, of 152,046 tons; and those which entered to load were 259. The goods in warehouse on December 31, 1850, were 68,121 tons.

Collier docks are about to be formed opposite Woolwich, near the North Woolwich station of the Eastern Counties Railway. A dock of 70 acres is planned, available not only for collier ships but for passenger steamers.

The construction of *floating dry docks* is now engaging the attention of engineers: the principle being, to adopt a means of buoying up a ship on some kind of floating support, so as to leave it high and dry. There are now being constructed for the United States Government, at Philadelphia, docks of a remarkable kind on this principle. There are ten closed compartments, called sections, capable of being exhausted of water by means of pumps; and when so exhausted, each section can buoy up a weight of 800 tons. Six of them together would bear up a ship of the line, while four would bear a frigate. There is a stone basin or dock, 350 feet long by 226 wide. When a ship is to be dry-docked, some of the sections are filled with water sufficiently for the vessel to be floated in on the top of them; and when brought into the basin, the water is pumped out of the sections, and the vessel thus buoyed up. There is a railway, also, by which the vessel may be brought up completely on dry land. These remarkable works are expected to be finished during the year 1851. Other works of a similar kind are being constructed in other parts of the United States.

The largest gates ever made for docks, perhaps, are those which Messrs. Rennie have recently made for the Russian government, to be fitted up at Sevastopol on the Black Sea. On account of the peculiar locality of the town with respect to the depth of the shores, three locks were made so as to raise a ship of war to a height of 30 feet above the sea level. These locks have nine pairs of gates, varying from 21 to 34 feet in height, and from 47 to 64 feet in width. On account of the ravages of a peculiar worm, the use of wood was determined against, and iron substituted. The gates consist of wrought iron plates in cast iron frames; and so enormous are some of the masses, that the engineers had to erect large and costly machinery for planing and punching them.

Our Government Dock Yards are briefly described under the names of the towns where they are situated. [CHATHAM; PLYMOUTH, &c.]

DOLL MANUFACTURE. Let not any one suppose that the making of dolls is too trifling an employment to merit notice in a work devoted to industrial pursuits. It affords bread to numerous persons, and is subjected to as many divisions and subdivisions as other manufactures. A glass manufacturer of Birmingham, some years ago, astonished a Committee of the House of Commons by stating that he had received, at one time, an order for 500*l.* worth of dolls' eyes!

There are two classes of dolls—*wooden* and *sewed;* the former cheap, and the latter more expensive. The wooden dolls make but little approach to anatomical correctness; whereas the sewed dolls are the results of more ambitious skill. The wooden doll passes through few hands in the process of making; but the sewed doll is the work of many distinct classes of artificers—such as the doll sewer and stuffer, the dolls' head maker, the dolls' arm and leg maker, the dolls' wig maker, the dolls' eye maker, and the doll dresser.

In wooden dolls the body is turned in a lathe, thereby giving to the human bust a form which nature never gave—an equal rotundity on all sides. They are carved or cut by hand to impart certain improvements; and the legs are made—with calves or without calves—according to the price. A composition is laid on the face; and the painter's pencil is employed to supply lips, eyebrows, &c. Every doll, except in the humblest station of life, has jointed legs, which are fixed to the body by a kind of wooden hinge. Unless the doll have painted ringlets, real ringlets are purchased from the dolls' wig maker. The arms are usually made of stuffed leather.

The *sewed* dolls go through a larger number of processes, and employ more persons. The maker cuts out the calico which is to form the outer surface, and gives it together with sawdust or wool to the doll sewer and stuffer, by whom the structure of the doll is built up. The composition heads for these dolls are usually made of *papier maché*; but they have a superficial coating of wax; they are painted flesh colour, and then dipped into melted wax. The mould for the papier maché is made from a wax model, and the substance itself is a kind of sugar paper, reduced to a pulp. The arms and legs, and the wig, are made by other persons.

Dolls' eyes seem to form the most curious department of this curious manufacture. They are of two kinds, the cheap and the expensive. The more cheaply constructed eyes are simply small hollow glass beads or spheres, made of white enamel, and coloured either black or blue, but without any attempt at diverse colouring. The better kind of eyes, called by the makers natural eyes, are made in the same manner so far as concerns the glass or enamel, but the iris is represented by a painted or stained ring.

In one of the interesting papers recently published in the *Morning Chronicle*, some curious statistical facts are given respecting the doll manufacture. The commonest wooden dolls were formerly sold at a penny each, but now (competition having affected dolls as well as more important commodities) command a price of only one farthing. Some of the sewed dolls are stuffed with sawdust and sewed for half a crown per gross. The commonest dolls' eyes sell from five to six shillings per twelve dozen pairs; while the best or *natural* eyes obtain a price of fourpence per pair. Dolls' eyes are largely exported; in Spanish America *black* eyes only will find a sale, while in this country *blue* eyes are the favourites.

Gutta percha is now employed as a material for some dolls; and various costly novelties are from time to time introduced. The *speaking* doll is an object of great admiration to doll buyers; but the six guineas' price limits the sale to a small number. It was the invention of a London doll maker, who, after nine years of experimental trial and failure, succeeded in making his doll speak the two favourite nursery words 'mama' and 'papa.' One of these was sent to St. Petersburg; it became injured on the way, and lost its speech, which no Russian doll-maker was found able to restore.

DOLLOND, JOHN, as an eminent practical optician, calls for a few words of notice in this place. He was descended from a French refugee family, settled in Spitalfields, and was born in 1706. His father was an operative silk-weaver, and his own boyhood was spent in the drudgery of a manufactory; he found time however to make considerable progress in the study of mathematics and natural philosophy; besides which he cultivated anatomy, and devoted his leisure moments to ecclesiastical history and to languages. About the year 1755 he commenced a series of experiments on the dispersion of light, and in 1757 he made the decisive experiment which showed the error of Newton's conclusion respecting the proportional refrangibility of light in all media. In consequence of the discovery, Mr. Dollond was enabled to construct what are called achromatic telescopes, or such as afford images of objects almost wholly free from coloured fringes. The discovery was rewarded, by the Council of the Royal Society, with the Copley Medal. After this he became eminent as the first optical instrument maker of his day, and communicated many papers to the Royal Society.

Mr. Dollond died in 1761; but his establishment has ever since maintained its high character, under various members of his family.

DOLOMITE. This rock, having the aspect and general geological history of limestone, but composed of carbonate of magnesia united to carbonate of lime, usually atom to atom, occurs as a part of the oolitic system of the Alps and Apennines, and of the German Jurakalk; and it is perhaps proper to call by the same name the crystallised magnesian limestone of Nottinghamshire, Derbyshire, Yorkshire, and Durham. The best example of this English dolomite is at Bolsover, in Derbyshire, whence the stone is taken to build the new Houses of Parliament.

DOME, a term applied to a covering of the whole or part of a building. The word *dome* is strictly applied to the external part of the spherical or polygonal roof, and *cupola* to the internal part.

The most magnificent dome of antiquity is that of the Pantheon, supposed to be a chamber of the great baths of Agrippa. Internally it is divided into five rows of square compartments, which are supposed to have been decorated with plates of silver. The external part of the dome appears also to have been decorated with bands of bronze. The base of the dome externally consists of a large plinth with six smaller plinths or steps above it; and in the curve of the dome a flight of steps is formed which leads to the opening at the top. The dome is constructed of bricks and rubble. The thickness is about 17 feet at the base, 5 feet 1½ inches at the top of the highest step, and 4 feet 7 inches at the top of the dome. The circular wall which supports the dome is 20 feet thick.

The Thermæ, or baths, of Caracalla, Titus, Constantine, and Diocletian, were all surmounted by domes. Near Pozzuoli there is a very perfect circular building with a dome 96 feet in diameter, built of volcanic tufo and pumice stone. The temple of Minerva Medica, without the walls of Rome, had a dome of ten sides built of brick and pumice stone. The dome of Santa Sophia, at Constantinople, built in the reign of Justinian, rests on the square formed at the intersection of the arms of a Greek cross. The dome is supported by four corbellings placed in the angles of the square, surmounted by a kind of cornice which supports a circular gallery. Externally the dome is divided by projecting ribs, rounded and covered with lead. The top is surmounted by a lantern or finishing like a baluster, on which is a cross. The dome of San Vitale at Ravenna, is curiously constructed. The lower part of the plan is a regular octagon, which is supported by eight piers placed at the angles of the dome; in the spaces between the piers are seven niches, divided into two stories. The wall above the niches sustains a hemispherical dome, the plan being a circle described within a regular octagon. The dome is built of a double row of pipes, hollow at one end and pointed at the other, the point of one being placed in the hollow of the preceding; it is covered with mortar both within and without. The church of San Marco at Venice, built in the tenth century, is decorated with five domes. One of these, placed in the centre of the church, is much larger than the others. Each dome is enclosed within four pieces of semi-cylindrical vaulting, forming together a square, in the angles of which are four corbels, which gather in the circular base of each dome. The dome of Santa Maria del Fiore, at Florence, built by Bruneleschi, stands upon an octagon tower 175 feet high; it is double, being the first of the kind that is known. The internal dome is connected only at the angles to the external one, and forms a species of gothic vault. The first modern dome constructed in Rome was that of the church of Our Lady of Loretto, built in 1507; it is double, and circular in plan, and is constructed on double consoles.

The dome of St. Peter's at Rome, as planned by Michael Angelo, and executed by himself and succeeding architects, is thus constructed. It stands upon four piers 62 feet high. From the arches spring corbellings, which are finished by an entablature; upon this is a plinth, octagonal within and circular without; upon this is a circular stylobate, 12 feet high. Above the stylobate is the drum of the dome, built of rubble and fragments of brick, and pierced by sixteen lofty windows: the height of the drum is about 52 feet. On this is placed a circular attic story, 19 feet high, and then comes the double dome. The space between the two domes varies from three to ten feet in width. The thickness of the inner dome is about six feet; the outer dome is of less thickness: the two are joined together by sixteen strong walls or spurs. Above the dome are a lofty lantern and cross: the dome is about 102 feet high above the drum, and the lantern and cross 90 feet above the dome.

The dome of St. Paul's Cathedral, London, is placed over the intersection of the four naves. The ground plan is a regular octagon: four of the sides are formed by the four great arches of the naves; the other four sides are formed by false arches of the same size. The corbellings gather in a circle, and are surmounted by a complete entablature decorated with consoles. The drum, which surmounts the entablature, is 62 feet in height; and from the summit of this rises the double dome. The inner dome is much less lofty than the outer: the outer one is constructed of wood, covered with lead.

The dome of the Invalides at Paris is raised on the centre of a Greek cross, on an octagonal base with four large and four small sides A circular entablature is placed over the corbellings, and on the entablature is raised the drum of the dome. The dome, which is double, rises from a springing common to both. The lower or internal dome, constructed with masonry, is spherical; whereas the outer dome is of a spheroidal form, and constructed of stone at the base, and of brick above. The dome of the Pantheon at Paris is constructed entirely of stone, and is placed in the centre of a Greek cross. It is supported by four triangular piers, pierced above with arched openings, and between the piers with the openings are large arches. Between these arches rise the corbellings, which are gathered in to form the circular plan of the drum. The arches and the corbellings are crowned with a large entablature about 13 feet high, and above this is the circular drum, 55 feet high. There are three domes one within another; one forming the interior vault or roof, a second forming the exterior, and a third shaped like the small end of an egg, and intermediate between the other two, for supporting the lantern.

The following admeasurements of most of the principal domes of Europe are from Mr. Ware's 'Tracts on Vaults and Bridges.'

	Feet in diameter externally.	High from the ground line.
Dome of the Pantheon	142	143
" Minerva Medica	78	97

DONEGAL. This Irish county is rich in quarries of fine stone. The white marble of Dunlewy, near the mountain Erigal, is stated to be of an excellent quality, and its bed very extensive; it has been traced over a space of half a mile square, and is so finely granular, that it may be employed in the nicest works of sculpture. 'Its texture and whiteness,' says Mr. Griffith, 'approach more to those of the Parian than of the Carrara marble. It is very well known that perfect blocks of the Carrara marble are procured with great difficulty, and I firmly believe that the marble of Dunlewy is free from mica, quartz grains, and other substances interfering with the chisel, which so frequently disappoint the artists who work upon the marble from Carrara.' A large supply of fine siliceous sand was formerly drawn from the mountain of Muckish by the glass-houses of Belfast, and considerable quantities have been exported to Dumbarton for the manufacture of plate and crown glass.

The linen manufacture is carried on to a very considerable extent, and is increasing in the cultivated country about Raphoe and Lifford, and also in the neighbourhood of Ballyshannon. Bleachgreens are numerous in the neighbourhood of Stranorlar. Strabane, in the county of Tyrone, within two miles of Lifford, is the principal linen market for the southern district. Londonderry and Letterkenny are the markets for the district to the north. Burning kelp continues to be a profitable occupation along the coast. About the beginning of the present century private distillation was carried on to an immense extent all over this county, particularly in the baronies of Inishowen and Kilmacrenan: repeated baronial fines and the vigilance of the authorities have latterly checked the practice, but it still exists to some extent in the mountain districts. Considerable numbers of whales have from time to time been taken off this coast; but this, as well as the herring fishery, is now neglected. In 1802 there were but two flour mills in this county. There was a few years back an export of 3000 to 4000 tons of corn annually from Letterkenny, and the remaining export of the county is from Londonderry; but it has suffered in the recent general depression of Ireland.

DORSETSHIRE. This county yields many mineral substances useful in the arts. The eastern parts of the county are mostly occupied by the plastic clay. Potters' clay in beds of various thickness and at different depths alternates with loose sand in this formation in the Trough of Poole; it is sent to Staffordshire, where it is mixed with ground flints, and employed in the finer kinds of pottery. Beneath the potters' clay lies a seam of very friable earthy brown coal, somewhat like Bovey coal. The Purbeck strata, belonging to the upper series of the oolitic formation, consist of argillaceous limestone alternating with schistose marl; they crop out from under the iron-sand in the Isle of Purbeck. A variety of the Purbeck stone, known as Purbeck marble, was formerly much used in buildiug. The Portland oolite, another member of the same series, which succeeds the Purbeck stone, occupies the remainder of the Isle of Purbeck and the whole of that of Portland. It consists of a number of beds of a yellowish white calcareons freestone, generally mixed with a small quantity of siliceous sand. The varieties of this formation afford the greater part of the stone used for architectural purposes in London. In the Portland quarries, the saleable stone occupies layers of strata situated several feet beneath the surface; and the quarrymen have to exert great labour in the removal of the superincumbent rubbish, before they can reach the stone. The thickness of workable stone varies from 7 to 16 feet, and the works proceed at the rate of about an acre of good stone per annnm. Almost the entire mass of Portland Isle consists of the Purbeck series.

The Dorset butter is in good repute in London and Portsmouth for ship provision as well as domestic use: it is not so salt as the Irish, and is therefore preferred, although the Irish is richer when it is of the best quality. Dorset salt butter, when well washed, is very commonly sold in London for fresh butter. The butter is made from the cream, and the skimmed milk is made into cheese. The Dorsetshire skim-milk cheese is preferred on account of streaks of blue mould which frequently run through it.

In 1847 an act was passed for the formation of a harbour of refuge off the Isle of Portland by the construction of a breakwater, extending northward from the north-eastern point of the island for 2¼ miles, so as to include a large part of Portland Road. Owing to the facilities afforded by the presence of an abundant supply of suitable stone on the island, it is estimated that the cost will not exceed 500,000*l.* The works are now steadily advancing.

Dorsetshire contains very few towns of a manufacturing character, and will only to a limited extent take part in the Industrial Exhibition.

DOUAI. The inhabitants of this ancient French city are engaged in the manufacture of linen, lace, thread, gauze, cotton, soap, glass, leather, beer, gin, pottery, paper, oil, chemical products, and refined sugar. A considerable trade is carried on also in corn, wine, brandy, chicory, wool, hops, flax, woollen cloth, and cattle. Exhibitions of the industrial products take place every two years. The commerce of the town is more active than formerly, in consequence of its connection by railroads with the chief towns of France and Belgium. Douai has also extensive communication by means of the Scarpe, which falls into the Schelde, and by numerous canals that connect it with the principal trading towns of France, Belgium, and Holland.

DOUBLE-BASE, or *Contra-Basso*, is the largest musical instrument of the viol kind. In England, Italy, and France, it has three strings: in Germany a fourth is added. From the body and firmness of its tone, it is considered to be the foundation of an orchestral band.

DOVER HARBOUR. [HARBOURS OF REFUGE.]

DOVETAIL is the end of a piece of wood fashioned into the fan-like form of a dove's tail, and let into a corresponding hollow of another piece of wood.

DOWN. In this Irish county the linen manufacture is the staple trade, and gives employment to a greater number of operatives, in proportion to the population, than in any other part of Ireland. It has been estimated that the linen trade gives employment, in various ways, to 10,000 persons in the county. Much of the flax employed is grown in the county; and seed for this flax is imported from Flanders. The new impetus now being given to the flax manufacture will probably lead to favourable results in this county. Machine-spun yarn is now mostly used for the warp-thread of linen, but hand-spun yarn is preferred for the weft. The weaving is mostly done in cottages, by persons who devote a part of their time to farming. There are about a dozen towns in Downshire where linen markets are held. The bleaching of the woven linen is a large branch of manufacture, conducted in bleach fields on the banks of the river Bann. The remaining articles of manufacture in the county are chiefly muslin, leather, salt, glass, and vitriol. The fisheries on the coast are rather extensive. The chief exports of the county are shipped at Belfast and Newry.

At Ardglass, Banbridge, Downpatrick, Portaferry, Newtownards, &c., much manufacturing is carried on. Belfast, though the principal port for this county, is in Antrim. Newry ranks high in exports, and the imports are very considerable. Steamers sail regularly to Liverpool and Glasgow, and many vessels trade to America, the Baltic, the Levant, and various parts of England. Besides flour and oatmeal mills, there are various manufactures carried on connected with ship-building, and the retail trade of the town is extensive.

DRACHM, or DRAM. There are two drachms or drams remaining in our system of weights. The first is the sixteenth part of the ounce, which is the sixteenth part of the pound avoirdupois of 7000 grains. In the national standard, the troy pound of 5760 grains, there is no dram; but this weight occurs in that particular division of the troy pound which is used by apothecaries, in which the dram is the eighth part of the ounce, which is the twelfth part of tne pound of 5760 grains. The *drachma* was a Greek silver coin, the weight of which was abont 61 grains.

DRACI'NA, or *draconin*, is the colouring matter of Dragon's Blood gum. It is of a fine red colour, and very fusible; it may be worked between the fingers, and drawn into threads. It melts at about 130°

DRAINING. As a certain quantity of moisture is essential to vegetation, so an excess of it is highly detrimental. In the removal of this excess consists the art of *Draining*, which presents three principal features:— 1. To drain land which is flooded by water coming over it from a higher level, and having no adequate outlet below. 2. To drain land where springs rise to the surface, and where there are no natural channels for the water to run off. 3. To drain land which is wet from its impervious nature, and where the evaporation is not sufficient to carry off all the water.

The first branch includes all those extensive operations where large tracts of land are reclaimed by means of embankments, canals, sluices, and tunnels. Such works are generally undertaken by associations under the sanction of the government, or by the government itself: the BEDFORD LEVEL is an example of them. In Switzerland many marshes have been laid dry by tunnelling through solid rocky obstructions; and in Holland vast tracts are protected from flooding by embankments.

Where the land is below the level of the sea at high water, it requires a constant removal of the water which percolates through the banks or accumulates by rains; and this can only be effected by sluices and mills, as is the case in the fens in England. The water is collected in numerous ditches and canals, and led to the points where it can most conveniently be discharged over the banks. In hilly countries it sometimes happens that the waters which run down the slopes of the hills collect in the bottoms where there is no outlet, and where the soil is impervious. In that case, it may sometimes be laid dry by cutting a sufficient channel all round, to intercept the waters as they flow down, and to carry them over or through the lowest part of the surrounding barrier. In draining a great extent of land, it is often necessary to widen and deepen rivers, and alter their courses; and not unfrequently the water cannot be let off without being carried by means of tunnels under the bed of some river, the level of which is above that of the land.

The draining of land which is rendered wet by springs arising from under the soil is a branch of more general application. The object is to find the readiest channels by which the superfluous water may be carried off; and for this purpose an accurate knowledge of the strata through which the springs rise is indispensable. Abundant springs which flow continually generally proceed from the outbreaking of some porous stratum in which the waters were confined, or through natural crevices in rocks or impervious earth; and these, as well as land-springs, are traced by geological means. Wherever water springs, there must be a pervious and an impervious stratum to cause it, and the water either runs over the impervious surface, or rises through the crevices in it. When the line of the springs is found, the obvious remedy is to cut a channel with a sufficient declivity to take off the water in a direction across this line, and sunk through the porous soil at the surface into the lower impervious earth. The place for this channel is where the porous soil is the shallowest above the breaking out, so as to require the least depth of drain; but the solid stratum must be reached, or the draining will be imperfect. When there is a great variation in the soil, and it is difficult to find any main line of springs, it is best to proceed experimentally by boring in various parts; whereby it will generally be easy to ascertain whence the water arises, and how it may be let off. When the drains cannot be carried to a sufficient depth to take the water out of the porous stratum, it is often useful to bore numerous holes with an auger in the bottom of the drain through the stiffer soil, and the water will either rise through these bores into the drains and be carried off, or it will sink down through them if it lies above. This method is often advantageous in the draining of peat mosses. If the soil, whatever be its nature, can be drained to a certain depth, it is of no consequence what water may be lodged below it. It is only when it rises so as to stagnate about the roots of plants that it is hurtful.

The third branch in the art of draining is by far the most expensive operation, in consequence of the number of drains required to lay the surface dry, and the necessity of filling them with porous substances, through which the surface water can penetrate. There is often a layer of light earth immediately over a substratum of clay, and after continued rains this soil becomes filled with water, like a sponge, and no healthy vegetation can take place. In this case numerous drains must be made in the subsoil, and over the draining tiles or bushes which may be laid at the bottom of the drains loose gravel or broken stones must be laid to within a foot of the surface, so that the plough shall not reach them. The water will gradually sink into these drains, and be carried off, and the loose wet soil will become firm and dry. The slope of the field and the fall which can be obtained for the drains, their size and depth below the surface, the angles at which they intersect each other, and their number—all are circumstances which require the drainer's best attention. In draining clay land, where there is only a layer of a few inches of loose soil over a solid clay which the plough never stirs, the drains need not be deeper than two feet in the solid clay, nor wider than they can be made without the sides falling in. The common draining tile, which is a flat tile bent in the form of half a cylinder, is the best for extensive surface draining. In solid clay it requires no flat tile under it; it is merely an arch to carry the loose stones or earth with which the drain is filled up. In grass land the sod may be laid over the drain after it has been filled up, so as to form a slight ridge over it. Sometimes a drain is covered with a sod, without any tile whatever; and at ether times a twisted rope of straw is thrust into the drain. Draining tiles are now made of various shapes and sizes.

As the draining of wet clay soils is the only means by which they can be rendered profitable as arable land, and the expense is great, various instruments and ploughs have been contrived to diminish manual labour and expedite the work. Among these are the common mole plough, the draining-plough, Smith's subsoil plough, tapering spades, and hollow spades. Weir's improved draining level is one of the instruments now often employed in these works.

The draining of Haarlem Lake is one of the greatest hydraulic enterprises ever conducted. We have nothing in this country that can give an adequate idea of this lake, or the necessity of its being drained. Three centuries ago there were several small lakes in the flat district which lies between the towns of Amsterdam, Leyden, and Haarlem, in Holland; but by the gradual wearing away of the soft ground between them, many of these became converted into one large lake; and the shores continued to be washed away so extensively, that by the beginning of the 18th century a lake was formed covering an area of 45,000 acres. As the level was 13 feet below the level of the neighbouring sea, there was no outlet for the water; and although the Dutch incurred heavy expenses to endeavour to arrest the enlargement of the lake, they had no means of diminishing it. At length, in 1836, two inundations occurred of so serious a character, as to determine the Dutch government to drain the lake at any cost; one inundation covered 10,000 acres of low land near Amsterdam, while another covered 19,000 acres near Leyden. The first work was to dig a canal entirely around the lake, 38 miles long, 120 feet wide, and 9 feet deep; this canal was to accommodate the immense water traffic which was conducted on the lake, and to serve as a receptacle for the water of the lake. The next point was, to close with large earthen dams all inlets into the lake, so that it should have no increase, except from rain water. Other hydraulic works were executed in other places, to facilitate the flow of water into the sea as soon as it was raised from the lake. These preliminary works occupied the time from the year 1840, when the enterprise was determined on, till 1845, when the steam-engines were set to work. These engines are the largest that have ever been constructed; they were made by Cornish engineers, who have acquired great skill in the manufacture of steam-engines which shall perform a great amount of work with a small amount of fuel. Each steam engine has an enormous cylinder 12 feet in diameter, with an annular or ring-shaped piston; and within this piston cylinder is another cylinder and piston 7 feet in diameter. Eleven pumps, more than 5 feet in diameter of barrel, are ranged around a sort of tower, on which the steam engine is placed; and all these enormous pumps are worked at once by the steam engine. The water is lifted by the pumps from the lake into the canal, whence it flows by sluices into the sea. It was calculated that about a thousand million tons of water would have to be lifted from the lake; and that after it was drained, there would regularly be about fifty millions of tons that would require to be annually removed, the result of drainage and rain. It will serve to convey some idea of the enormous power of the engines employed, that each engine raises 112 tons of water 10 feet high at one stroke.

A draining operation of great magnitude is about to be commenced at the æstuary called the *Wash*. This æstuary forms a sort of bay between Norfolk and Lincolnshire, and into it flow the rivers Witham, Nene, Welland, and Ouse. It has become so silted up, that a large area is utterly useless—too shallow to be available for navigation, and too wet to be used for agricultural purposes. To deepen the mouths of all the rivers, and to reclaim many thousand acres of marshy useless land, are the great objects of the Wash Drainage enterprise. All the rivers will be greatly improved by these works; while it is estimated that the reclaimed land, as an agricultural estate or estates, will pay for the operation, and yield an adequate profit. The towns of Lynn, Wisbeach, Spalding, and Boston, situated respectively on the four rivers, will all be benefited by the operation, as vessels of larger tonnage will be enabled to reach those towns than can ascend the present partially-choked streams.

DRAWBRIDGE is a bridge used in ancient castles and in modern fortresses over a ditch or fosse, and capable of being raised up at one end, so as to cut off the means of access. Drawbridges are usually formed of boards nailed to a frame constituting a platform, which is furnished at one end with hinges fastened to a beam placed parallel to one end of the frame. The bridge is raised by means of chains passed through the masonry of the gate, and these chains are worked either by wheels or by hand.

DRAWING, in its strict meaning, is the art of representing objects on a flat surface by lines describing their forms and contours alone, independently of colour or even shadow, although the latter is closely allied with drawing, both in practice and in theory. Although drawing embraces all objects and their forms, in its more restricted technical sense it is usually understood to imply the drawing of the human figure, as that species of it which is the most scientific in itself and the most important in art. Perspective, which is generally treated of separately, and is therefore ordinarily considered a distinct study, is neverless a most essential part of drawing—in fact, its very grammar, all objects being subject to its laws, although they do not admit of being delineated according to the processes employed for drawing buildings, furniture, and such things as consist of strict geometrical forms.

There are various manipulations or modes of drawing, distinguished according to the materials or implements made use of, such as chalk, black lead pencil, sepia or other tinted drawings, which last-mentioned class are sometimes called washed drawings, in which some indication of colouring is occasionally introduced. But what is termed water-colour drawing, as now practised, is altogether a species of painting, although the process is totally different from that of oil colours, or even distemper. Pen and ink drawings, in the style of etchings, either with or without the addition of wash or shadow, are capable of producing considerable effect.

The invention of Lithography has been applied with great success to making fac-similes of such drawings; it also enables artists to make drawings at once upon stone, from which impressions may afterwards be taken that are equivalent to autograph delineations.

Our Schools of Design are becoming every year more and more the means of diffusing a knowledge of drawing among artisans and pattern designers; a knowledge, the fruits of which will be shown at the forthcoming Exhibition.

DREDGING-MACHINES are employed for clearing away deposited matter from the beds of rivers, canals, harbours, and basins. Some machines for this purpose may be compared to harrows or shovels, which loosen the deposit preparatory to its removal either by the action of the tide or by sluicing. But, for the most part, they remove as well as loosen the deposit. The spoon dredging machine consists of a strong hoop of iron, about two feet in diameter, attached to a pole thirty or forty feet long, and carrying a large bag of perforated bullock's hide. This apparatus is connected by ropes with a barge, from the side of which it is let down and manœuvred in such a manner that the edge of the hoop cuts into the soft bottom, and scoops a large quantity of silt into the bag, which is then drawn up to the surface. The bucket dredging machine is a long massive framework with a wheel at each end, over which a series of endless chains is placed; so that by turning one of the wheels the whole chain is set in motion. Attached to the chain is a series of perforated iron buckets. By means of tackle the bucket-frame is let down until it reaches the bottom, when, the steam-engine being set to work, the chain of buckets begins to perform its circuit, by which every bucket is, in succession, made to scoop up a quantity of silt, which it carries up to the top of the oblique frame, and pours out its contents into a barge.

Dredging machines are constantly in use in the Thames, to deepen those parts which have become too much shallowed by mud and sand.

DRESDEN. However interesting the capital of Saxony may be as a repository of works of art, it has no external trade or manufactures of much importance. It is a place of transit for colonial and other foreign produce from Magdeburg, Hamburg, &c., and has six general fairs. Its mechanics have obtained some note in Germany for the manufacture of mathematical, mechanical, and musical instruments, engraving on steel and stone, the making of gloves, carpets, turnery ware, jewellery, straw hats, painters' colours, &c. These mechanics are incorporated into 60 fraternities. Morocco and other leather, refined sugar, tobacco, white lead, tin ware, glass, stockings, cotton goods, &c., are also manufactured.

The part which Dresden will take in the

approaching display of the world's industry, will have its leading feature in the celebrated Dresden China, of so great celebrity. This, however, is not a Dresden manufacture; it is made at Meissen, a town several miles distant from that metropolis. We shall notice the factory and the manufacture in a later article. Among the articles to be sent from Dresden is a beautiful model of that city, in porcelain, large enough to admit of accurate models of the principal churches and buildings. A porcelain vase of great size and artistic beauty is also said to be in preparation. These works are being prepared at the Royal Porcelain Manufactory.

DRILL. [Boring.]

DRILLING is a mode of sowing by which the seed is deposited in regular equidistant rows, at such a depth as each kind requires for its most perfect vegetation. It has been practised by gardeners from time immemorial, and from the garden it has gradually extended to the field. The drill husbandry, by combining the advantages of continued tillage with those of manure and a judicious rotation of crops, is a decided improvement on the old methods of sowing all seeds broadcast. The crops which are now most generally drilled are potatoes, turnips, beans, peas, beet-root, cole-seed, and carrots; and in general all plants which require room to spread, whether above or under the ground. The distance between the rows in these crops is generally such as to allow the use of a light plough or horse-hoe to be drawn by a horse between them. The most common distance is twenty-seven inches. The Northumberland mode of cultivating turnips, which is adopted by most scientific farmers, consists in placing the manure in rows immediately under the line in which the seed is to be drilled, and keeping the intervals in a mellow and pulverised state by repeated stirring.

The instrument used for sowing seeds in single rows is sometimes a small light wheelbarrow, which a man pushes before him; hence called a *drill-barrow.* It has a box in which the seed is put, with a slide to regulate the quantity. This is allowed to fall on a wooden or metal cylinder below. In the circumference of this cylinder are several cavities where the seed lodges, and is carried down into a tin funnel below; the remainder is prevented from falling through by small brushes in which the cylinder turns. The motion is communicated from the wheel which runs on the ground to the cylinder by means of a chain and pulleys. The improved drills, of which there are many patented varieties, are complex but very efficient machines, which sow several rows at once.

At the Smithfield cattle shows, and at the annual exhibitions of the Royal Agricultural Society, the variety of ingenious drills displayed every year is very considerable. One machine, exhibited at the Smithfield show in 1850, is Hensman's eight-row corn and turnip drill, for which a prize was awarded by the Agricultural Society at the York meeting in 1848. It is adapted for all sorts of corn and seeds; the hopper into which the grain or seed is put is self-acting; the axles slide, to give a shifting movement to the drills; and there is a steering lever behind to guide the action of the drills. Another useful apparatus is Wedlake's corn and seed drill. Smith's Uxbridge drill is another kind, which has been introduced within the last few years. Some drills are formed so as to deposit manure only without seed or grain; the hoppers are filled with soot, lime, ground bones, or some other manure brought to a fine state.

DROGHEDA, although not strictly a manufacturing town, contains iron foundries, cotton spinning mills, flax spinning mills, corn mills, salt works, tanneries, soap works, and breweries. Drogheda carries on a considerable trade, particularly in grain. Vessels of 250 tons can discharge at the quay; and goods are carried inland by the Boyne navigation, in barges of 50 tons, to Navan. There are several steamers which ply constantly between Drogheda and Liverpool.

DROITWICH, in Worcestershire, owes its present commercial importance to the vast store of salt embosomed in the earth in its immediate vicinity. This, and the mode of obtaining table-salt therefrom, will be noticed in a later article. [Salt Manufacture.]

DRUGS; DRUGGISTS. The difference between drugs and chemicals is vague and indeterminate; and the professions of the chemist and druggist and the apothecary are in like manner generally confounded together in popular estimation. The rules established by the medical corporations, such as the College of Physicians, the College of Surgeons, and the Apothecaries' Company, have had much to do in producing this uncertainty. The acids, alkalies, salts, and oxides, used in largest quantity, are made on a scale which requires complete manufacturing arrangements, with large furnaces, stills, and other apparatus. Such is the case in respect to sulphuric and nitric acids, chlorides of lime and of sodium, alum, &c.; such articles are made by manufacturing chemists, at the vast chemical works which are met with at Glasgow, Liverpool, Newcastle, Hull, and Bristol. A retail shopkeeper who calls himself a chemist and druggist, is a chemist in so far as he retails, and understands the general character of, the chemicals made on a large scale by others; while he may be regarded as a druggist to the extent that he understands, and sells by retail, the substances used in medicine. If he can himself prepare, on a small scale, a considerable number of the substances which he sells, it is now customary to term him a pharmaceutist or pharmaceutical chemist.

The druggists of the metropolis have agreed to send a very extensive and valuable collection to the Exhibition of 1851, illustrative of the chemical and pharmaceutical productions of the country. The towns of Manchester, Glasgow, and Newcastle-upon-Tyne have also taken very active steps in order to secure a complete representation of the chemical manufactures of the country.

Dr. Normandy has recently published a valuable work on drugs and chemicals, under the name of 'The Commercial Handbook of Chemical Analysis.' It is especially designed to afford aid in the detection of fraud in the manufacture of food, drugs, and chemicals. The list of articles of which the processes of adulteration, and the means of detection, are given, is very comprehensive; including not only ordinary viands, as bread, porter, tea, coffee, chocolate, and cocoa, spirits, liquors, and wines, but the drugs used in medicine, and a great variety of miscellaneous substances. They are alphabetically arranged, for convenience of reference.

'Country druggists,' it has been remarked, 'form a class of persons to whom this book would be very serviceable; for, although there are of course highly creditable exceptions, particularly in great provincial towns, the bulk of them are not distinguished for chemical or even pharmaceutical knowledge. Few are capable of conducting an analysis or organic research, and they are frequently imposed upon by wholesale dealers, who send them damaged or spurious drugs, which, if administered in dangerous maladies, might induce aggravation of disease, and very probably cause death.'

DRUM. Of this musical instrument there are three kinds,—the *Side Drum;* the *Base* or *Turkish Drum;* and the *Double Drum.* The first is a cylinder, made of brass, on each end of which is a hoop covered with vellum or parchment. The second is formed like the first, but of oak, on a much larger scale. The third is made of copper, nearly hemispherical, covered with a strong head of calf's skin, and stands on three iron legs. The Double Drums vary in dimensions, from nineteen inches to three feet in diameter. They are always in pairs, and are tuned by means of many screws (or of a lever and hooks in the patent drum) which tighten the head to the key-note and the fourth below.

DRUMMOND'S LIGHT. The difficulty of distinguishing the stations chosen for the angular points of the triangles in a geodetical survey, such as the Ordnance Survey of the United Kingdom, when those stations are many miles asunder, renders it necessary to have recourse to illumination even in the day-time; and the late Captain Drummond, of the Royal Engineers, invented a heliostat which reflected the sun's rays in sufficient abundance to render visible the station which was to be observed.

This was a plane mirror of a rectangular form and mounted on a stand with joints by which it could be fixed at any angle with the horizon. On the stand was a telescope which was capable of being moved horizontally, with the mirror, and directed to the distant station while another telescope was directed to the sun. The adjustments of the mirror were such that, when the telescopes were directed as has been said, the face of the mirror reflected the rays of the sun on the distant station, and illumined it sufficiently to render a mark there visible in the telescope of the theodolite by which the required angle was to be taken.

In order to observe the angles subtended between distant stations at night, Captain Drummond employed a light which has been found to exceed in brilliancy any before used. This is produced by placing a ball or disk of lime, about a quarter of an inch in diameter, in the focus of a parabolic mirror, at the station to be rendered visible, and directing upon it, through a flame arising from alcohol, a stream of oxygen gas.

The cistern containing the alcohol is supported on a stand, behind the reflector, and is connected by a tube of caoutchouc with the lower part of a hollow stem supporting the upright wire at the top of which is fixed the ball of lime on a level nearly with the cistern: the spirit ascends in the stem, and afterwards through three or more tubes to the ball. The vessel containing the oxygen gas is connected, by a flexible tube, with an orifice in a cylindrical box on the same stem, from which it ascends through three flexible caoutchouc tubes to the ball, after passing with friction through three small cylinders. The whole apparatus is attached to a stand which carries the mirror; and adjustments are provided by which the ball may be placed exactly in the focus of the mirror. The intensity of the flame is from sixty to ninety times as great as that of an argand burner, while the expense is only about ten times as great. The lime made from chalk is preferred to any other; and such is the brilliancy, that stations above sixty miles from one another have been very distinctly visible even in hazy weather.

Captain Drummond suggested that burning lime should be employed for lighthouses; and he proposed that, instead of alcohol, hydrogen gas should be employed with the oxygen gas. The gases are to proceed from separate vessels, or gasometers, and enter a chamber through a series of small apertures: the united gases are then to pass through two or three pieces of wire gauze, and issue in two streams against the ball or disk of lime. To prevent the latter from wasting too rapidly in one place, it is made to revolve once in a minute; and in order to keep up a constant light, it is proposed to have an apparatus by which a number of balls may be successively made to fall in the focus of the mirror.

A light of this kind may also be employed as a signal in determining the difference between the longitudes of stations.

The *Electric* light, brought under public notice since Captain Drummond's death, has not yet, we believe, been applied to geodetical purposes.

DRYING MACHINES. A valuable improvement has been made within the last few years in the mode of drying woven cloth which has been bleached or otherwise wetted. In the ordinary mode of drying by exposure to the open air, the moisture gradually evaporates; in a hot room this evaporation is expedited; but in the drying machine the mechanical principle of centrifugal force is brought into use in a singular way.

A drying machine was brought into use in Paris in 1839, by Messrs. Penzolt and Levesque. It acted on the centrifugal system. It consisted of two drums or cylinders, one within the other; the inner one being pierced with holes. The textile goods, wetted by the process of washing, scouring, or bleaching, were placed within the inner cylinder, which was then made to revolve with a rapidity of 4000 turns in a minute; the cloth was driven forcibly against the perforated surface, and the water driven through the holes with such irresistible force that the cloth became nearly dry in three or four minutes.

In 1844 Messrs. Keeley and Alliot, of Nottingham, patented a very elaborate machine to facilitate the scouring, bleaching, or dyeing of cloth. The same inventors had before introduced a machine very similar in principle to that of Messrs. Penzolt and Levesque; but in the new machine, the cloth is put into a certain compartment, the bleaching or dyeing liquid into another compartment, and the machine is made to revolve rapidly; when the centrifugal force generated by the movement drives the liquid speedily and effectually through every pore of the cloth—leaving the cloth instantly afterwards almost in a state of dryness, and bleached likewise.

DRY ROT. This is the name given to a disease affecting timber, and particularly the oak, employed for naval purposes. When dry rot is produced by the attacks of fungi, the first sign of it consists in the appearance of small white points, from which a filamentous substance radiates parallel with the surface of the timber. This is the first stage of growth of the seeds of the fungus, and the filamentous matter is their thallus, or spawn. As the thallus gathers strength it insinuates its filaments into any crevice of the wood, and they, being of excessive fineness, readily pass down and between the tubes from which the wood is organised, forcing them asunder, and completely destroying the cohesion of the tissue. When the thalli of many fungi interlace, the radiating appearance can no longer be remarked; but a thick tough leathery white stratum is formed wherever there is room for its development, and from this a fresh supply of the destructive filamentous thallus is emitted with such constantly increasing rapidity and force, that the total ruin of timber speedily ensues where circumstances are favourable for the growth of the fungi.

There is reason to believe that any of the fungi that are commonly found upon decaying trees in woods are capable of producing dry rot. The circumstances that are most favourable to the development of the dry rot fungi are damp unventilated situations, and a subacid state of the wood. Whatever other causes may combine to promote the decomposition of wood by dry-rot, or other forms of decay, there can be no doubt that imperfect seasoning, by leaving in the pores of the timber a large portion of the fermentable juices always found in recently-felled timber, is one of the most important, and therefore that good seasoning is as essential in promoting the durability of wood as it is in lessening the tendency to those changes of form and bulk which so greatly increase the difficulties of the carpenter and joiner. The process of seasoning usually consists simply in the exposure of the timber to the action of air in a dry situation, in stacks or piles so constructed as to allow the free circulation of air in contact with as much as possible of the surface of each piece of timber, until the sap or vegetable juices shall have dried up so far as to offer no facility for the germination of the microscopic fungi which constitute various kinds of rot. In order to the success of this operation it is important that the pile of timber be so far elevated from the ground as to allow the circulation of air beneath as well as through and around it; and also that, if exposure to rain be not entirely avoided, care be taken to prevent the lodgment of moisture in any place where it would be likely to remain long.

The protecting power of metallic oxides, when applied to the surface of wood in the form of paint, is well known; and many abortive schemes for the preservation of timber have been devised to act upon the same principle, which is that of excluding such external influences as might promote decay. To imperfectly-seasoned timber, however, such applications are worse than useless, because by filling up the pores they impede the natural drying of the vegetable juices, and therefore rather promote than check internal decay. Far more efficient than these are the numerous modes of protection which involve the impregnation of the timber with some antiseptic substance, or with such matters as, by preoccupying the pores, may render the reception and germination of destructive fungi mechanically impossible.

Of plans for protecting timber by impregnation, perhaps none has attained such general celebrity as Mr. Kyan's, which was patented in 1832, and has since been very extensively used. The preservative agent in this process is bi-chloride of mercury, commonly called corrosive sublimate, which is dissolved in water, and forced into the pores of the timber, in closed tanks, by means of forcing-pumps, and which combines with the albumen of the wood, and converts it into a compound capable of resisting the ordinary chemical changes of vegetable matter. Chloride of zinc, creasote obtained from the distillation of tar, oil of tar, and other bituminous matters containing creasote, and pyrolignite of iron, have all been successfully used. Coal-tar is stated to be very superior to vegetable tar, and its efficacy in resisting the worm is attributed to its containing sulphocyanic or sulpho-prussic acid, which is highly destructive to animal and vegetable life. Piles protected with coal-oil are stated to have resisted the attacks of the terédo better than those protected by Kyan's process. It is necessary however to observe that the coal must be deprived of its ammonia, which would produce immediate decay if thrown into the timber.

Another process, called *Paynising*, from the name of the inventor, consists in first filling the pores of the wood with a solution of chloride of lime, and next forcing in a solution of sulphate of iron, by which an insoluble sulphate of iron is formed in the body of the wood, rendering the latter extremely hard. Timber so prepared has been recently much used.

DUBLIN. This large and populous city resembles a great metropolis in this respect, that its manufactures are of a general kind, adapted to the varied wants of its inhabitants, rather than belonging to any particular group of manufactures. At the exhibition of manufactures at Dublin in 1850, noticed in the *Introduction*, the manufactures of the citizens were surprisingly varied, comprising a very full collection both of the useful and the ornamental, in house fittings, furniture, dress, implements and machines, vessels and apparatus, &c.

Dublin is to be the general place of collection for the specimens to be forwarded to the Industrial Exhibition in Hyde Park. The extent of the collection will be found noticed under IRELAND. It is understood that the Dublin manufacturers intend to put forth all their skill in certain branches of industry which are largely carried on by them.

DUCTILITY is the property of bodies which admits of their being drawn out in length, while their diameter is diminished, without any actual fracture. Gold, silver, platinum, iron, copper, zinc, tin, lead, nickle, are ductile in the order here given. Wire-drawing depends on ductility.

DUDLEY. This is one of the great iron manufacturing towns of the South Staffordshire district. It is, in truth, in one corner of Worcestershire; but it lies over that valuable bed of coal and iron which is independent of mere topographical names, and which includes within its range parts of the counties of Stafford, Worcester, Warwick, and Shropshire. Iron is cast and forged in large quantities at Dudley; innumerable articles are there manufactured of iron; and the nailers, or makers of nails by hand, congregate in and about Dudley to the number of many thousands. Useful stone is quarried near the town; and there are all the indications of a busy manufacturing population.

Dudley is at present accommodated only by the South Staffordshire Railway; but it will shortly be connected by railway with towns in various directions.

A few specimens of Dudley manufactures will have a place at the Industrial Exhibition.

DULCIMER is the name of a very ancient musical instrument, supposed to be the psaltery of the Hebrews. In the modern form, it is a trapezium in shape, has many strings, two to each note, and is struck by a pair of sticks with wooden or metallic knobs.

DUMBARTON. This Scottish town has some extensive manufactures in glass. In the county to which it belongs, the principal mineral production is coal, of which there is a large field, but of inferior quality, which is wrought at Langfauld, in the southern extremity of the county. In the eastern division of the county iron-stone is dug, and conveyed on the Clyde and Forth Canal to the great iron-foundry at Carron. Some large quarries of limestone and of freestone are worked. There are also several slate quarries.

On the banks of the Leven are numerous and very extensive works for cotton printing, and bleaching fields, the pureness of the Leven water being peculiarly adapted for this process. Some large iron works are established at Dalnotter.

DUMFRIES. The Nith, near the mouth of which Dumfries is situated, has been deepened within these few years, and vessels of a good size can discharge their cargoes close to the town. There is also a quay at the bend of the river near Castledykes; one for vessels of greater burthen a mile and a half farther down; and another near the mouth of the river for vessels of still larger size. The foreign trade is in timber from America. The coasting trade is with Liverpool, Whitehaven, Maryport, and other places on the west coast of England. A steam-boat plies once a week in the summer months between Whitehaven and Dumfries, in connection with one between Whitehaven and Liverpool.

The county of Dumfries contains coals only at Sanquhar and Canobie; a great portion of the county being supplied with coal from Cumberland, and from Lanarkshire and Ayrshire. At Wanlockhead, near Leadhills, are extensive lead mines. From this lead silver is extracted in the proportion of six to twelve ounces in the ton. Gold is occasionally found in the mountains at Wanlockhead, in veins of quartz, or washed down into the sand of the rivulets. Gypsum occurs in thin veins.

A great quantity of hams and bacon of the very best quality are cured in this county, and sent off to the Liverpool, London, and Newcastle markets. A great number of pigs are kept by the farmers and cottars, and bacon may be considered a staple commodity of the county.

Annan has a small import and export trade; and there are a few other places where commerce is pretty well kept up.

DUNDEE. This important town, the third in rank among the manufacturing towns of Scotland, has deep shipping-quays on the Tay which accommodate a large amount of export and import trade. In 1815 the renovation and extension of the harbour gave an impulse to its manufactures and commerce, which has led to its present state of prosperity. The harbour now consists of three wet docks, two tide-harbours of large extent, a graving-dock, a patent slip, yards for ship-building, &c.

The chief manufactures of Dundee consist of the spinning of flax, the weaving of linen, and the making of cordage and ropes. Besides the fine linen, a large quantity of sail-cloth is woven.

Steam-vessels ply regularly between Dundee and Perth, Newport, Leith, Glasgow, London, and other places. About 350 vessels belong to the town, some of large tonnage; and about 4000 vessels enter and leave the port yearly, engaged in coasting and foreign commerce.

From a return recently laid before Parliament, it appears that in 1850 the following were the statistics of the factories for flax and linen goods in the county of Forfar, in which Dundee is the chief manufacturing town. There were 85 flax-spinning factories, with 135,311 spindles, 2559 horse-power for moving machinery, and 12,365 persons employed, of whom about 9000 were females; there were 11 factories for flax-weaving, with 1347 power-looms, 219 horse-power moving-force, and 1888 persons employed, of whom 1500 were females: and 5 factories both for spinning and weaving flax, with 22,686 spindles, 240 power-looms, 345 horse-power, and 2011 persons employed, of whom nearly 1400 were females. The cotton, woollen, and mill factories in Dundee are but small in number.

All the chief varieties of Dundee manufactures in flax will be represented at the Industrial Exhibition.

DURA'MEN is the name sometimes given to the central wood or heart-wood in the trunk of a tree. It is the oldest part of the wood, and is filled by the secretions of the tree, so that fluid can no longer ascend through its tubes, which are choked up by the deposition of solid matter; otherwise it is of the same nature as the alburnum. It is only where plants form solid hard secretions that heart-wood is distinguished from sap-wood: in the poplar, willow, lime, &c., no secretions of this kind are formed; the two parts of the wood are both nearly alike, and consequently the timber of such trees is uniformly perishable.

DURERTYPE. Mr. Dicks, in 1845, proposed a new mode of copying engravings, to which he gave the name of *Durertype*, for the somewhat insufficient reason that it enables a person to copy Albert Durer's prints, and others of a similar kind. To effect this, a clean flat piece of glass is coated on one side with a thin smooth film of pure white bees'-wax: the glass being first washed with spirits of turpentine, and then warmed; and the wax being applied in a melted state to one side of the glass. When laid upon a print, the lines can be seen through the thin film; and those lines are traced or etched on the waxen surface by a pointer of ivory or steel. The design is thus marked over the wax surface in a series of cavities or depressions; and a cast from this is then taken in copper, by the common electrotype process.

DURHAM COLLIERIES. The colliery operations which form so large a part of the industrial and commercial enterprises of Durham are noticed in an earlier article [COAL AND COAL MINING].

DÜSSELDORF is one of the most manufacturing districts in Rhenish Prussia. There are extensive manufactures of woollens, silks, cotton, thread, leather, steel, iron, ironware, and cutlery, tobacco, soap, &c. Iron, coals, and potters' clay, are among the native products. At Duisberg there is a large vitriol factory, steam cloth mills, slips for building steam and sailing vessels, and several other industrial establishments. Lennep has important cloth factories, and dye-houses, and trades in wines, hats, iron ware, &c. Mühlheim has large silk and cotton factories, zinc, and iron works, and establishments for the manufacture of steam machinery. Neuss, Ronsdorf, and Ruhrort are busy manufacturing towns. Solingen, sometimes called the German Sheffield, is famous for the manufacture of sword blades, foils, cutlery, and iron ware. At Wesel the inhabitants manufacture woollen and cotton cloths, soap, hats, cordage, leather, beer, &c., and carry on a considerable trade with Holland by the Rhine, and with Westphalia by the Lippe, which has been made navigable; the chief articles of commerce are corn, timber, coals, salt, wine, brandy, and colonial produce. Düsseldorf, the chief town of the district, has manufactories of woollens, cotton, leather, hats, tobacco, jewellery, mirrors, stockings, &c., and carries on a considerable trade in cotton, wool, wines and spirits, colonial produce, coals, timber, slates and other commodities. It has been a free port since 1829. The growing importance of Düsseldorf as a commercial port is seen from the following table of the quantity of merchandise imported and exported in the years stated:—

	Imported. Cwts.	Exported. Cwts.
1836	855,533	113,144
1840	1,160,952	135,825
1843	1,332,465	219,647
1844	1,311,310	193,773
1845	1,535,926	206,370

The manufacturers of this part of Prussia are about to take an active part in the approaching great Exhibition.

DYEING is the art of staining textile substances with permanent colours. It was an art known and practised to a considerable extent by the ancient Egyptians, Phœnicians, Greeks, and Romans. The moderns have obtained from the New World several dye-drugs unknown to the ancients; such as cochineal, quercitron, Brazil wood, logwood, arnotto; and they have discovered the art of using indigo as a dye, which the Romans knew only as a pigment. But the vast superiority of our dyes over those of former times must be ascribed principally to the employment of pure alum and solution of tin as mordants, either alone or mixed with other bases; substances which give to our common dye-stuffs remarkable depth, durability, and lustre. Another improvement in dyeing of more recent date is the application to textile substances of metallic compounds, such as Prussian blne, chrome yellow, manganese brown, &c.

Bergman appears to have been the first who referred to chemical affinities the phenomena of dyeing. Having plunged wool and silk into two separate vessels containing solution of indigo in sulphuric acid diluted with a great deal of water, he observed that the wool abstracted much of the colouring matter, and took a deep blue tint, but that the silk was hardly changed. He ascribed this difference to the greater affinity subsisting between the particles of sulphate of indigo and wool, than between these and silk; and he showed that the affinity of the wool is sufficiently energetic to render the solution colourless by attracting the whole of the indigo, while that of the silk can separate only a little of it. He thence concluded that dyes owed both their permanence and their depth to the intensity of that attractive force. We have therefore to consider in dyeing the play of affinities between the liquid medium in which the dye is dissolved and the fibrous substance to be dyed. By studying these differences of affinity, and by varying the preparations and processes, with the same or different dye-stuffs, we may obtain an indefinite variety of colours of variable solidity and depth of shade.

Dye-stuffs, whether of vegetable or animal origin, though susceptible of solution in water, and, in this state, of penetrating the pores of fibrous bodies, seldom possess alone the power of fixing their particles so durably as to be capable of resisting the action of water, light, and air. For this purpose they require to be aided by another class of bodies, *mordants*, which bodies may not possess any colour in themselves, but serve in this case merely as a bond of union between the dye and the substance to be dyed. Mordants may be regarded in general as not only fixing but also occasionally modifying the dye, by forming with the colouring particles an insoluble compound, which is deposited within the textile fibres. Such dyes as are capable of passing from the soluble into the insoluble state, and of thus becoming permanent, without the addition of a mordant, have been called substantive, and all the others have been called adjective colours. The first principle of dyeing fast colours consists in causing the colouring matter to undergo such a change, when deposited upon the wool or other stuffs, as to become insoluble in the liquor of the dye-bath. The more powerfully it resists the action of other external agents, the more solid or durable is the dye.

In the following details concerning the art of dyeing we shall consider principally its application to wool and silk, having already treated, in the article COTTON OR CALICO PRINTING, of what is peculiar to cotton and linen.

The operations to which wool and silk are subjected preparatory to being dyed are intended, 1, to separate certain foreign matters from the animal fibre; 2, to render it more apt to unite with such colouring particles as the dyer wishes to fix upon it, and also to take therefrom a more lively and agreeable tint, as well as to be less liable to soil in use.

Silk is scoured by means of boiling in soap and water, whereby it is freed from a sort of varnish: if intended to be very white, it is bleached by humid sulphurous acid. Wool is first washed in running water to separate its coarser impurities; it is then deprived of its *yolk* (a species of animal soap secreted from the skin of the sheep) either by the action of ammoniacal urine, by soap and water, or by a weak lye of carbonate of soda. It receives its final bleaching by the fumes of burning sulphur, or by aqueous sulphurous acid.

Tinctorial colours are either simple or compound. The simple are black, brown or dun, blue, yellow, and red; the compound are gray, purple, green, orange, and others. Gall-nuts, pyrolignite of iron, logwood, copperas, and verdigris, are the chief materials for producing black. Walnuts, sumach, madder, cochineal, cudbear, acetate of iron, catechu, Brazil wood, arnotto, are all employed in producing brown. Indigo, Prussian blue, and woad, are employed for blue. Fustic, Persian berries, quercitron, turmeric, and weld, for yellow. Cudbear, Brazil wood, cochineal, kermes, lac, logwood, madder, safflower, for red; and various compounds for purple, green, orange, &c.

The black dye for hats is communicated by logwood, copperas, and verdigris, mixed in certain proportions in the bath. The ordinary proportions used by the English black dyers for 100 pounds of cloth, previously treated in the indigo vat, are about 5 pounds of copperas, as much nut-galls bruised, and 30 pounds of logwood. They first gall the cloth, and then pass it through the decoction of logwood in which the copperas has been dissolved. A finish of weld is often given after fulling.

Silk is dyed black in two methods, according to the market for which it is made. When sold by weight, it is an object with the dyer to load it with as much colouring or other matter as possible. When silk is sold by superficial measure, on the other hand, it becomes the dyer's object to give it a black colour with as little weight of materials as possible. Hence the distinction well known in trade of heavy and light silks, The silk dyers keep up from year to year a black vat, often of very complex composition. The essential constituents of the vat are sulphate of iron and gum; but many vegetable matters, as well as filings of iron, are usually added.

The infusion of walnuts, as used by the continental dyers, affords very agreeable and permanent brown tints without any mordant, while it preserves the downy softness of the wool, and requires but a simple and economical process in applying it. Sumach is usually employed in this country to dye fawns, and some browns; but more beautiful browns may be given to woollen stuffs by boiling them first with one-fourth their weight of alum and some tartar and copperas; washing, and afterwards dyeing them in a madder bath. The shade of colour depends upon the proportion which the copperas bears to the alum. The finest browns are produced by boiling each pound of the wool with two ounces of alum, dyeing it in a cochineal bath, and then transferring it into a bath containing a little cochineal darkened with acetate of iron.

Silk may receive a ground of arnotto, and then be dyed in a bath of logwood or Brazil wood, whereby a fine brown tint is obtained. Catechu is used for giving a bronze and brown to cotton goods.

Additional details are given under the

names of the colours and of the dye-materials, such as ARNOTTO, COCHINEAL, INDIGO, MADDER, &c.

The dye-materials imported from foreign countries which find a place among the Customs Returns prepared by the Board of Trade are chiefly the following:—Cochineal, fustic, gum arabic, gum Senegal, gum animi, gum copal, gum tragacanth, indigo, lac dye, shell lac, logwood, madder, Nicaragua wood, safflower, sumach, smalts, valonia, yellow berries, and zaffre. Of these nineteen substances, about 4000 cwts. were imported in 1848.

There are few manufacturing arts in which the English may more profitably study the productions of the French than dyeing. The French chemists have studied the production of colour more than those of our own country; and the French dyers have availed themselves of every aid which science has been able to afford. It is one of the good features in the Exhibition which is about to take place, that the dyes of various nations will fairly be brought into comparison. If the French are really our superiors in this art, it will be just to acknowledge, graceful to commend, and profitable to imitate their skill.

DYNAM; DYNAMOMETER. In estimating the effect of mechanical labour, it is desirable to have some idea of a simple unit well fixed in the mind. All who have studied know how much advantage there is in referring every kind of pressure to weight, and measuring it by the weight which will balance it. Thus if one hundred pounds weight will bend a spring into a certain position, we have no difficulty in substituting an opposite force to the weight for the recoil of the spring at the point of application. It is equally convenient to arrive at a distinct notion of a unit of useful effect in the workmanship of machines. We may consider any machine as simply applied to raising a weight, and look upon the weight raised as a dynamical equivalent for any possible effect that the machine could have produced; observing that the useful effect of any application of power varies jointly as the weight raised and the height to which it is raised. Accordingly, the product of the number of pounds raised, is a *relative* measure of the quantity of power.

We can convert the above relative measurement into an absolute form by assuming as a unit one pound raised through one foot: let this be called a *dynam*, or dynamical unit. Thus, what is commonly called a horse power is meant by our engineers to signify 550 dynams in a second; a steam-engine which can raise one pound through 550 feet in every second is said to be of one-horse power.

This term was introduced by French writers, who called the effect of a cubic metre of water raised through one metre, a *dynamie* or *dyname*. Dr. Whewell in his 'Mechanics of Engineering,' has proposed to naturalise the term dynam, as applied to our most convenient units, the pound and the foot. Mr. Watt was really the first who assumed, as a dynamic unit, the simple notion of one pound raised one foot: but he did not venture on a name, though the now common term, the *duty* of an engine, first used by him, has reference to the number of such simple units as may be obtained from the engine.

The name of *dynamometer* has been applied to an instrument which measures anything to which the name of power has been given, whether that of an animal, (or to take a very different instance) of a telescope.

A dynamometer, registered in 1849, by Messrs. Elce, is used to ascertain the power required to drive, or the power exerted by, any machine. The differential qualities of oil may also, the inventors state, be detected; and when a machine requires too much driving power owing to a strained shaft, or some other radical defect, the loss of power may be ascertained. The difference in the power required to drive similar descriptions of machines by different makers can be estimated; or when any improvement is introduced into a machine by which it is proposed to gain power, such gain, if there be any, can be ascertained.

E

EAGLE-WOOD. This is a highly fragrant wood, much esteemed by Asiatics for burning as incense, and known in Europe by its present designation ever since the Portuguese visited and imported the substance direct from the Malayan islands and the kingdom of Siam, where it has always been abundant, and long established as an article of commerce. The Malayan name is *Agila*, whence the wood was called *Pao d'Agila* by the Portuguese, and has since been converted into *Pao d'Aguila*, and *Pao d'Aquila*, *Bois d'Aigle*, and *Eagle Wood.* The term eagle wood is also applied to the wood known to the ancients by the name of *Agallochum.*

Of the two kinds of agallochum which are most valued, and both considered genuine, one is distinguished by the name of Calambac, and the other as the Garo of Malacca. Calambac appears, as far as hitherto known, to be a native of Cochin China only, growing on the mountains of that country in about 13° of N. lat. It has been described as a lofty tree with erect stem and branches, long lanceolate shining leaves, and terminal bunches of flowers. The other kind, Garo, to which the name of Eagle Wood is more frequently applied, has long been an article of export from Malacca and the kingdom of Siam. Specimens of the tree which yield this were first obtained by M. Sonnerat in his second voyage to India, from which probably have been given the figure and description by Lamarck. The fragrant nature of genuine agila or eagle wood is well known, and that it has from very early periods been employed both by the natives of India and of China as incense. Mr. Finlayson, in his visit to Siam, says, that the consumption of this highly odoriferous wood is very considerable in Siam, but that the greatest part is exported to China. In China it is used in a very economical manner. The wood being reduced to a fine powder, and mixed with a gummy substance, is laid over a small slip of wood, about the size of a bullrush, so as to form a pretty thick coating. This is lighted, and gives out a feeble but grateful perfume. Eagle wood was burned as a perfume by Napoleon in the imperial palace.

EAR-TRUMPET. We may refer on this subject to ACOUSTICS and SPEAKING TUBES, under which latter title the recent remarkable applications of gutta percha are noticed.

EARTHS. The old chemists imagined that all material substances were ultimately resolveable into four simple bodies, viz., air, fire, water, and earth, which were therefore called the four elements. It is now universally admitted that the bodies called earths are compounds of oxygen and a base, and in fact they are mostly metallic oxides. The principal earths are *alumina*, *barytes*, *glucina*, *lime*, *magnesia*, *silica*, *strontia*, *yttria*, *zirconia*.

EARTHENWARE. [POTTERY.]

EAST INDIES. This immense and important country is deeply interesting to us in an industrial and commercial point of view, both for its natural riches, and for the influence which an English company has so long exerted in that quarter. We shall touch briefly on both these characteristics, so far as is consistent with the scope of the present volume.

The East Indies are usually considered to include the peninsula of Hindustan lying to the east of the river Indus, and thence eastward as far as the boundary of the Chinese empire, by which empire, and by Tartary, India is also bounded on the north. The East Indies include also the islands of the Indian Ocean which lie between Hindustan and Australia as far north as the Philippine Islands, and as far east as Papua, but without including either the Philippines or Papua. It is not in so wide a sense that the term is used when speaking of the operations of the East India Company; but in truth the names India, East Indies, British India, and Hindustan, are all vague in their geographical limits.

Our power in those regions has wholly risen through the intermedium of the East India Company. This association—the most remarkable which commerce has yet known—was first formed in London in 1599, when its capital, amounting to 30,000*l.*, was divided into 101 shares. In 1600 the adventurers obtained a charter from the crown, under which they enjoyed certain privileges, and were formed into a corporation for fifteen years, with the title of 'The Governor and Company of Merchants of London trading to the East Indies.' The first adventure of the association was commenced in 1601; and this, as well as seven or eight subsequent voyages, yielded a commercial profit of 100 to 200 per cent. The charter was renewed for an indefinite period in 1609, subject to dissolution on the part of the government upon giving three years notice to that effect. In 1611 the Company obtained permission from the Mogul to establish factories at Surat, Ahmedabad, Cambaya, and Goga. The capital was increased by a new fund of 1,600,000*l.* in 1617. The functions of government were first exercised by the Company in 1624, when authority was given to it by the king to punish its servants abroad either by civil or by martial law, embracing even the power of taking life. In 1632 a third fund of 420,700*l.* was raised. The king encouraged the formation of a rival company in 1636, but the rivals coalesced to form a joint company in 1650.

In 1652 the Company obtained from the Mogul, through the influence of a medical gentleman, Mr. Broughton, the grant of a licence for carrying on an unlimited trade throughout the province of Bengal, without payment of duties. An increase of capital, an extended charter, and a successful attempt to keep down a new rival company, marked the next ten years. Factories were established at Bantam in 1602, Surat in 1612, Madras in 1639, Bengal in 1652, and Bombay in 1668.

The first occasion on which the Company was brought into collision with any of the native powers of India occurred in 1664, when Sevajee, the founder of the Mahratta States, attacked the city of Surat. The aid which the Company's servants gave on this occasion to the inhabitants won for them the good will of the Mogul; and the Company gradually obtained increased power, both from the Mogul and from Parliament. In 1693 the Company obtained a new charter by gross bribery of the highest officers of state; but the House of Commons refused to sanction it. Another new company was formed about the same time, and another amalgamation took place, which left the United Company on the footing which it maintained from 1702 till 1833. The capital has been gradually increased to 6,000,000*l.*, on which dividends are paid.

The home government of the Company consists of the Court of Proprietors, the Court of Directors, and the Board of Control, between whom it has been sometimes difficult to maintain harmonious relations. The act of Queen Anne gave the Company exclusive trading powers to the East, which lasted with little alteration till 1813. In this year much of the trade was thrown open by a new charter for twenty years: that with China being however retained as a monopoly. In 1833 another renewal for 20 years was granted, which took away from the Company the right of trading either to its own territories or the dominions of any native power in India or in China, and threw the whole completely open to the enterprise of individual merchants. The time is now rapidly approaching when another charter will be applied for, and its terms canvassed.

The Company's nominal profits in the 18th century were very high; but as their trade was conducted in a costly way, and was burdened with military charges, it yielded little real profit. Private traders have always been able to outbid the Company, when allowed to compete. Thus, in the 20 years from 1813 to 1833, the value of goods exported by the private trade increased from about 1,000,000*l.* sterling to 3,979,972*l.*, while the Company's trade fell from 826,558*l.* to 149,193*l.* The impossibility, as thus shewn, of the Company's entering into competition with private merchants had a powerful influence with parliament; and in the charter of 1833 the Company was confined altogether to the territorial and political management of its vast empire. The dividend guaranteed by the act of 1833 is 650,000*l.*, being 10½ per cent. on a nominal capital of 6,000,000*l.* The dividends are chargeable on the revenues of India, and are redeemable by parliament after 1847.

The following table is given, in the deficiency of official returns, merely as an approximation, in order to afford such a general view as may be useful, though not accurate, of the areas and population of the territories of Hindustan :—

British Possessions.	Sq. Miles.	Inhabitants.
Bengal Presidency ..	220,000	47,000,000
North West Provinces	100,000	20,000,000
Madras Presidency..	140,000	14,000,000
Bombay Presidency	70,000	7,500,000
Sinde..............	70,000	1,500,000
Lahore	60,000	3,000,000
	660,000	93,000,000
Dependent States.		
Hydrabad..........	95,000	9,000,000
Berar, or Nagpoor ..	45,000	2,200,000
Mysore	27,000	3,500,000
Gwalior and Malwa..	34,000	4,000,000
Gujerat............	25,000	2,000,000
Oude	20,000	4,0000,00
Balwulpoor	12,000	500,000
Cashmere States	20,000	1,000,000
Sikh Hill States	20,000	1,000,000
Bundelcund States ..	8,000	1,000,000
Rewah	7,000	600,000
Bhopal	6,000	500,000
Indore	8,000	600,000

	1,170,000	140,000,000

Such is the immense territory whch is vaguely known to us as the East Indies. Commerce between India and the western nations of Asia appears to have been carried on from the earliest historical times. The spicery, which the company of Ishmaelites mentioned in Genesis were carrying into Egypt, must in all probability have been the produce of India; and in the 30th chapter of Exodus, where an enumeration is made of various spices and perfumes, cinnamon and cassia are expressly mentioned, which must have come from India or the islands in the Indian Archipelago. This trade appears to have been carried on by means of the Arabs. Indian articles were also brought from the Persian Gulf to Phœnicia, and Europe was thus supplied with the produce of India.

The produce of India was also imported into Greece by the Phœnicians in very early times. Many of the Greek names of the Indian articles are evidently derived from the Sanskrit. The western nations of Asia appear to have had no connection with India, except in the way of commerce, till the time of Darius Hystaspes. The expedition of Alexander into India first gave the Greeks a correct idea of the western parts of India, and paved the way for a further extension of Indian commerce. After the foundation of Alexandria in Egypt, the Indian trade was almost entirely carried on by the merchants of that city. We may form some idea of the magnitude of the Indian trade under the emperors by the account of Pliny, who informs us that the Roman world was drained every year of at least fifty millions of sesterces (upwards of 400,000*l.*) for the purchase of Indian commodities. The articles imported by the Alexandrian merchants were chiefly precious stones, spices and perfumes, and silk. Alexandria supplied the nations of Enrope with Indian articles till the discovery of the passage round the Cape of Good Hope by Vasco de Gama in 1498. But the western nations of Asia were principally supplied by the merchants of Basra, which was founded by the caliph Omar, near the mouth of the Euphrates, and soon became one of the most flourishing commercial cities in the East. In addition to this, a land trade, conducted by means of caravans which passed through the central countries of Asia, existed from very early times between India and the western nations of Asia.

The modern commerce of India has taken many fresh directions. Nearly all that depends on the East India Company is transacted at the three ports of Calcutta, Madras, and Bombay. The native merchants in the north west of India carry on a large inland trade to Persia, Bokhara, Siberia, and other Asiatic countries. In respect to Great Britain, the exports of British manufactures to India in 1849 amounted in value to nearly 7,000,000*l.* In respect to the imports from India into Great Britain in 1848, the following will give an idea of the principal commodities and quantities:—

Cassia	.. ..	40,000 lbs.
Cloves	.. ..	60,000 lbs.
Coffee	.. ..	33,000,000 lbs.
Indian cottons	..	120,000 pieces
Gums	.. ..	30,000 cwts.
Hemp	.. ..	260,000 cwts.
Hides	.. ..	70,000 cwts.
Indigo	.. ..	60,000 cwts.
Mace	.. ..	40,000 lbs.
Senna	.. ..	800,000 lbs.
Silk	.. ..	800,000 lbs.
Silk goods ..	..	300,000 pieces
Skins and Furs	..	60,000
Rum	.. ..	900,000 gallons.
Sugar	.. ..	1,400,000 cwts.

Cotton has hitherto been exported from India only in small quantity; but strenuous exertions are now being made to extend the culture. The other chief products are noticed in the above list. Other commercial and industrial details will be found under the names of the chief countries and cities, such as Bengal, Bombay, Calcutta, Delhi, &c.

Ceylon, although close to India, does not belong to the Company. That territory is about to take up a worthy position at the approaching exhibition [Ceylon]; but in India the preparations do not seem to have been on so complete and well-organised a scale. There will however be many individual specimens of great interest. For example, the Maharajah Goolab Singh has arranged to send a magnificent collection of shawls from Cashmere, to the Great Exhibition. They are said to be worth nearly 100,000 rupees (10,000*l.*), and to be of the most exquisite kind. Various other articles have been forwarded to Bombay from Lahore and its principal towns; including papier maché articles (which it will be interesting to compare with those now made at Birmingham), a carpet of large dimensions, a gold-inlaid suit of armour, cotton and silk manufactures, fire-arms, agricultural implements, and other articles.

EBONY is well known as a hard black-coloured wood, brought from tropical regions. From its hardness, durability, susceptibility of a fine polish, and colour, (which has almost become another name for blackness,) ebony has always been in high estimation, and in the present day is much used for mosaic work and ornamental inlayings, though cheaper woods dyed black are frequently substituted. Several trees yield this kind of wood, but all belong to the genus *Diospyrus*. The species are found chiefly in the tropical parts both of Asia and America, as in the Malayan archipelago and peninsula, and in almost every part of India.

The species called *Diospyrus ebenus*, the true ebony, and that which is considered to be of the best quality, is a large tree, a native of the Mauritius, Ceylon, and Madagascar. Large quantities of the ebony of this species have been sometimes imported into Europe.

One of the most remarkable productions in which ebony takes a part, is perhaps the ebony and satinwood bridge in Ceylon. It is at Paradina, about five miles from Kandy, and forms part of the coach-road from Kandy to Colombo. It consists of a single arch, resting on stone abutments. The timbers are all light and simple in form; and it affords a proof of the abundance and cheapness of these kinds of wood in Ceylon, that ebony and satinwood should be employed for such a purpose.

ECUADOR. This South American republic has a soil and climate which yields sweet potatoes, mandioca, yams, bananas, rice, Indian corn, sugar, cocoa, cotton, tobacco, fruits, and numerous other plants and roots. Sheep and cattle are reared in great numbers; horses, asses, and mules to a smaller extent. Gold, silver, lead, and quicksilver mines are worked, but not so largely as in other parts of South America.

The traffic between England and Ecuador is not considerable, owing mainly to the circumstance that Guayaquil, the only port, is on the Pacific shore, and therefore not to be reached without a voyage round Cape Horn. In 1848 the total value of our exports to Ecuador amounted only to about 6000*l*. Cocoa is the commodity with which Ecuador supplies us in largest quantity, the import in 1848 amounting to more than 1,100,000 lbs.

EDDYSTONE LIGHTHOUSE. [LIGHTHOUSES.]

EDINBURGH. Important and interesting as the Scottish metropolis may be in many particulars, it is not in respect to manufactures or commerce that it appeals to our notice. Its maritime commerce is all conducted at Leith; while its manufactures of paper, types, and other commodities, are of the miscellaneous kind which belong to a large metropolitan city, rather than partaking of any one distinctive character. The same may be said of Dublin, except that Dublin has no such great rival to its industry as Edinburgh has in Glasgow.

It is in the aid which the educational and literary talent of Edinburgh affords towards the study of all sciences, and their application to the arts, that we are to look for the chief link which connects Edinburgh with the industry of the age. The Scottish Society of Arts, among other institutions, has rendered valuable aid in this direction.

The county to which Edinburgh belongs has a few industrial towns. Dalkeith contains a large iron-foundry, a gas-work, and there are manufactures of felt and beaver hats, straw hats, and woollen stuffs. At Musselburgh, besides a small coasting-trade, there are manufactures of sail-cloth and hair-cloth; and there are coal mines in the neighbourhood. Leith claims a word of notice elsewhere. [LEITH.]

The number of parties who have come forward at Edinburgh as exhibitors at the Great Industrial Exhibition amounts to 163. Of these, 14 will be in the section for raw materials and produce, 68 in the section for machinery, 62 in the section for manufactures, and 19 in the section for sculpture, models, and the plastic art. The entire space which will be required extends to 10,143 square feet, of which 3,558 is floor space, 1,939 table space, 4,646 wall space. The articles that are proposed to be exhibited are very miscellaneous.

EFFERVESCENCE is the rapid disengagement of a gas, which takes place in a liquid in consequence of chemical action and decomposition.

EFFLORESCENCE is the property by which certain salts containing water of crystallization lose it, and become opaque by exposure to the air.

EGG TRADE. The egg trade is now one of great magnitude. What the number of English eggs produced and eaten may be, it is impossible even to guess; for there are no returns which can apply to this subject; but of foreign eggs we find that there have been imported the following quantities in four recent years:—

1847	77,485,487
1848	88,012,585
1849	97,903,151
1850	105,761,995

These are principally obtained from France.

Eggs are largely employed in the leather manufacture, in the preparation of kid skins into leather for gloves and shoes. In one process of the manufacture, yolk of egg is mixed with alum, salt, and flour in a barrel, and the skins are agitated with this mixture for some time. Much of the softness of good kid leather is due to this use of egg-yolk. There is one leather-factory in Bermondsey where 60,000 to 80,000 eggs are used for this purpose every year; they are imported from France in the spring, and are kept good throughout the year in lime-water.

EGYPT. This remarkable country is possessed of very little mineral treasure. It depends more upon the alluvial subsoil left by the Nile than upon the metal and stone found in the rocks. On the west of the Nile however, above the Delta, the mountain range which bounds the valley contains limestone, sandstone, slate, and quartz; while the eastern range contains the famous granite quarries which furnished material for the great works of the ancient Egyptians. In the mountainous region between the Nile and the Red Sea are found mines of various metals, and quarries of porphyry and other valuable stone.

The agriculture of Egypt depends on the annual inundation of the Nile. This inundation, occasioned by the periodical rains of Central Africa, begins in June about the summer solstice, and it continues to increase till September, overflowing the lowlands along its course. The Delta, or Lower Egypt, then looks like an immense marsh, interspersed with numerous islands, with villages, towns, and plantations of trees just above the water. The inundations, having remained stationary for a few days, begin to subside, and about the end of November most of the fields are left dry, and covered with a fresh layer of rich brown slime: this is the time when the lands are put under culture. From thence till the next inundation, the Delta goes through the alternatives of a delightful spring and a fiercely hot summer.

The agricultural produce of Egypt consists of the following winter plants, which are sown when the inundation has ceased, and reaped in three or four months after: wheat, barley, beans, peas, lentils, vetches, lupins, clover, flax, coleseed, lettuce, hemp, cummin, coriander, poppy, tobacco, water-melons, and cucumbers; and of the following summer plants, which are raised by artificial irrigation by means of water-wheels and other machinery: doorah, Indian corn, onions, millet, henneh, sugar-cane, cotton, coffee, indigo, madder. Rice and numerous fruits are also cultivated. Mehemet Ali pensioned off the landed proprietors, and seized the land himself; so that the poor fellah farmers became his immediate tenants, and a wretched life they seem to have led.

In regard to constructive and mechanical arts, Egypt is more distinguished for its ancient than its modern works. The wondrous pyramids, the temples, the statues, the obelisks, the sphinxes, are among the most striking antiquities of any nation. In respect to modern industry, Mehemet Ali strove zealously to establish the cotton manufacture and other branches of industry in Egypt; and to a certain extent he succeeded.

Of the towns of Egypt, there are only four of commercial importance. *Alexandria* has been already briefly noticed [ALEXANDRIA]. *Cairo* or *Kahira* carries on a number of manufactures connected with the wants of a large metropolis; but as it is not a sea-port town, and is distant a mile from the Nile, it has no shipping. *Rosetta* and *Damietta* are sea-ports, having considerable trade.

Engineers are now, and have long been, impressed with the desirability of establishing some better mode of communication between the Mediterranean and the Red Sea, across Egypt. The India mail, after being landed at Alexandria, has to be navigated up the Mahmoudieh Canal to Boulak, then carried one mile to Cairo, and then transferred across the desert to Suez. A ship canal across the isthmus, from Pelusium to Suez, is one of the schemes under discussion. Mr. Robert Stephenson, the eminent engineer, has lately been to Egypt. A recent correspondent at Alexandria of one of the London journals says, 'He (Mr. Stephenson) seems impressed with the advantages Egypt and the trade with our Indian and Eastern possessions would derive from the establishment of railway communication between the two great trading cities of Alexandria and Cairo. The cumbrous navigation of the Nile at the best seasons, and impracticability at others, for laden boats, render the advantage of such a highway so palpable, that men of less discernment have been recently agitating the question, and urging it on the viceroy's attention. Produce of the value of 15,000,000 of piastres is annually brought down the river in native craft, subject to the delays of navigation, the danger and neglect of those charged with it, and the uncertainty of arrival to meet the engagements or the wants of the trader."

The exports and imports at Alexandria in 1849 amounted to,

Exports	£1,661,000
Imports	1,474,000

The export of cotton in that year was 183,878 bales, valued at 515,000*l*. The corn exported was of the value of 460,000*l*. of which Great Britain took 325,000*l*. worth. The total exports to Great Britain were 808,000*l*.; and the imports thence were 607,000*l*. There were 3200 ships sailed and arrived during the year, of which 708 were English. The chief articles of export, besides corn and cotton, consist of gums, incense, ivory, senna, coffee, tamarinds, rice, flax, flax-seed, sesame, mother-of-pearl, tobacco. Those of import consist of cotton, woollen, hardware, silk and glass manufactures, machinery, drugs, spices, sugar, oil, candles, soap, tar, timber, wines, cordage, &c.

The trade formerly carried on through Egypt from the Red Sea is now quite inconsiderable. The imposition of heavy transit duties, and the monopoly of certain articles by the government, have given a new direction to it, and created markets elsewhere.

EIDOGRAPH, is an instrument invented in the year 1821, by the late Professor Wallace of Edinburgh. It is a species of pantograph, and, like the latter, it is used for the purpose of copying plans or other drawings on the same or on different scales.

EIDER DOWN. This beautiful substance is obtained from one species of the duck, called the eider duck, found extensively in the icy seas of the north. There are two kinds of eider down, the live and the dead. The live down consists of the exquisitely light feathers which the duck strips off from herself to keep her progeny warm in the eggs. Its lightness and elasticity are such that two or three pounds of it, squeezed into a ball which may be held in the hand, will swell out to such an extent as to fill a case large enough for the foot-covering of a bed. The quantity of down afforded by one duck during the whole period of laying is about a pound. The down-gatherers are obliged to be cautious not to carry their somewhat cruel robbery too far, or the ducks will not again return to the same spot. Any district in which the eider duck is willing to locate itself is regarded as a valuable property in Norway and Iceland, and the landowners do their best to encourage the location. The *dead* down is that which is taken from the dead duck; it is inferior to the live down.

ELASTICITY. When the form of a body is affected by the pressure of another extraneous to it, the reacting force by which it sustains or tends to remove that pressure is its elasticity. Amongst bodies whose elasticity is very apparent, we may enumerate glass, ivory, caoutchouc, gutta percha, sponges, and fibrous substances, as beams, muscles, and artificial webs, some gums, steel, and all the gases and vapours. In gases and vapours its effects may be produced to any extent, but they are limited in solids by their softness and facility of fusion, as in wax, lead, &c.; by their absorption of moisture, as in clay, feathers, catgut, straw; or by their friability, as in glass, dry resins, and copper or iron which have been exposed to a stream of ammoniacal gas.

The elastic force of steam is found to increase nearly in a geometrical progression when the temperature is increased in an arithmetical progression; from which property steam has now become a great mechanical agent.

ELATERIN, a vegetable principle extracted from the wild cucumber (*Momordica elaterium*). Elaterin has a bitter and somewhat styptic taste. It is insoluble in water, and in diluted and alkaline solutions. It melts at a few degrees above 212°, and at a higher temperature it is volatilised in very acrid white vapours. It is a powerful medicinal agent.

ELBERFELD is a large manufacturing town in Rhenish Prussia. The waters of the Wupper river are said to possess most valuable bleaching properties, and to this circumstance Elberfeld is indebted for its origin and prosperity. The town is the seat of an extensive cotton and silk manufacture, but is more important still for its dyeing, printing, and bleaching establishments. The cotton printers and silk-dyers consume a large quantity of piece-goods that are woven by hand in the surrounding districts; their patterns, which are very superior, are designed on the premises of the large printers, who keep French artists at high salaries in their employ. Merinos and fancy woollen goods are also manufactured here. The town has about 70 dyeing establishments, 10 bleaching-grounds, 6 cotton-spinning factories, 1 large woollen mill, with machine-makers, and colour-works; it has also block-pattern cutting, printing, engraving, and lithographic printing establishments. Tapes and ribands are an important article of manufacture, with which this town and Barmen (which touches Elberfeld on the north extremity) supply all Germany. The colour called Turkey red is produced in Elberfeld more cheaply and of better hue than in any other place of Europe.

KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 20.

Elberfeld will supply a notable part of the Prussian contribution to the Industrial Exhibition.

ELBEUF, a large manufacturing town in France, has had many extensive factories built within the last few years. It has a *conseil des prud'hommes*, or council of experienced men, for the settlement of questions between manufacturers and their workmen. The factories of the town and neighbourhood, which exceed 200 in number, and are mostly worked by steam power, produce a great quantity of woollen cloths; the descriptions are various, and include double-milled and waterproof cloths, zephyrs, and fancy cloths of all colours. From 60,000 to 70,000 pieces of 60 yards each, at from 10 to 20 francs a yard, are produced annually. The cloth is purchased of the manufacturers by large commission houses, of which there are about 70 in the town, and by them it is sent to various parts of France. This town is also celebrated for the manufacture of billiard-table cloth and flannel. It contains several dye-houses, fulling-mills, and large wool-stores, besides establishments for washing wool, which lie along the Seine and the Puchot, a small winding stream that traverses the town.

ELECTRIC LIGHT. Among the numerous practical applications of electric power, not the least curious is that of maintaining a steady light for public streets. The scheme has not yet assumed a fully satisfactory position; but it is not improbable that it may do so ere long.

In 1846 Messrs. Greener and Staite patented the electric light, as a means of illuminating public thoroughfares and buildings. The plan described by the patentees involves the use of small lumps of pure carbon, enclosed in air-tight vessels, and rendered luminous by currents of galvanic electricity; pieces of platinum are also mentioned as being fitting substitutes for the carbon. The idea was not new; but the patentees claimed to have placed it in a more practical form than it had before assumed. During the year 1847 Mr. Staite exhibited his electric light in many parts of the country; and in a lecture on the subject at Newcastle, he gave the following statistical estimate of its capabilities:—'With a battery consisting of 40 small cells in series, the light was equal to 380 tallow candles, 300 wax candles, or 64 cubic feet of gas: this being effected by the consumption of little more than $\frac{3}{4}$ of a lb. of zinc per hour. The relative cost was by the electric light 1*d.*, gas 6*d.* or 8*d.*, tallow candles 7*s.* 6*d.*, and wax candles 12*s.* 6*d.* per hour.' We may remark however that this mode of comparison is open to many fallacies.

In 1848 the electric light was exhibited very frequently in different parts of London. The general arrangement is as follows:—Two small cylinders of carbon are placed with their ends nearly in contact, being distant apart some fraction of an inch, which is made to depend for its amount on the size and purpose of the apparatus. A train of wheels is attached to the machine to keep these carbon points always at the same distance apart during their slow combustion. There are also the galvanic apparatus and the wires; and the principle of action depends on the fact that the galvanic circuit is not completed unless the fluid can traverse the small distance from one piece of carbon to the other: the resistance which the carbon offers to the transit occasions the evolution of a most intense light. The mechanism by which the points are kept at such a distance as to give *continuous* instead of an *intermitting* light, is very ingenious, and such as had not previously been applied.

In the same year an electric light of somewhat similar character, but differing in many working details, was introduced at Paris, and was afterwards exhibited also in London, by MM. Achereau and Fourcault. During 1849, in a lecture by Mr. Grove at the Royal Institution, and at the meeting of the British Association in Birmingham, as well as in scientific and practical papers in the public journals, the merits and demerits of the electric light were discussed at considerable length.

In Mr. Allman's electric light, brought under public notice in 1850, the mechanism differs from that of the older form in maintaining the carbon points always at a proper distance apart. When more of the electric fluid is passing than is necessary to maintain the required intensity of light, the mechanism so adjusts itself as to bring the carbon points farther apart; whereas, when the electric force is below its proper limit, the points approach more closely. The apparatus possesses therefore something of the self-governing or self-adjusting power which is so admirably exemplified in modern steam-engines. There are many circumstances which seem to indicate that we are not far removed from the period when light produced by electric agency will be rendered practically available in manufactures and the arts of life.

ELECTRIC TELEGRAPH. The marvels of this admirable contrivance will be better appreciated if viewed in connection with telegraphic agency in general. [TELEGRAPH.]

ELECTRO-METALLURGY. In this beautiful modern department of manufacture, articles in gold, silver, and other metals are arrangements. There will be three dials, in the middle of the east, west, and south fronts respectively, all worked by an electro-magnetic apparatus. The south dial is a remarkable one; it is a semicircle, instead of a circle, with hours marked from 6 in the morning to 6 in the evening. There will be two hands, a minute hand, 16 feet in length, and an hour hand somewhat shorter; each hand will be double pointed, or have the pivot in the middle of its length; and that half which happens to be at any time above the horizontal line will mark the hour on the semicircular dial. The hour figures tend to decorate the south transept end of the building.

An Electric Gun was exhibited in London in 1845, and described in the public journals at the time. It was invented by Mr. Benningfield; but as he had not secured his invention by a patent, the mechanism was not made known; but it was understood that the motive power was derived from a galvanic battery. The gun was capable of discharging balls five-eighths of an inch in diameter; and 1000 of these could be propelled in a minute. The barrel was supplied with shot from two chambers; and these chambers, as well as the gun and the electro-motive apparatus, were placed upon a single-horse carriage.

ELECTROTYPE. Besides the larger works produced by Electro-metallurgy, many exquisite copies of delicate works of art are produced by a modification of the same process, called *Electrotype.*

Let the object to be copied be a small bas-relief of about six inches by four, executed in a material such as marble, ivory, or plaster of Paris. A wax mould is made from the bas-relief; and this wax is made a conductor of electricity by being brushed over with powdered plumbago. The mould and a plate of copper are placed parallel, in a convenient vessel containing a solution of sulphate of copper. The copper plate must have a wire soldered to its upper edge, for the purpose of connecting it with that of the battery; and the wax mould must be similarly connected with the zinc element of the battery. The mould and the copper plate being thus placed in the metal and connected by wires with the battery and the solution being poured in, the whole is left undisturbed from 24 to 36 hours; at the end of which time, the mould, being detached from the battery and withdrawn, will be found covered over with pure bright metallic copper, rough on the outer surface; but when separated from the wax by gently heating, it will, if the operation has been successful, present a perfect copy of the bas-relief, every line of which, to the most delicate markings, will be found transferred to the metal with more precision and delicacy than could have been produced by a cast made with the copper in a state of fusion. Perhaps few facts connected with the laws of aggregation of homogeneous matter are more striking than this, and few facts indirectly afford a more remarkable instance of the chemical divisibility of matter.

The copying of coins, medals, seals, and plaster casts, is extensively practised by the process above described. The production of copper busts, made entirely by deposition from solution, is also an example of the application of this process. Stiglmayer, the sculptor, devised a mode of coating colossal plaster statues with copper by the electro-process in the short space of two or three hours. Daguerreotype pictures are capable of being copied in electrotype, by a kind of etching by galvanism; and Mr. Smee has suggested the employment of a plan somewhat similar for etching in general.

The terms *Electrotint* and *Glyphography* have been applied to two methods of etching by electricity, in which the device is produced in rather a peculiar way. The methods are adapted, one for plate-printing, in which the design is in intaglio: and the other for surface printing, as in common typography. Both have been partially brought into use, but not to any considerable extent.

A most curious instance of the extensive applicability of the art of electrotyping, is the fact of calico having been printed by means of it. The linen, steeped in proper liquids, is made to pass between rollers, one of which has patterns formed in it of different metals inserted into its substance, and connected with the zinc of a battery: the other roller is a simple metallic conductor: the current between these surfaces produces different colours by the difference in their action on the common fluid, and thus the pattern is imparted to the calico.

The electrotype process has been recommended not only for copying engravings, but for making the copper-plate itself on which an engraving is to be executed. The copper-plates prepared for engravers generally contain a small portion of other metals, which render both the engraving and the etching somewhat uncertain. By the substitution, therefore, of plates produced by electro-deposition, in which the copper is quite uncontaminated with other metals, an advantage is anticipated. To produce these plates, a copper-plate is prepared in the usual way and suspended in a copper solution, by which a film of any desired thickness may be produced; and by a previous adjustment of the plate, the new portion may be separated from the old in the form of a distinct plate, susceptible of after-preparation for the engraver. Or, the copper-plate, instead of being made by deposition upon another plate of the same material, may be produced on a flat surface of wax or plaster properly prepared.

ELEMI, is a resin obtained from the *Amyris zeylanica, Eleagnus Hortensis*, and other trees, in the East Indies and elsewhere. It occurs in irregular-shaped small pieces, which run into masses, of a yellowish colour and agreeable odour. Elemi is recommended as an ointment, but is chiefly used to form pastiles, or to burn as incense.

ELGIN MARBLES. Among the choicest treasures of the British Museum are the Elgin Marbles, a collection of ancient sculptures, chiefly from the Acropolis of Athens, whence they were obtained by the Earl of Elgin (who had been the English ambassador to Turkey) between the years 1801 and 1812. This collection was purchased in pursuance of an act of the legistature, dated July 1st, 1816, for the sum of 35,000*l*., and is now deposited in the British Museum, in a room built for its reception.

The Parthenon, or Temple of Minerva, at Athens, whence the more important of these sculptures were obtained, was built during the administration of Pericles, about the year B.C. 448. It was constructed entirely of white marble from Mount Pentelicus; Callicrates and Ictinus were the architects: and the sculptures were produced partly by the hand and partly under the direction of Phidias. Two models of the Parthenon have been placed in the Elgin Saloon at the British Museum, one of which represents the building in its ruined state, and the other restored to its perfect state, with the sculptures occupying their proper places.

The sculptures of the Parthenon in the Elgin collection contain the Metopes, most of which represent the combats of the Centaurs and Lapithæ; a portion of the Frieze of the cella, which represents the Panathenaic procession; and the Statues, or parts of them, from the tympana of the pediments.

The possession of the Elgin collection has established a national school of sculpture in our country, founded on the noblest models which human art has ever produced. A tribute of thanks is due to the nobleman to whose exertions the nation is indebted for it. If Lord Elgin had not removed them the greater part would long since have been totally destroyed. In the last siege of Athens the Parthenon suffered additional damage.

ELLIPTIC COMPASSES, the name given to any machine for describing an ellipse. A simple method of forming the curve is to fasten a pin in the paper at each of the two foci, and to attach to the pins the opposite ends of a thread whose length is equal to the major axis of the ellipse. Then, if a pencil move in such a way as to keep the thread always stretched, it will describe an ellipse.

The ordinary machine consists of two bars of metal at right angles to one another, in each of which is a groove: two pins in a ruler, of which one extremity carries a pencil, are made to travel in the grooves, when the motion of the ruler causes the pencil to describe an ellipse. The distances of the pencil from the two pins are made equal to the semi-axes of the curve.

ELM. The elm-tree frequently grows to a very large size; and the timber thus yielded has a scantling sufficient to adapt it for use in the keels of ships. The wood of the elm is of a brownish colour, hard, and fine-grained. Besides the keel, it is used for blocks, dead-eyes, and other parts of a ship's fittings. It is frequently used for the naves of wheels; and in London for coffins. It is used for the brine pipes or tubes in salt works. Many specimens of elm are so beautifully grained and knotted, that this wood is largely used in the form of polished veneers.

As fuel and as charcoal the elm is not quite equal to the beech. The ashes are rich in alkali. The leaves and young shoots are employed in France as food for cattle, and they are boiled as food for pigs. In some parts of Russia the leaves are used as tea. The outer bark is sometimes prepared into an astringent medicine; the inner bark is made into nets and cordage; and both are made to yield a substance which serves as glue. In Norway the bark is kiln-dried and ground with corn as a material for bread.

Most of the above details refer to the common or English elm. The mountain or Scotch elm is likewise useful to the ship and boat builder, the pump and block maker, the cartwright, the coachmaker, the cabinet-maker, and other manufacturers. Floor-timbers of ships; naves, poles, and shafts of carriages; swingle trees for gun-carriages; dyers' and printers' rollers—all are frequently made of Scotch elm.

ELSINORE, a seaport town in the Danish island of Seeland, at the narrowest part of the Sound, is remarkable for being so placed that all ships entering the Baltic must pass it. Ships passing the Sound pay duties to the Danish government at Elsinore. The number of vessels which passed the Sound during the first nine months of 1847 was 17,404, which was an increase of 2,843 over the same period of 1846; of this number 9,100 came from the North Sea, and 8,304 from the Baltic.

ELUTRIATION, the process of separating substances reduced to powder, when of different specific gravities, by means of water. It is also employed as a method of reducing any one substance to a fine powder.

EMBANKMENT. It is often necessary to raise mounds or dykes along the course of rivers to keep them within their channels, and prevent their flooding the lands which lie near them. Many parts of Holland could not be inhabited if the sea were not kept out by strong embankments: and the destruction of a dyke frequently desolates great tracts of country.

The first thing attended to in forming embankments is to enable them to resist the pressure of the highest floods which are likely to occur, and to prevent the effect of the waves and currents in washing them away. When it is the mere pressure of a column of water which is to be withstood, a simple earthen bank made of the soil immediately at hand, provided it be not of a porous nature, is sufficient. Its form should be a very broad base with sloping sides, and with a flat top, which may serve as a path or even a carriage road. When the dykes are only intended to check the waters at the time when they flow over their natural banks, it is best to raise them at some distance from the river on each side, and parallel to its course; because, in sudden floods, the water, having a greater space to flow through, will not rise so high, and will sooner recede.

Where embankments are made against the sea, greater skill is required to resist the force of the waves. If there are materials at hand to lay a bank of stones imbedded in clay, with a broad base, and the sides sloping very gradually upwards, a very safe barrier may be opposed to the waters. It is not the direct impulse which is the most destructive; waves striking against a sloping surface lose their force and rise over it; but it is in returning that they draw the materials with them, and scoop out the foundations. In a place where shingles were usually thrown up by the waves, and the bottom was a strong clay, their retreat has been intercepted by rows of strong piles driven in a line along and parallel to the shore, and covered with boards nailed to them on the land side; in one night the shingles have been thrown over the piles; and being retained by the boarding, have formed a perfect wall. In other cases several rows of piles are driven in, and stones thrown into the spaces between them.

Where the land lies very flat for a considerable distance from the shore, it is of advantage to have two complete banks, one within the other; so that if the outer bank is broken through, the second will keep back the waters until the first can be repaired. The water which accumulates within the banks, and is collected in the internal ditch and those which divide the marshes, must be let off occasionally by means of channels and sluices at the time when the tide is out, and the water outside the bank is lower than that which is within it.

EMBOSSING is the art of producing raised figures upon wood or other materials, by means of pressure, either applied by a sudden blow, as in a stamping press, or in a more gradual manner, as by an ordinary screw or hydraulic press, or by revolving cylinders. The pattern is usually produced by forcing the face of the material against an engraved die in which the design is cut; and sometimes, when the article to be embossed is in the form of a thin sheet, a counterpart to the die is applied at the back to aid the process. In many cases heat is employed during the operation with great effect.

Mr. Straker has proposed a method of embossing, by pressing a device forcibly on a surface of wood, planing down the rest of the surface, and bringing up again into relief the pressed portion, by exposing it to the action of water. Leather is capable of being embossed in a beautiful manner, by being pressed into metallic moulds while in a very moist, soft, and pliable state.

At the Mediæval Exhibition in 1850, many beautiful specimens of this art were exhibited, in metal, in leather, and in other materials.

EMBROIDERY, is a mode of working devices on woven substances. In some examples of this kind a rich effect is produced by inserting slips of parchment cut to suit the devices, between the fabric upon which the embroidery is executed and the threads of silk or other material of which the pattern is formed, so that the embroidery may be raised considerably above the surface. Gold and silver thread are often used in embroidery with good effect, and spangles or tinsel are occasionally mixed with the needlework. The fabric to be embroidered is usually stretched in a kind of frame or loom, and the pattern is drawn either upon its surface, or upon a piece of paper applied underneath it.

Although embroidery has, until within a few years, been a purely handicraft employment, it has latterly assumed the character of a manufacture, a most ingenious machine for executing it having been invented by M. Heilmann of Mühlhausen, and brought into use in France, Germany, Switzerland, and England. Attended by one grown person and two children, each machine does as much work as fifteen embroiderers. The machine is figured and minutely described in Ure's 'Dictionary of Arts.' The embroidery of the middle ages is noticed under TAPESTRY.

Embroidery has its periods of success and decline, like other arts. At present there is a disposition towards its revival; and it is pleasing to find that Ireland is doing her share towards bringing about this result. At the Dublin Exhibition of Manufactures in 1850, many exquisite specimens of Irish Embroidery were displayed, mostly contributed by Messrs. McGee of Belfast. They were principally waistcoatings or vestings, of velvet, satin, and other rich materials, embroidered with gold, silver, silk, &c., in a variety of tasteful designs. Many of the designs or patterns were made by pupils of the Belfast School of Design, and all the embroidery was done by young females at Belfast. Arrangements are being made to teach this beautiful art to poor and industrious females in Dublin.

What is now called *Berlin Work*, though not exactly embroidery, may be briefly touched on here. Miss Lambert, in her 'Handbook of Needlework,' gives some interesting details concerning the origin of Berlin work. The kind of work itself is, of course, old enough; the only novelty consists in the care bestowed on the production of patterns. About the year 1805 a Mr. Phillipson published some patterns, which, being badly executed and devoid of taste, did not meet with encouragement. In 1810 Madame Wittich, a lady of great taste and an accomplished needlewoman, justly appreciating the advantages which the art would derive from the production of superior patterns, prevailed upon her husband, a printseller of note at Berlin, to undertake the publication of a series of designs. He did so; and the designs were got up in so superior a manner, that many of the first patterns which were issued from his establishment have had a continued demand almost to the present time. The designer and engraver of these designs are paid as *artists*, in proportion to their talents. The cost of the first coloured design on point paper, (divided into small squares) varies from three to thirty or forty guineas; but in some instances, such as the large patterns of Bolton Abbey, Boccaccio's Garden, &c., it is considerably more. The colouring affords employment for men, women, and children. A dozen or so of copies are given to each person at a time, with the original design as a guide. The earnings are from sixpence to three shillings a day, according to the age and skill of the persons employed.

Berlin workers have had their work facilitated by an ingenious frame, registered by Mr. Lisle in 1843. From a flat horizontal stand rise two pillars, which support the frame somewhat in the same way as a toilet looking-glass is supported, so that the frame may be placed and secured in any convenient position. The canvass or other woven material is wound on rollers, which turn easily on their axes; all the canvas is wound on one roller in the first instance, and is unwound to the other roller as fast as the work proceeds: the space between the two rollers being occupied by a smooth well-stretched portion of the canvas. The rollers are worked by small handles, and there are crotchet wheels to prevent them from slipping backwards. The side or selvage edges of the canvas are kept stretched by two rods. By this apparatus the Berlin worker or embroidress can work on a piece of canvas of almost any length.

Embroidery and needlework were imported to the following amount in four recent years, viz.—65,345*l.* in 1846, 82,889*l.* in 1847, 96,449*l.* in 1848, and 104,699*l.* in 1849.

EMDEN, the principal seaport of Hanover, has been a free port ever since the year 1751. Ship-building is carried on to a considerable extent; the herring fishery, which is a source of great profit, is carried on by four companies who send out between fifty and sixty ships. Emden has brandy distilleries, sawing and oil crushing mills, manufactures of fustians, cottons, stockings, sail-cloth, cordage, needles, leather, soap, tobacco, &c. It has considerable trade in linens, thread, grain, butter, and cheese.

EMERALD. [BERYL.]

EMERY. The nature of emery is noticed under CORUNDUM. Emery-paper consists chiefly of powdered emery secured by glue or some other cement to paper. In 1849 Mr. Day took out a patent for a mode of making emery paper or emery cloth which should resist damp. He coats the paper or cloth on one side with a composition formed of boiled linseed oil, African copal, Venice turpentine, Venetian red, Prussian blue, and litharge; the pounded emery is sifted on this moistened surface, and the other surface is afterwards treated in a similar way.

EMPYREUMA, is the name given to the peculiar smell and taste resulting from the action of heat upon organic substances in close vessels. Destructive distillation goes on so as to produce an oil which has a strong empyreumatic smell and taste.

EMULSION is a term applied to mixtures

which generally have a milky appearance, and which, in some cases, are partial solutions, in others merely mechanical suspensions, of oily or resinous substances: thus oil of almonds may be for a time diffused through water by trituration, but will ultimately separate and float on the surface. Emulsions should be used soon after being formed, as in a few hours the constituent parts separate or become acrid.

ENAMELS and ENAMELLING. There exists evidence that the Egyptians practised this beautiful art; but this cannot be affirmed of the Greeks. The Romans, however, have bequeathed abundant evidence that they were acquainted with the art, and practised it extensively, at least in the time of the Lower Empire.

Enamels are vitrifiable substances, and may be divided into two kinds, transparent and opaque. The basis of all enamel is a white transparent glass. The addition of some of those metallic oxides which merely impart colour, as gold, silver, copper, cobalt, &c., convert this into a transparent enamel; while those of tin and antimony, which render it opaque without imparting colour, form a white opaque enamel. There is also a material, of which the commercial name is glass enamel, the opacity of which arises from the presence of arsenic. This substance is very glassy, brittle, easily scratched, readily fusible, and very white: it is used for making the common kinds of watch and clock dials, ornaments for the mantel shelf, the toilet, &c.

Enamel is made in some of the English glass houses, but the best is imported from Italy. This is in the form of circular cakes, measuring from about three to about seven inches in diameter, and half or three quarters of an inch in thickness. It is cream coloured, heavy, less brittle than glass, is sufficiently hard to scratch crown glass; its fracture is conchoidal, and exhibits a resinous lustre, and it fuses at a temperature a little below that which melts gold. It is sold at from 12*s.* to 20*s.* per lb.

Enamelling divides itself into two branches—transparent and opaque. The first is employed for the purpose of ornamenting gold and silver snuff-boxes, watch cases, and various articles of jewellery. Previously to the application of the enamel, various patterns and devices are *bright-cut* with the graver or the rose-engine, when the cuts reflecting the rays of light from their bright and numerous surfaces exhibit through the richly coloured enamels with which they are encrusted a beautiful play of colours. Sometimes this enamelled bijouterie is further adorned with paintings in enamel executed on rich transparent grounds.

Opaque enamelling is employed in the manufacture of watch and clock dials and of plates for pictures. For this purpose the enamel is first broken with a hammer into small pieces, and then ground with a pestle and mortar formed of agate. It is then spread evenly on a plate of copper, which has been prepared for its reception, and, being passed through the furnace, the enamel is melted, and adhering firmly to the metal, thus forms an enamel plate. For the best kind of dials, a second coat of enamel is laid over the first, and for pictures a third is added. The figures are painted on the dials in a vitrifiable colour, when they are again subjected to the heat of the furnace, which melting the colour and softening the enamel at the same time, incorporates the two into one body, and thus permanently fixes the painting. Gold is frequently used instead of copper for small enamel pictures. When the enamel plate is prepared, the artist proceeds to paint his picture in a similar manner to that which is pursued by the painter in oil or water colours; a principal difference being, that instead of waiting for the colours to dry before proceeding to lay on another coat of colour, he has his work passed through the fire, by which process the colours are imperishably and immoveably fixed. Paintings in enamel are usually subjected to the furnace ten or twelve times, and in some cases oftener. The colours are composed of a colourless glass as a base, the colouring matters being metallic oxides. Thus silica, borax, and the red oxide of lead, form a base or flux for some colours. The habitudes of the various oxides, however, require that each should be treated with reference to its peculiar properties: for instance, the flux which, employed with gold, is best adapted for the production of a useful and beautiful colour, is wholly inefficient if used with cobalt.

In a lecture on Ancient and Modern Enamels, delivered by Mr. Digby Wyatt to the Society of Arts in 1848, attention was drawn to six different kinds of enamel-work, which marked six different periods from the time of Justinian to modern dates. The Byzantine process consisted in the formation of cavities of gold filagree, filled with enamel. The Early Limoges style, instead of having a framework of filagree, had the enamel fixed into cavities scooped from thick copper plate by the graver. The Early Italian method consisted in engraving silver after the manner of medallic relief, and then floating over it with variously-coloured transparent pastes. In the Later Italian method, small gold or silver objects were covered with glass powder mixed with water in which the pips of pears had been steeped; this held the paste in its place until vitrification took place, and was yet so delicate a cement as in no degree to interfere with the purity of the enamel. The Later Limoges style consisted in covering entirely the surface of the metal with an opaque paste, and then painting with transparent colours: regaining the effect of a translucent ground by applying silver leaf in particular situations fastened with a glaze of colourless enamel, and then tinting over it. The sixth style is the modern miniature painting on enamel.

The nature of the material and the expense attendant upon attempts to produce large works in enamel, have tended to restrict the dimensions of enamel paintings. Until the time of the late H. Bone, R. A., but few attempts had been made to extend their size beyond that adapted for trinkets. This artist, with amazing perseverance and industry, overcame innumerable difficulties, and exhibited for a long series of years enamels of large dimensions. The largest works which have been executed in enamel are, 'Bacchus and Ariadne,' after Titian, by H. Bone, R. A.; and a 'Holy Family,' after Parmigiano, by Charles Muss. The former measures 16½ inches by 18; and the latter 15¼ inches by 20½. George Bowles, Esq., purchased the Bacchus and Ariadne for 2200 guineas, and His Majesty George IV. gave 1500 for the Holy Family. This last now forms part of the collection in Buckingham Palace.

The power of resisting decay renders enamel a valuable medium for preserving for ages the likenesses of celebrated individuals. The artists who practise this durable and beautiful style of painting have not at any time been numerous.

At the Mediæval Exhibition in 1850, enamels of exquisite beauty were displayed, chiefly of French and Italian workmanship.

Another kind of enamelling, much humbler in rank, but practically of great usefulness, is that of enamelling the interior of cast-iron and other hollow articles, such as saucepans and other culinary and domestic utensils. The superior cleanliness of such articles, and the security which they afford against any metallic taint, render them peculiarly valuable for some delicate operations in cookery and confectionary, and for the preparing of pharmaceutical decoctions, extracts, &c. The enamel used for this purpose may be stated, in general terms, to consist of silica, soda, borax, and potter's clay. Until within the last few years, enamelled iron saucepans were imported from Germany; but they may now be regarded as a home manufacture rapidly extending.

ENCAUSTIC PAINTING is a kind of painting in which, by heating or burning in, the colours were rendered permanent in all their original splendour. It was not, however enamelling, but a mode of painting with heated or burnt wax, which was practised by the ancients. Pliny describes three modes of encaustic painting. In the first mode, the wax was melted, mixed with as much earth colour finely powdered as it could imbibe, and then this mass spread on wood, or on a wall, with a hot spatula. When it became cold it was the ground, in which the designer cut the lines with a cold pointed tool (style, cestrum). In the second mode, ivory tablets were covered with red or black wax, and the design cut into it with the style, the object being to use the clear and smooth surface of the ivory for the lines, that they might look the more beautiful. The third kind was the applying the colours with the pencil; the wax was dissolved, the colours mixed with it, and laid on with the pencil, and the painting then finished by careful approximation to the fire: for this purpose a hot iron (cauterium) was used. When painting had been greatly improved by the invention of the pencil, a new method of encaustic was attempted. Encaustic wax painting had hitherto been designing on a coloured ground; it now became painting with wax colours burnt in. When the artist had laid on the wax ground, and traced the outlines with the style, he proceeded to the colouring. From the wax mixed with the colours he separated with the hot style as much as he wanted to cover a certain space, and spread it over the ground, put a second, third, &c., colour next the first, so that he had local tint, half tint, and shade together, which he softened into each other with the hot style.

This art, having been long lost, was revived by French and German artists in the 18th century, and is now occasionally practised.

ENDOSMOSE and EXOSMOSE. These names are given to a remarkable filtering process which takes place through membranes. Endosmose is the attraction through an animal or vegetable membrane of thin fluid by a denser fluid. M. Dutrochet found that if he filled the swimming bladder of a carp with thin mucilage and placed it in water, the bladder gained weight by attracting water through its sides: to this phenomenon he gave the name of *Endosmose*. He also found that if he filled the same bladder with water and placed it in thin mucilage, it lost weight, its contents being partially attracted through its sides into the surrounding mucilage: this counter-phenomenon he named *Exosmose*. The same circumstances occur in the transmission of fluids through the tissue of plants. The parts of vegetables may be gorged with fluid by merely placing them in water, and may be emptied again by rendering the fluid in which they are placed more dense than that which they contain. This phenomenon takes place with considerable force. Water thickened with sugar in the proportion of 1 sugar to 2 water, is productive of a power of endosmose capable of sustaining a column of mercury of 127 inches, or the weight of 4½ atmospheres.

Dutrochet considers endosmose to be owing to what he calls intercapillary electricity, grounding his opinion partly upon the experiment of Porret, who found that when two liquids of different levels are separated by a membrane, they may be brought to a level by establishing an electrical current between the two, thus rendering the membrane permeable; and partly upon experiments of his own. But M. Poisson, on the contrary, has demonstrated that endosmose may be the result of capillary attraction joined to differences in the affinity of heterogeneous substances.

A few applications of this principle have been made in the arts; but it still remains chiefly in the domain of science.

ENGINEERING (from the French word *engin*) is properly the art of constructing and using engines or machines; but the term is also applied to that of executing such works as are the objects of civil and military architecture, in which machinery is in general extensively employed.

A distinction has long been made between the civil and military engineer; and since every thing relating to the service of artillery is now confided to a particular corps, the duty of the military engineer may be said to comprehend the construction of fortifications, both permanent and temporary, including the trenches and batteries required in besieging places; also of barracks, magazines, and other works connected with warlike affairs.

The profession of the civil engineer comprehends the design and execution of every great work by which commerce and the practice of the useful arts may be facilitated. Thus, in creating or improving the communications of a country, he would be called upon to form a road through hills, or over valleys or rivers, or to excavate a canal in connection with the waters by which it may be supplied, and to build the locks for retaining the surface at different levels, in different places, when the inequalities of the ground are considerable. He raises embankments to resist the encroachments of the sea or to reclaim the land which it may have covered, and dams to break the force of its waves at the mouths of natural harbours. He renders rivers navigable when their course is obstructed by rocks or banks; he forms docks or artificial harbours where ships may remain in security; he is required to penetrate by mines to vast depths for the purpose of seeking the mineral treasures contained within the bosom of the earth; and the formation of iron roads or railways is now a most important branch of the profession. Such are the occupations of this class of men; and it is necessary to observe that they frequently, in addition, practise the avocation of the machinist in executing the presses, mills, looms, and other great machines employed in the arts and manufactures; particularly in constructing steam-engines and the apparatus by which they are rendered available for giving motion to ships, carriages, or machinery.

In France the title of engineer is extended to persons who are employed for the public service in trigonometrical surveying in the interior of a country or on the coasts, and in the practice of naval architecture. The French have thus a corps of ingénieurs géographes, of ingénieurs d'hydrographie, and of ingénieurs de marine.

Of the national works executed by the ancients, and which are to be considered as properly falling within the province of the engineer, one of the first of which we have any intimation is the canal uniting the Red Sea and the Nile, which, according to Pliny, was begun by Sesostris, or, according to Herodotus, by Necos, the son of Psammetichus, and finished by Darius the First. The canal of Xerxes across the isthmus of the peninsula of Athos is another example of works of this kind. The introduction of arches in works of magnitude may be said to have constituted an epoch in the profession of the architectural engineer, since the idea of giving to blocks of stone a form which would enable them to sustain themselves in balanced rest by their mutual pressures, the discovery of the means of arranging them on a curve surface, and the determination of the magnitudes of the piers or abutments so that the lateral pressure of the vault might be adequately resisted, imply a higher degree of intellectual power than is exhibited in covering a space with a horizontal roof. The Cloaca Maxima [CLOACÆ] at Rome is probably the most ancient example in Europe of this scientific construction. The dome of the Pantheon, and the various arches of the Thermæ and of other public buildings, both at Rome and in the provinces, such as aqueducts and bridges, attest the grandeur of design, combined with purposes of public utility, which characterised the architects who lived under the early emperors.

Previously to the commencement of the eighteenth century, the most celebrated practical engineers were Brunelleschi, who built the dome of St. Mary at Florence; Peruzzi, San Gallo, and Michel Angelo, who executed that of St. Peter at Rome; San Micheli, the supposed inventor of the bastion system of fortification; and to these may be added Sir Christopher Wren, the architect of St. Paul's Cathedral in London.

But the extension of the manufactures of this country, and the consequent augmentation both of its internal and foreign commerce, have, in more recent times, called forth all the energies of the people, who, in the works performed for facilitating the means of communicating between one place and another, and in the practice of the useful arts, have risen to an eminence which other nations have not been able to attain. Among the former may be mentioned the numerous canals and railways which intersect the country; the majestic bridges executed in stone over the Thames; in cast iron over the Avon, the Thames, &c.; those on the suspension principle at the Menai Strait, and across the Thames at Hammersmith and Hungerford Market; and those on the tubular principle over the Menai and the Conway. Among the men to whose talents in this branch of engineering the nation is indebted, may be named Brindley, Smeaton, Jessop, Telford, the Rennies, Walker, the Brunels, and the Stephensons.

The course of education by which a student may qualify himself to become an engineer, whether civil or military, must necessarily comprehend a greater extent both of the pure and physical sciences than would be required for a person who is to follow any other profession. It will be, perhaps for ever, a matter of opinion how much mathematics should enter a school course of engineering; and there are no doubt some persons who contend that no more is required than would serve to compute the cost of materials and the wages of labour; this and the observation of existing examples being supposed sufficient to enable a man to enter upon the practice of the profession. It is not, however, with such knowledge only that an engineer is qualified to design an important work which it may be required to conduct under new and difficult circumstances. On the other hand, mere diligence in observing the results of practical operations will never raise a man to proficiency in art unless he is gifted with very extraordinary powers. A judicious combination of theory and practice is indispensable, and such a combination can only be made by a man in whom great natural talent is blended with all the aids that the sciences can afford.

Of the military engineer it may be said that a greater knowledge of the more minute details of construction is required than would suffice in the civil practitioner; because it may happen that the former is called upon to exercise his profession in some colony where workmen adequately skilled in the mechanical operations may be wanting. The accomplishment of the work may then become impossible, should the officer not be qualified to give the necessary instructions to those who are placed under his direction.

There is now near the metropolis a college for the education of young persons who are destined to act as civil engineers, where the science and practice of the profession are effectively taught; while the military seminaries at Woolwich, Sandhurst, and Addiscombe, afford corresponding advantages for those who have adopted the military service.

The *Institution of Civil Engineers*, formed at London in 1828, cannot fail, by the publication of its transactions, to be the means of greatly assisting such persons as may hereafter enter the profession; and, through them, of rendering service to society itself. Even established practitioners may occasionally derive benefit from the theoretical investigations and the practical details of construction which are the subjects of the papers read at the meetings of the members.

An *Institute of Mechanical Engineers* was established at Birmingham in 1847, for encouraging experiments and essays relating to engineering subjects. It is under the presidency of Mr. Robert Stephenson, and seems to be a sort of miniature Institute of Civil Engineers.

ENGLISH MANUFACTURES AND TRADE. We retain an entry under this heading, simply to explain how the subjects of English manufactures and trade are treated in the present volume. All the principal *substances* employed in the arts, organic or inorganic, are briefly described under their proper headings, the commercial name being retained rather than the scientific name. All the principal *processes* employed in the arts and manufactures are set forth in simple form, without any attempt at minute or technical detail. All the important *machines* are described in a similarly brief and simple way. Nearly all the *counties* are glanced at, with a view to show what productive and industrial resources they exhibit. All the principal *towns* are similarly noticed, in so far as they are connected with manufacturing or shipping operations. A few commercial *principles* are touched upon which bear closely on manufactures. Lastly, a few *persons* are made the subjects of biographical sketches, in cases were they were especially connected with mechanical or manufacturing celebrity.

In respect to foreign countries, a smaller degree of the same system is acted upon. An attempt is made to show what are the chief natural products of each country, what are the chief manufactures of the countries and their large towns, and what are the chief imports and exports at their shipping ports. As such elements are really the elements of the 'Industry of all Nations,' they form a fitting part of the present work. All merely geographical detail is beyond the scope of this volume.

Besides the minor statistical details scattered through the work, larger illustrations of commercial and manufacturing statistics will be met with under such articles as CUSTOMS DUTIES, EXCISE DUTIES, FACTORIES, IMPORTS AND EXPORTS, SHIPS AND SHIPPING.

ENGRAVING. From the book of Exodus we learn that when Moses had liberated the Jews from Egyptian bondage, he was commanded to 'make a plate of pure gold, and grave upon it, like the engravings of a signet, holiness to the Lord.' He was also commanded 'to take two onyx stones, and grave on them the names of the children of Israel according to their birth, with the work of an engraver on stone, like the engravings of a signet.' Both these passages distinctly imply the practice of gem and seal engraving, and also of engraving on metal plates. From Herodotus we learn that one of the earliest uses to which engraving was applied among the Greeks was the delineation of maps on metal plates. Some of the Egyptian hieroglyphic inscriptions are evidently executed with instruments similar to those now in use. Some of the lines narrowing downwards have clearly been cut with the lozenge-shaped graver now chiefly used; but other lines, being of the same width through their whole depth, must have been produced with that species of graver called a scooper, still used for effecting broad incisions. It is believed that some of the relics of Etruscan art in the British Museum are of as high antiquity as any existing specimens of engraving. In India, also, the art of engraving on plates of copper appears to have been practised long before the Christian æra. It would appear that it was there customary to ratify grants of land by deeds of transfer actually engraven on plates of copper, as we now write them on skins of parchment.

In England, before the Conquest, many of the buckles, clasps, rings, and military accoutrements were engraved. In the museum of Oxford is preserved a finely engraved gold jewel, which belonged to Alfred the Great. About the 12th century was introduced the art of engraving sepulchral brasses. They are executed entirely with the graver, and in the same manner that a copper plate is now engraved.

We now approach the period when the invention of *printing* gave to engraving a new direction. The first prints were obtained from engraved wood blocks. The earliest print with a date attached to it is one known as the St. Christopher, which is from a wood block, and dated 1423; but no impression from an engraved *plate* has been found with a date anterior to 1461. The art of engraving on metal plates for taking impressions on paper was first practised by Tommaso Fineguerra, a Florentine goldsmith, about the year 1460. Some writers have claimed the invention for Germany; but it is generally considered that the art was first practised in Italy, and had its origin in the workshops of the goldsmiths. Many of these goldsmiths were *niellatori*, or workers in *niello*—a mode of ornamental engraving usually performed on silver plates—the design engraved on which was afterwards filled in with a black composition.

An accident is said to have suggested to Fineguerra the possibility of taking an impression from the engraved design with ink on moistened paper. When once established, the new art was eagerly taken up by Baldini, Botticelli, Pollajuoli, and Mantegna; and in Germany by Martin Schoen, Israel van Mecheln, Leydenwurf, and Wolgemut. The first *book* printed at *Rome* (an edition of Ptolemæus's Geography) was illustrated by the first *plate engravings*, twenty-seven in number, which were maps, and were executed there by two Germans, Sweynheym and Buckink. This work is dated 1478, but was commenced in 1472. Another early work was an edition of Dante's 'Inferno,' published at Florence in 1481, and embellished with engravings by Baccio Baldini, after the designs of Botticelli.

One of the best engravers in Italy in the early part of the 16th century was Raimondi, who studied under Francia and Raffaelle. His great merit lay in the correctness and beauty of his outline. He engraved many of Raffaelle's pictures, which he copied with great truth, although defective in respect to light and shade. He was succeeded in Italy by Agostino de Musis, Marc de Ravenna, Caraglio, Giulio Bonasoni, and Enea Vico, all pupils of Raimondi; Georgi Ghisi of Mantua, and his relatives Diana and Adam Ghisi, Cornelius Cort, &c. The principal painters who have practised engraving in Italy are Agostino

Carracci, Stefano della Bella, Spagnoletto, Guercino, Salvator Rosa, Claude Lorraine, Swaneveldt, Canaletto, Piranesi, &c.

In Germany engraving made more rapid strides towards excellence, in the mechanical parts of it; and at the commencement of the 16th century appeared Albert Dürer, a man whose universality of talent extended the boundaries of every department of art, and carried all to a degree of perfection previously unknown in that country. He had great command of the graver, and carried his plates to a much higher degree of finish than his Italian contemporaries. He is also believed to have invented the art of etching by corrosion: three of his specimens are dated 1515, 1516, and 1518 respectively. On examining the etchings of Albert Dürer, we see that they have all been corroded at one biting-in; which sufficiently explains their monotonous appearance, and proves that 'stopping out' was not then understood. The principal German engravers, after Albert Dürer, are Aldegraver, the Behams, Altdorfer, Bink, Penz, Solis, &c.

Lucas Jacobs, best known by the name of Lucas van Leyden, was the father of the Dutch and Flemish schools, and the contemporary and friend of Albert Dürer. After Van Leyden the art was maintained in the Low Countries by the Wierinxes, the Sadelers, whose works are multifarious, and embrace every class of subject; the elder and younger Jode, Cornelius, Theodore and Philip Galle, Abraham and Cornelius Bloemart, Goltzius, Sprangher, Müller, Lucas Killian, Matham, Saenredam, and the two brothers Bolswert. Many of these introduced improvements in the art. To mention the artists of this school from whose hands we have etchings, would be to name nearly all the most eminent painters belonging to it: Rembrandt, Berghem, Cuyp, Karel du Jardin, Paul Potter, Ruysdael, Ostade, Waterloo, Adrian Vandervelde, with many others.

In France engraving has been practised with pre-eminent success in the departments of history and portraiture. The celebrity of the school dates from the time of Louis XIV. The family of the Audrans produced six eminent engravers; but of those the most distinguished was Gerard Audran, who was the first engraver who successfully united, to any extent, the use of the graver and the etching point. Gerard Edelinck, although born at Antwerp, may be fairly considered of the French school, and was an engraver of the highest order. In portrait Nanteuil is no less celebrated than his contemporaries. The Drevets, John Louis Roulett, Le Clerc, Simoneau, Chereau, Cochin, Dupuis, Beauvais, Balechou, Le Bas, John George Wille, are among the best of the French engravers.

The English school of engraving dates only from about the middle of the eighteenth century, previous to which those who practised the art in England were chiefly foreigners.

Hogarth engraved many of his own designs. Francis Vivares introduced the favourite art of landscape etching; he, Woollet, and Browne, produced some of the finest landscape engravings extant. Sir Robert Strange excelled in portrait engraving. Mezzotinto engraving, although not strictly born among us, has been in no other country practised with a degree of success at all approaching that attained by M'Ardell, Earlom, Smith, Valentine Green, and others. Bartolozzi, Ryland, Sharpe, Paul Sandby, Middiman, Milton, Fitler, aud Raimbach, are among the most eminent of deceased engravers.

A modern engraving is usually the result of two processes, namely, of direct incision with the graver or the dry point, and of etching by corrosion. The principal instrument is the *graver*, or *burin*, which is usually of the form of a quadrangular prism, fitted into a short handle. The square graver is used in cutting broad lines, and the lozenge-shaped for more delicate ones. In making the incision, it is pushed forward in the direction of the line required, being held by the handle at an angle very slightly inclined to the plane of the copper. An instrument called a *scraper* is required to scrape off the barb or burr which is formed by the action of the graver and dry point. A roll of cloth dipped in oil, called the *rubber*, is also used to make the surface smooth. The *burnisher* is used to polish the plate and to erase any scratches which it may accidentally receive, and also to make lighter any part of the work which may have been made too dark. *Etching-points*, or *needles*, are nearly similar in appearance to sewing-needles, but fixed into handles four or five inches long; some are made of an oval form, to produce broader lines. The *dry point* does not, like the graver, cut the copper clean out, but throws it up on each side of the line produced by its progress through the metal.

Etching is the superaddition of the chemical process of corrosion to drawing, when performed on a plate of copper over which a substance called *etching-ground* is laid. This etching-ground is a substance composed of wax, asphaltum, gum mastic, resin, &c., incorporated by melting over a fire, and capable of resisting the action of aquafortis; it is applied by the aid of heat, so as to lie in a thin stratum on the copper. To transfer the design to the copper, an outline is made with a black lead pencil on a piece of paper, and laid with the face downwards on the etching-ground; the whole is then passed through a rolling-press, the effect of which is to transfer an impression of the outline on to the prepared ground. After this the design is completed with the etching-needles, which remove the ground from the copper wherever they pass, and expose it to the action of the acid during the process of biting-in. The aquafortis continues on the plate until the fainter parts are supposed to be corroded sufficiently deep; after which it is poured off, the plate washed with water, and left to dry. The parts which are bitten-in enough are now to be covered with what is called *stopping-ground*, which is a mixture of lamp-black and Venice turpentine; this is applied with a camel-hair pencil, and allowed to dry. After this the acid is again poured on, and this process of *stopping-out* and *biting-in* is repeated till the darkest parts are sufficiently corroded.

Engraving in stipple is performed with the graver, which is so managed as to produce the tints by small dots, rather than by lines, as in the ordinary method.

Engraving and *etching on steel* are performed in the same manner as on copper, for which steel has of late years been often substituted on account of its yielding a greater number of perfect impressions, owing to its superior hardness.

Medallic engraving is a species of etching introduced by M. Collas and Mr. Bate. By this mode very beautiful representations are obtained of medals, &c., by means of a machine of peculiar construction.

Etching on glass is performed by laying on the glass a ground of bees' wax, and drawing the designs thereon with the needle, as in etching upon copper. Sulphuric acid is then poured on, and fluor spar, or fluoric acid, sprinkled on it. After four or five hours it is taken off, and the work cleaned with oil of turpentine.

[AQUATINTA; ELECTROTYPE; LITHOGRAPHY; MEZZOTINT.]

ENHARMONIC ORGAN. It is familiar to all who have observed the construction of a pianoforte or an organ, that the same black key serves as the sharp of one note and the flat of the note next above it. This is convenient, but it is not strictly accurate; the sharp of one note is *not* in strictness the flat of the note next above it; it differs from it by some small fraction of a semitone. Hence it has been an object with some persons of refined musical ear to increase the keys to such a degree as to provide a series for the flats, differing from that which constitutes the sharps. But there are two inconveniences attending such a plan; the keys become embarrassingly numerous, and unless the instrument be tuned with most delicate precision, the nicety of the double system is wholly lost. An organ with such an arrangement of parts is called an *enharmonic organ*; at one time the subject attracted much attention, but the plan is now pretty nearly abandoned. A violin player with a correct ear can produce enharmonic intervals easily, as the strings can be stopped at any part of their length.

ENTRE-DOURO-E-MINHO is the most fertile province in Portugal. The principal productions are wine, oil, flax, Indian corn, wheat, oats, vegetables, and fruit of all sorts. Pastures are rather scarce, yet a considerable quantity of cattle, both large and small, are reared. The principal article of exportation is wine, which is made chiefly from the vineyards in the valley of the Douro, and is shipped at Oporto under the name of port-wine. There are fisheries along the coast, which occupy a great number of hands. The commerce is briefly noticed under OPORTO and PORTUGAL.

ENTRESOL, a French term used to signify a floor between other floors. The entresol consists of a low apartment or apartments, usually placed above the first floor. There is a very good example of an entresol over the shops of the Quadrant in London, just beneath the terrace of the colonnade (lately removed). In continental cities the entresol is frequently employed.

ENVELOPES. Before the introduction of the Penny Postage, the number of written letters put into envelopes was comparatively small; but since that period the use of envelopes has increased to an astonishing extent. The cutting out has been for some years performed by machinery; but the folding, until within the last three or four years, has been done by hand. An ingenious machine, however, patented by Messrs. Hill and De la Rue, now folds envelopes with great celerity. From a description of this folding machine given by Mr. Faraday at the Royal Institution in 1849, it appears that it can fold 42 envelopes in a minute. There is a flat metallic surface on which the piece of paper is laid; a sort of hollow frame descends and creases the paper at the four edges: and four levers or folders press down the four flaps of the envelope. There are two finger-shaped projections, made of caoutchouc, which, owing to their property of adhering slightly to a paper surface, never fail to carry off each envelope as fast as it is folded. Though there are twenty-two movements for folding each envelope, all succeeding each other with great rapidity, there is no blow or jar of any kind in the working of the machine.

Mr. Worsdell's patent for making envelopes, enrolled in 1850, relates to mechanism of a very complicated construction. Under the usual methods envelopes are made partly by hand and partly by machinery, with certain intervals of time between the several processes. Mr. Worsdell has sought to carry on two or more of the processes simultaneously, and to make other processes succeed them uninterruptedly. There are shaping, cutting, stamping, gumming, creasing, pasting, and applying processes. A web of paper is unrolled, laid upon a bed or plate, and a series of fine knife edges descend and cut out a piece the proper size and shape for an envelope; this same piece of paper, before it is removed, is creased into an oblong quadrangular form, and the four corners turned up. The roughly-shaped envelope falls out of this machine, and is placed in another where the subsequent processes are carried on. By one movement a die is brought down, and made to stamp a device on the seal-flap; by another movement two bits of sponge, moistened with some kind of gum or cement, and held at the ends of small cylinders, are passed lightly over the edges of the two end flaps; by a third movement the sponges are brought back again; by a fourth movement another bit of sponge, moistened with adhesive composition, is made to touch the inside of the seal flap; by a fifth movement the three flaps are pressed down, leaving the seal flap, with its adhesive composition, untouched; and by a sixth movement the finished envelope is thrust out of the machine. Considerable mechanical ingenuity is displayed in this apparatus.

It is supposed that there are upwards of a million envelopes manufactured *daily* in this country.

EPROUVETTE is an apparatus consisting of a gun or mortar suspended from a horizontal axis for the purpose of determining the strength of gunpowder by the recoil of the piece when a charge is fired in it. Mr. Robins ('New Principles of Gunnery') first proposed the employment of such a machine, but Dr. Hutton, of Woolwich, afterwards considerably improved its construction.

A gun suspended in the manner above described has been employed, instead of the ballistic pendulum, to determine, by its recoil, the initial velocity of the shot fired from it with a given charge of powder.

EPSOM SALTS. This valuable medicine is sulphate of magnesia. It obtained its common commercial name from having been first obtained from a spring at Epsom. The mode of obtaining it first adopted when it became a popular medicine was by evaporating and crystallising the bitter deposit remaining after preparing common salt from sea-water; but the late Dr. Henry invented a much superior mode of preparing it from magnesian limestone. Epsom salts are not only valuable as a medicine, but a source whence common magnesia is largely obtained.

EQUATORIAL INSTRUMENT. This name is generally given to astronomical instruments having their principal axis of rotation in the direction of the poles of the heavens. When the purpose of a machine of this nature is simply to carry a telescope, it has been called a *machine parallactique* or *parallatique* by the French, and sometimes *Polar Axis* by English writers.

It results from the general form of the management, that if a telescope is fixed equatorially, it always points to some spot or other of the celestial equator. These instruments are described with great fulness and completeness in the PENNY CYCLOPÆDIA. Some of the largest telescopes in this country are equatorial.

ERBIUM, is the name given to a metal discovered by Mosander associated with yttria. Its properties are little known. Some of them are as follows:—Its oxide becomes of a dark orange colour when heated in contact with the air, which colour it loses with a little weight when heated in hydrogen gas. It is to the presence of this oxide that yttria owes its yellow colour, when prepared as hitherto directed. The sulphate and nitrate of erbium are free from colour. It does not appear to have been reduced to the metallic state.

ERECTHEIUM, is the name of one of those buildings in Greece which have acquired a world-wide celebrity. It is a beautiful Ionic temple dedicated to Erectheus, built near the western brow of the Acropolis at Athens, and at the time when Stuart visited the place forming part of the modern fortress of the Acropolis. Connected with this building, and placed on one side of it at the end of the cella, is a tetrastyle Ionic portico, in the same style as the portico of the Erectheium, forming a small temple which was dedicated to Minerva Pólias; and on the opposite side is a small roofed building supported by caryátides placed on an elevated basement, forming another small temple dedicated to Pandrosos, and called the Pandrosium. It would appear from the regularity of the plan of the Temple of Erectheus, that it was constructed before the other buildings, and was of that regular parallelopipedal figure most commonly employed in such edifices: and that at a later period the Pandrosium was constructed, with the portico on the opposite side forming the entrance or vestibule to the cella of the temple, which was formed from a part of the cella of the Temple of Erectheus, cut off from the end of that cella, which was either at that time or previously lighted with windows.

Mr. Inwood, the architect, has imitated the Erectheium and Pandrosium in the external design of part of new St. Pancras Church, London.

EREMECAUSIS is the name given by Liebig and other chemists to the act of gradual combination of the combustible elements of a body with the oxygen of the air. This process is constantly going on in combustible bodies exposed to the atmosphere, and one of the first changes which take place during the decomposition of animal and vegetable substances, is the union of one or more of their elements with oxygen, The changes in colour, consistence, and other properties which vegetable juices, saw-dust, leaves of trees, blood, &c., undergo when exposed to the atmosphere, are owing to the same cause. Eremecausis differs from fermentation and putrefaction in the fact that it cannot take place without the access of atmospheric air, through which means the oxygen is supplied to the decaying body. Eremecausis must precede any decomposition of an organised substance; and it is by virtue of this law that animal food may be kept from putrefaction by being heated to the temperature of boiling water, and then secured in air-tight vessels. Food thus prepared has been kept for fifteen years, and when the vessels were opened in which it was contained, it has been found as fresh as when first secured.

ERFURT is a busy province or government of Prussian Saxony. The chief products are grain, flax, tobacco, hops, oil, and salt. Great numbers of horses, horned cattle, sheep, goats, and swine are reared. In the circles of Weissensee and Schleusingen there are mines of iron, lead, and copper. Marble and gypsum, as well as sulphur, are also among its mineral productions. Erfurt is likewise distinguished for its manufactures of iron and steelware, tin plates, seed-oil, woollen yarns, cloths, flannels, and carpets, linens, silks, cottons, stockings, paper, porcelain, glass, brandy, wooden clocks, &c.

Erfurt, the chief town, has considerable manufactures of cottons and woollens, besides less extensive ones of linens, ribbons, leather, soap, earthenware, meal, seed-oil, stockings, gloves, tobacco, &c., and it carries on a brisk trade in fruits, seeds, grocery and drugs, grain, &c. *Mühlhausen*, an antient walled town, has manufactures of woollen cloth, calicoes, beer, tobacco, spirits, leather, oil, glue, starch, &c.; it has also several dyeing and fulling mills. *Nordhausen*, an old fashioned place girt with walls and towers, has very large distilleries, and manufactures woollen cloths, flannels, chemical products, rape-oil, and leather; great numbers of oxen and swine are fattened on grains and pressed rapeseed. *Suhl*, a thriving manufacturing town, produces large quantities of ticking and dimity, and fire-arms, swords, bayonets, ramrods, surgical instruments, &c.; the iron and steel (7000 cwts.) for these last are furnished by 9 forges in the neighbourhood. Suhl stands in a district of the Thüringerwald, entirely separated from the rest of the Prussian territory.

ERGOT is a name bestowed upon a peculiar state of the seed of several cereal grains, but most frequently of the rye, which resembles a spur, or horn; hence, likewise, termed *Secale cornutum*, or Spurred Rye. The spur is of variable length, from a fraction of an inch to two inches, and is from a sixth to a fourth of an inch in thickness; when large, only a few grains in each ear are affected; when small, in general all of them are diseased. In colour the exterior or husk is of a blueish-black or violet hue, with two or three streaks of dotted gray; the interior is of a dull whitish or gray tint. It is specifically lighter than water, which affords a criterion for distinguishing sound from tainted grain. When fresh it is tough and flexible, but brittle and easily pulverised when dry. The powder is apt to attract moisture, which impairs its properties; and time destroys them.

Spurred rye occurs more frequently in some countries and districts than in others, and more abundantly in some seasons than in others. Rye raised in poor soil, and in a humid close air, such as that of the district of Sologne in France, is most liable to be infected; but, according to the experiments of Willdenow, it may be brought on at any time, by sowing the rye in a rich damp soil, and watering the plants freely in warm weather. A very rainy season, such as was that of 1816, is apt to produce it.

Bread prepared from grain which has a large admixture of the spur, occasions very distressing and often fatal effects, which are shown more or less rapidly according to the quantity present in the food, and the circumstances in which those who use it are placed. Ergot of rye is sometimes employed in medicinal practice. The Ergot is produced by a fungus.

ERMINE. This beautiful substance is the fur of the *stoat*, one among many species of *weasel*. It is a native of the northern parts of Europe and Asia , and the finest furs, both as to colour and quality, are brought from the northernmost regions. Ermine-skins formed part of the Canada exports in the time of Charlevoix ; but they have since sunk so much in value, that they are said not to repay the Hudson Bay Company the expense of collecting them ; and very few are now obtained from that quarter. Our chief supply is obtained from Norway and Siberia. In Siberia ermines are taken in traps baited with flesh. In Norway they are either shot with short arrows, or taken in traps made of two flat stones, one being propped up with a stick, to which is fastened a baited string ; the animal nibbles at the bait, and the stone falls and captures him. In Lapland two logs of wood are used for this purpose, and in the same way.

There were 183,547 ermine furs imported in 1848.

ERZERU'M, in Turkish Armenia, is important as a commercial town. Besides the produce of its manufactures it exports corn, cattle, sheep, and dried meats. But it derives other commercial advantages from its being situated on one of the most frequented caravan roads of Western Asia, which leads from Persia and Georgia to the great commercial towns of Asia Minor.

ERZGEBIRGE (the Ore Mountains) is a mountain-range in Germany, which derives its name from the rich mineral treasures embosomed in the mountains. The surrounding district abounds in mines of silver, tin, lead, iron, cobalt, copper, &c., which afford employment to upwards of 200,000 persons. The silver mines are at Schneeberg, Schwarzenberg, Annaberg, and Marienberg. The most considerable tin mines are at Altenberg, Geier, and Schneeberg. The most productive iron mines are those of Johann-Georgenstadt. Near Aue and Bockau, to the south of Schneeberg, lie the largest cobalt mines and smalt works in Germany ; of these smalts the yearly produce is between 9000 and 10,000 cwts., besides large quantities of arsenic, &c. The white porcelain earth used in the royal china manufactory at Meissen is procured and prepared in this district. Sulphur and vitriol are made at and near Beierfeld and Geier : magnesia and porcelain earth are obtained at Elterlein ; and there are coal mines of importance at Planitz, and other spots near Zwickau. Gold is found in some places, but no mines are worked.

Besides considerable manufactures of iron, tin, steel, and copper ware, the province has extensive manufactuaes of thread, twist, linen, cotton goods, woollen cloths, flannel, woollen stockings, bobbinet, tape, ribbons, &c.

ESPALIER is a trellis for training fruit trees or bushes upon, instead of nailing them to walls. The stakes which form the espalier are made of different materials, some of wood, others of wire and wood, and some of cast iron. The first of these is by far the most simple, and is composed of stakes, five or six feet in height, driven into the ground from one to two feet apart ; along the top a bar, which is nailed to each, connects the whole together. The wire and wood rail is formed by strong vertical wires, strained from two wooden horizontal rails, which are connected and held fast by wooden posts fixed in the ground. The iron rail is constructed like a common street railing.

The best wood for this purpose is young larch, the thinning of plantations.

ESSENCES. This name is given to a large variety of pharmaceutical preparations ; but there is a good deal of vagueness in the designation, Concentrated infusions, decoctions, tinctures, and liquors, are often termed essences ; and it is by no means easy to distinguish the limits of each kind of preparation. Some essences are made by digesting vegetable substances for a long time in spirit. The essences of lavender, of musk, of ginger, and some others, are made by simply dissolving the essential oils of those substances in spirit. Many of the fragrant essences prepared by the perfumer and the druggist, in which the aromatic and volatile principles are alone wanted, are made by digesting the ingredients in spirit for a few days, and then distilling. In preparing the essences used for perfuming and flavouring, spirit is employed which is perfectly tasteless, scentless, and colourless.

The delicate substance called *Essence d' Orient* is made from the scales of the fish called the blay or bleak, and is used as a paint for the inside of glass beads, to make artificial pearls. A few other essences are used in the manufacturing arts, and a few in medicine ; but most of them are employed either as perfumes or for flavouring food and beverages.

ESSEX is almost entirely an agricultural county. The feeding of oxen in winter is now extensively practised by all good farmers in Essex, whether of strong or light loams. In those farms which have marshes attached to them a great number of cattle is constantly kept. Along the Thames the salt marshes are extensive, and are profitable from the number of horses which are sent to feed there from London. Besides the common crops usually cultivated, considerable quantities of cole or rape-seed, caraway, coriander, and teasels are raised. In that part of Essex which lies within a few miles of London, the cultivation of the soil partakes more of the garden culture. Vegetables, especially cabbages, are raised in great quantities, and very extensive fields are almost entirely devoted to the raising of potatoes. The cows and horses in Essex are chiefly reared in Suffolk, and Scotland supplies the oxen to fatten. Many calves are fatted, which are killed in the county, or go to London by railway. Essex is not a sheep-breeding county, although many fine lambs are reared; but they are generally bought from the breeders in Wiltshire or Sussex in autumn, and sold fat to the butcher in the succeeding spring.

In Barking, many of the inhabitants are fishermen, or employed in conveying coals and other necessaries from London for the supply of Barking and other places in the neighbourhood. At Coggeshall manufactures of silk have nearly superseded the former manufactures of woollen. At Harwich, Malden, Romford, and other towns, manufactures are carried on to a limited extent; but Essex can by no means be considered a manufacturing county. Women's stays and shoes, and small wares in silk, are made to some considerable extent in the neighbourhood of Stratford.

ESTHONIA one of the Baltic provinces of Russia, produces large crops of rye, barley, and oats; wheat, Indian corn, hemp, flax, hops, and tobacco are also raised. The produce of corn exceeds the consumption; the surplus is chiefly used for distillation. As the harvest season is attended by heavy rains, the farmers have subterranean kilns in most parts, into which the moist grain is carried for the purpose of being dried. Esthonia has large meadows, and produces abundance of hay; it has likewise good grazing grounds. The woods and forests, composed of the fir, pine, elm, birch, larch, and beech, occasionally intermixed with the oak, alder, linden, crab-apple, &c., are abundant. Next to agriculture, the rearing of cattle is the most important branch of rural industry. The fisheries along the coast and in lake Peipus are very productive. On the islands ship and boat building is a source of employment. The mineral products are building stone, potter's clay, and gypsum; there is abundance of peat.

The manufactures of Esthonia are extremely limited; the peasantry are clothed with linen and coarse woollen cloth woven in their own houses, or else with sheep-skins. There are about 400 distilleries scattered through the province.

ESTREMADU'RA, a province of Spain, is rich in pastures. About four millions of sheep come to graze, during the winter, from the other provinces on the open pastures of Estremadura. Other tracts are covered with underwood and wild odoriferous herbs. There are also forests of oak, beech, chestnut, and pine trees, where numerous herds of swine feed. Bacon and pork form the most important articles of commerce with the other provinces of Spain. Game of every sort is plentiful. The cultivated parts produce wheat, oats, Indian corn, flax, hemp, and the vine, olive, mulberry, and lemon trees. Excellent honey and wax are also gathered. There are mines of copper, lead, iron, and silver. The manufactures are few, consisting chiefly of leather and hats at Badajoz, Zafra, and Caceres.

There is also a province of the same name in Portugal, which is fertile and salubrious. The rivers, as well as the sea-coast, abound with fish. The principal products of the country are wine, oil, maize, fruits of every sort, and cattle. Wheat and oats are also raised, but in no great quantity. At Belem there are iron foundries. At Alhandra lime and brick kilns. At Alemquer a paper manufactory. At Thomar there is a large manufactory for spinning cotton, and manufactories of hats and worsted stuffs. Setubal exports large quantities of salt made from sea-water in the neighbourhood, and also wine and fruits, especially oranges. It is, next to Lisbon and Oporto, the most commercial place in the kingdom.

ETHAL is a substance separated from spermaceti. It is a solid, fusible at nearly the same point as spermaceti, and on cooling crystallises in plates. It is susceptible of union with various bases, with which it forms salts or soaps.

ETHER. [ÆTHER.]

ETHIOPS, a term now obsolete, was formerly used by the old chemists to denote various dark-coloured metallic preparations; as *Ethiops Martialis*, which is a black oxide of iron: *Ethiops Mineralis*, which is a black mixture of mercury and sulphur, &c.

E'TIENNE, ST., a large manufacturing town in the department of Loire, stands in the centre of one of the most important coal fields in France, from which about 500,000 tons of coal are exported annually. It is especially famous for the manufacture of silk ribbons and fire-arms. Its ribbons, which are exported to all parts of the world, are unequalled for richness of colour and beauty of pattern, and of the quantity manufactured an idea may be formed from the statement that their value amounts annually to upwards of 40,000,000 francs. Government orders for fire-arms having considerably fallen off since 1834, the workmen have turned their attention to making fowling-pieces, of which 30,000 a year are disposed of, besides a great number of pistols, &c. The manufacture next in importance is that of hardware and cutlery. To these leading articles of industry are to be added the manufactures of scythes, nails of all kinds, saw blades, foils, anvils, vices, files, silk and cotton velvets, &c., &c. The town has also many dye-houses and tanyards; and in the suburb of Terre-Noire there are important iron-forges and furnaces.

Many manufactured products from this important town will have a place in the approaching Exhibition.

ETRUSCAN WARE. The ancient Etrurians produced pottery ware, specimens of which still remain to illustrate the ingenuity of that very ancient people after a period of twenty-five or thirty centuries.

The Etruscan vases belong to three different periods of art, each exhibiting its peculiar style. The most ancient are those which resemble the Egyptian style: indeed it has been asserted that they were imported from Egypt; but it is more probable that they were manufactured in Etruria, from Egyptian models. They are partly coloured of black and red upon a pale yellow ground; and harpies, sphynxes, griffins, &c., are depicted on them. The next in order are those with black figures on a red ground, in stiff and ungraceful outline, while the form of the vase itself is very elegant. The third and most modern style exhibits a more graceful form of vase, and graceful and spirited figures; the designs, in red figures, represent stories of gods and heroes, as well as incidents of domestic life.

The Etruscan Room at the British Museum is well worth a study; the specimens of ancient pottery are numerous and highly curious.

EUDIO'METER, an instrument invented by Dr. Priestley, and originally employed by him in ascertaining the goodness of atmospheric air obtained from various places and under different circumstances. The use of the eudiometer, termed eudiometry, has, since its original contrivance, been extended to all gaseous mixtures, but especially to determining the quantity of oxygen which they contain when resulting from the operations of analysis.

The principle upon which the use of the eudiometer depends, so far as atmospheric air and oxygen gas are concerned, is that of exposing them to the action of some substance, whether solid, fluid, or gaseous, which, on account of its affinity for oxygen, combines with it and leaves the gas with which it is mixed unacted upon.

The eudiometer invented by Dr. Priestley was extremely simple. He filled a phial with water, and displaced the water with the gaseous mixture to be examined; the volume of this being noted, it was transferred into an air-jar. An equal volume of nitric oxide was added to it, and they remained together a few minutes. When this part of the process was over, the gas was transferred to a graduated glass tube. After noting the volume of the gas, the result was expressed in measures and decimal parts; thus, when equal volumes of common air and nitric oxide were mixed, and they afterwards occupied the space of one volume and two-tenths, Dr. Priestley, in speaking of the air so tried, said the measures of the test were 1.2, or the standard of the air was 1.2.

Numerous attempts have been made to render the eudiometrical application exact and certain by Cavendish, Fontana, Ingenhouz, Sardiniani, Dalton, Gay Lussac, Henry, Thomson, Davy, and others. The eudiometer of Scheele was a graduated glass tube containing a certain volume of air, which was exposed to a mixture of sulphur and iron-filings made into a paste with water. De Marté, instead of using sulphur and iron, employed a solution of sulphuret of potassium prepared by dissolving sulphur in a solution of potash. Guyton employed sulphuret of potassium also in his eudiometer, but he used it in a solid state, and applied heat to expedite its action. The eudiometer of Seguin is a glass tube, filled with and inverted in mercury; a small piece of phosphorus is put under the open end of the tube, and by its lightness it immediately rises to the top of it, where it is melted by the approach of red-hot iron. A measured portion of the gas to be examined is then passed into the tube; the phosphorus inflames on each addition of the gas, and the mercury rises, owing to the condensation of the oxygen. The quantity of the residual gas is determined by transferring it into a graduated tube, and the difference between the quantity submitted to experiment and that left after it indicates that of the oxygen absorbed. Berthollet also employed phosphorus in his eudiometer, but instead of heating it, as in the above-described method, he allowed combination to take place between it and the oxygen by slow combustion. Dr. Hope, Dr.

Henry, and Mr. Pepys, employed a eudiometer, in which the test liquid was either a solution of iron impregnated with nitric oxide, or a solution of sulphuret of potassium. Volta's method of determining the quantity of oxygen contained in gaseous mixtures is by means of combustion with a known volume of hydrogen gas; for it having been ascertained that when a mixture of oxygen and hydrogen gas is fired, one-third of the diminution is owing to the condensation of oxygen, we have only to observe the measure of the contraction of volume to ascertain that of the oxygen which was present. Various modes of effecting this have been devised by Volta, Mitscherlich, Dr. Ure, and others.

Dobereiner has suggested a eudiometrical process, founded on his curious discovery of the property which spongy platinum possesses of causing the combination of oxygen and hydrogen gases. In this eudiometer the combination occurs without explosion, and yields results of great accuracy. Dobereiner found that when the spongy platinum was mixed with certain substances, so as to prevent its immediate and explosive action, it caused the oxygen and hydrogen to combine with moderate rapidity. Dr. Henry and Dr. Turner employed modifications of this process.

EUPHO'RBIUM, improperly called a gum, or gum-resin, since it is entirely destitute of any gum in its composition, is the concrete juice of several species of *Euphorbia*, either exuding naturally or from incisions made in the bark. Much of the article found in British commerce is obtained from the *Euphorbia Canariensis*, while that which occurs on the continent is obtained from *Euphorbia officinarum*, and other African species, particularly from an undescribed species, called by the Arabs *Dergmuse*. The branches of this plant are used in tanning, and to it, according to Mr. Jackson, the morocco leather owes its peculiarities. By the most recent chemical analysis, euphorbium seems to consist of resin, wax, and saline matter (mostly malates). The resin is the active principle, and differs in some respects from most other resins.

Euphorbium is a powerful acrid substance, causing irritation and inflammation of the parts with which it comes in contact. It is less used in medicine now than formerly.

EU'PION is the name given to a liquid obtained from animal tar, especially that of bones or horns. It is very limpid, colourless, inodorous, and tasteless; it boils at about 340° Fahr.

EURE. This department is one of the cider districts of France; about 30,000,000 gallons are produced annually. The department is rich in iron ore; building stone, millstones, and paving granite are quarried; fullers' earth and potters' clay are found. The manufactures consist of fine and coarse woollen cloths, linen, thread, calico, paper, printed cottons, ,cotton yarn, cutlery, tape, cotton hosiery, blankets, carpets, wind instruments, horn and boxwood combs, glue, nails, pins, hardware, &c. There are numerous furnaces and foundries for the manufacture of iron, glass-works, numerous flour and paper-mills, dye-houses, fulling-mills, marble-sawing works, sugar-refineries, bleaching-grounds, important copper foundries, zinc-works, and a great number of tan-yards. The factories of various kinds are about eight hundred in number. The exports are composed of the various agricultural and industrial products named; the imports chiefly of the raw material required in the numerous manufactures, and of colonial produce.

Louviers, in this department, is one of the chief seats of the cloth manufacture in France; it has upwards of 40 factories, in which from 7000 to 8000 hands are employed. It has been long famous for the finest description of cloths (for uniforms &c.), which range from 30 to 65 francs an ell. Of late years coarser cloths, cassimeres, fancy goods for trousers, mantles, &c., are also made. There are also several woollen-yarn factories, large tan-yards, bleaching establishments, card factories, steam-engino and mill-work factories, dye-houses, brick-works, &c., and a brisk trade in corn, wood, charcoal, flax, wool, teazels, &c.

This department must not be confounded with that of *Eure-et-Loir*, which bounds it on the south. Eure-et-Loir is one of the cider districts of France. Besides wheat, rye, barley, oats, leguminous plants, teazels, weld, flax, hemp, &c., are grown. Hops grow spontaneously in some districts of this department. The number of wind and water mills for the manufacture of flour is about seven hundred. Along the course of the Avre or Aure there are important paper-mills belonging to the Messrs. Firmin Didot. There are also numerous other paper-mills, tanning and fulling-mills, cotton-spinning factories, iron forges and furnaces (which are supplied with ore partly from the mines of the department, and partly from those of Eure), and from 500 to 600 factories and workshops of different kinds. Besides the articles indicated, flannels, serges, druggets, blankets, linen, sieves, and woollen hosiery, are manufactured and exported. A great number of caps are knitted of the fine wool of Beauce or of Spain, and sent to Orleans, where they are dyed of different colours, and form an important article of export. The imports are wine, brandy, timber, wool, cloth, colonial produce, &c. Stone, marble, granite, and gypsum are quarried. Marl is very abundant, and is used for manure. Brick-clay and potters' clay are found.

EUROPE. All the countries of Europe are briefly noticed in other parts of this volume, in respect to their products, manufacturing industry, and commerce. We will here give, therefore, simply a few statistical details, covenient for reference.

Europe has an area of about 3,900,000 square miles. This area is drained by rivers which flow into five seas, or directly into the Atlantic, in the following proportion:—Into the Caspian 850,000 square miles; into the Baltic 900,000; into the Mediterranean 250,000; into the Atlantic direct 600,000; and into the Northern Ocean and White Sea 400,000. The areas of the seas themselves are—

Mediterranean	760,000
Black Sea	190,000
Baltic	180,000
Caspian	160,000
White Sea	40,000

The longest straight line that can be drawn through Europe is about 3000 miles, from Cape St. Vincent to the river Kara on the Frozen Ocean. The coast-line of Europe extends about 20,000 miles. The sovereign states of Europe are about 60 in number, and the population about 250 millions. Nearly one-half of the population profess the Roman Catholic religion, nearly a quarter Protestantism, and nearly a quarter the Greek church; the remainder comprise miscellaneous sects.

In mineral produce, Europe contains a supply of most of the chief kinds. In animal products, applicable to the arts, Europe contains a large number, but is deficient in many others. The botany exhibits the following features:—The southern districts exhibit a strong resemblance to the vegetation of Africa and its adjacent islands. The vine, the date, the pisang, the prickly pear, the castor-oil plant, the American aloe, rice, the sugar-cane, the cotton-plant, maize, Guinea corn, the fig, the olive, the orange—all are met with in different parts of the south of Europe. At about the parallel of the south of France, a marked change occurs in vegetation: most of the southern equinoctial forms of vegetation either disappear or become uncommon. Still more to the north, where the vine begins to languish, its place is better occupied by broad plains of wheat and other corn; the hardy trees of England, elms, limes, oaks, ashes, alders, beeches, birches, willows, and poplars, are found everywhere, with rich pastures, and verdant fields, unknown in the land of oranges and myrtles. At last, in the more northern districts of the continent, aspens, bird-cherries, birches, lime-trees, alders, junipers, spruce-firs, and pines, are the principal trees that remain; barley and oats are the only corn-plants, but potatoes continue to be reared in the short cold summer.

EVAPORATION is the transformation of a liquid into a gaseous state by the action of heat. If any liquid be placed in an open vessel, it gradually diminishes in quantity by evaporation, and at length disappears. The quantity of vapour produced in a given time is proportional to the area of the exposed surface; but, with equal temperatures, the escape of vapour from different liquids varies in rapidity. Over the surface of an ocean the aqueous vapour held in the atmosphere amounts to an enormous quantity. The quantity of vapour which rises from a liquid depends mainly upon the temperature; but it is influenced by the state of the atmosphere with respect to dryness or moisture, a dry and warm atmosphere being favourable to it. At equal temperatures, in a close vessel, the evaporation is the same in quantity whether the vessel containing the liquid contain also air, or have the air exhausted from it, but more rapid in the latter case.

It was found by Dalton, that at 212° Fahr., the evaporation of water from one square inch of surface is equal to 4.244 grains per minute; and at 138° Fahr., one grain per minute. Dalton and Gay Lussac have found that the evaporation from ice is equal to that from water at the same temperature. Dalton also determined that the quantity of vapour raised from a given surface of any liquid, at a given temperature, is directly proportional to the elastic force of the vapour at that temperature. Solid substances and liquids of great specific gravity have vapours of small elastic force. When, by evaporation, a liquid is transformed into a vapour, heat is abstracted from the liquid, and a thermometer in it indicates a depression of temperature.

EXCENTRIC, or ECCENTRIC, in machinery, is a kind of wheel in which the axis or centre of motion does not coincide with the geometrical centre, or in which the periphery is not circular. Eccentrics form an important class of mechanical expedients for converting one kind of motion into another. They also furnish means for producing, from the uniform speed of one revolving shaft, rotatory motion of continually varying speed in shafts placed in connection with it.

EXCISE DUTIES. This name is given to taxes or duties levied upon articles of consumption which are produced within the kingdom; and also upon licences to permit persons to carry on certain trades, the post-horse duties, and others of a similar kind.

Excise duties are said to have had their origin in this country in the reign of Charles I., when a tax was laid upon beer, cider, perry, of home production, by the Long Parliament in 1643. This act contains also a list of foreign articles upon which excise duties were imposed in addition to duties of customs already chargeable. This act was adopted and enforced under the protectorate of Oliver Cromwell; and under Charles II. the duties of excise were granted to the crown as part of its revenue.

In every highly taxed country, where consumption duties form part of the public revenue, it would seem to be hardly possible to avoid the adoption of this class of duties. In England a drawback is allowed on the exportation of domestic articles which are subject to excise duty.

Excise duties are liable to this among other very serious objections, that the regulations under which they are collected interfere with processes of manufacture, so as to prevent the adoption of improvements. Upon the same premises, with the same capital and the same amount of labour, double the quantity of cloths has been printed which could have been printed previous to the repeal of the duty and the consequent abolition of the excise regulations. The abolition of the excise duty on glass in 1845 was made principally with the object of facilitating improvements in the manufacture; and this result has been most remarkably apparent. The Crystal Palace, as it is termed, could not have been built six years ago, before the glass duties were removed; neither the market price of glass nor the manufacturing arrangements would have permitted its construction. The excise regulations respecting the manufacture of soap have prevented our soap manufacturers from entering into competition with the manufacturers of other countries. The effect of the paper duty has been already adverted to. [Book Trade.] Another great objection to excise duties is, the facilities which they offer for the commission of frauds against the revenue.

In 1797 the number of articles subject to excise duties was 28; 15 in 1833; 10 in 1835; and in 1845 there were only 9, including sugar. The post-horse duty is under the management of the Board of Excise, and in Ireland the duty on game certificates. The brick duty was repealed in 1850. The eight following articles are still subject to these duties, and with sugar made here constitute all the articles on which the excise duty is now collected: — Hops, Licences, Malt, Pepper, Soap, British Spirits, Vinegar. All such imposts as the window tax come under the designation of assessed taxes, and not excise duties.

In 1822 the excise duties yielded for the United Kingdom more than twice as much as the customs duties. In 1821 the excise duties reached to 27,400,300*l.*, which is the highest sum they ever attained. In 1845 they were again reduced to the amount at which they stood in 1797, a little above 11,000,000*l.*

In 1835 the number of traders in the United Kingdom who were surveyed periodically by excise officers was 588,000. The cost of these surveys in England alone amounted to 533,902*l.*; but since 1835 several of these surveys have been abolished.

The net produce of the excise duties, in the year ending October 10, 1850, was 12,913,102*l.* Under the names of the exciseable articles are given in this work a few statistical details concerning the duties.

Prior to 1823 there were separate and independent Boards of Excise for England, Scotland, and Ireland, and the total number of the excise commissioners was twenty-one. The business is now better conducted by seven commissioners, and by one board in London. The commissioners hold courts and decide summarily in case of the infraction of the excise laws. The number of persons employed at the chief excise office in London is about five hundred, while those employed in different parts of the country are about four thousand

For the management of the business of the excise department the whole of the United Kingdom is divided into collections, and these are subdivided into districts, rides, and divisions. There are fifty five collections in England and Wales, exclusive of the London collection, and at the head of each is a collector, who visits the principal towns in his circuit eight times a year to receive the duties and transact other business connected with the department; besides which he is required to have an eye generally upon the discipline and efficiency of the service. The number of officers in a collection varies from forty to ninety. The next subdivision of a collection is the district, at the head of which is a supervisor. Next come the subdivisions of the districts into rides and divisions, or foot-walks. Where the traders are scattered, the officer is obliged to keep a horse, and his circuit is called a ride; but, if a large number of traders reside

London: Charles Knight, 90, Fleet Street. Price Twopence

KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 21.

in a smaller circuit, they are visited by the officer on foot, and then each portion is termed a division or footwalk. Before going out each day, the officer leaves a memorandum at his home which states the places he intends to survey, and the order in which he will visit them; and the exact time at which he commences each must be entered in his journal. The supervisor resurveys some of the officer's surveys; but which they will be the officer is of course ignorant; and if errors are discovered they must be entered in the supervisor's diary. These diaries are transmitted to the chief office every two months, and no officer is promoted unless the diaries show him to be efficient. The periodical removal of officers from one part of the country to another was Mr. Pitt's suggestion, and is still acted upon: about 1100 officers change their residence yearly. At the chief office in London there is a department of Surveying-General Examiners, who are despatched to any district without previous intimation, as a check upon the accuracy and integrity of the supervisors. Promotions take place in the excise department after a certain fixed period in each grade, and only then when the officer petitions for advancement. This involves a rigid examination into his qualifications, which is termed 'taking out a character.'

EXETER is a sort of western metropolis. Its manufactures are very miscellaneous, and such as befit the centre of a large agricultural district. Its contributions to an exhibition of manufactures must necessarily be of the same miscellaneous character as its products generally. Its importance depends mainly on its being a cathedral city, and the focus for a large and fruitful district of country.

EXPLOSION is the sudden displacement of gaseous particles, accompanied by a loud report. The bursting of a bladder under the air-pump, the bursting of a steam-boiler, and the firing of gunpowder are examples. The explosions which, in the atmosphere, accompany a flash of lightning, are ascribed to the rush of air into the vacua produced when the aqueous vapours in large portions of space become rapidly condensed. DETONATION is a species of explosion.

The bursting of steam-boilers is sometimes occasioned by the formation of an incrustation on the interior, which prevents the heat from radiating freely through the metal.

EXPORTS. [IMPORTS AND EXPORTS.]

EXTRACTS are medicinal preparations of vegetable principles, obtained in various ways. Sometimes they are merely the juices expressed from the fresh plants, brought by careful evaporation to the consistence of honey, and then more properly denominated *inspissated juices*; at other times they consist of certain principles of the fresh or dried plant extracted by some menstruum in which they are soluble, such as water, proof spirit, or vinegar, and afterwards evaporated, as in the former case. According to the nature of the menstruum employed the extract is called *aqueous*, *alcoholic*, or *acetous*.

The preparation of extracts requires the greatest care. The plants must be in every respect of the best quality, as regards the place of their growth, season when collected, &c., and the evaporation must be conducted rapidly, yet at a low temperature. Extracts are simple or compound, according as they are prepared from one plant or from several different kinds.

A well-prepared extract should possess in a great degree the odour, and especially the taste, of the plant from which it is obtained; it should not have either an empyreumatic smell or taste, and it should have a proper and uniform consistence. It is necessary to preserve extracts in a dry situation. To assist in keeping aqueous extracts, it is customary to sprinkle a little alcohol over the surface before covering them up; but such extracts, if made with cold water and with due care, rarely require this precaution. It is proper to examine the condition of all extracts very frequently, both during very warm and very wet weather: any portion which seems spoiled should be immediately thrown out.

F

FAÇADE, is a French term of modern introduction into the English language. It expresses the face or front view of an edifice, and is often used in speaking of architectural buildings, as the façade of the Louvre, or the façade of St. Peter's at Rome.

FACTOR is a mercantile agent, who buys and sells the goods of others, and transacts their business on commission. He is intrusted with the management and disposal of the goods, and he buys and sells in his own name, in which particulars consists the main difference between factors and brokers. The chief part of the foreign trade of a country is carried on through the medium of factors, who generally reside at a distance from the merchants or manufacturers who employ them. The common duty of a factor is to receive consignments of goods, to sell them, and to make remittances either in money, bills, or purchased goods, in return; and he is paid by a commission upon the money which passes through his hands. It is usual for a factor to make advances upon the goods consigned to him, for which, and for his commission, he has a general lien upon all the property of his employer which may at any time be in his hands.

It is the duty of a factor to keep the goods with which he is intrusted free from injury, to keep a clear account of his dealings, and at proper times to transmit it to his employer, with information of all the transactions and liabilities which he has entered into and incurred in the course of his employment, by which his principal can be affected; also to send him advice of all bills accepted or drawn upon his credit, and generally to act with fidelity to him.

There is another description of factor, who acts under what is called a *del credere* commission, where, for an additional per centage he engages for the solvency of the purchasers of the goods consigned to him. In this case, the factor stands in the relation of a surety for the persons with whom he deals on account of the employer, and he is liable to his employer only in case of their default.

FACTORIES; FACTORY-SYSTEM. The word factory has had two different meanings. It formerly meant an establishment of merchants and factors resident in foreign countries, who were governed by certain regulations adopted for their mutual support and assistance against the undue encroachments or interference of the government of the countries in which they resided. In modern times these factories have, in a great measure, ceased to exist, because of the greater degree of security which merchants feel as regards both the justice of those governments and the protection, when needed, of their own country. The Venetians, Genoese, Portuguese, Dutch, French, and English have all had establishments of the nature of factories. In China the Portuguese established a factory at Macao, and the English at Canton. In most instances factories have at first obtained the privilege of trading, and afterwards procured for the precinct assigned to them some exemption from the jurisdiction of the native courts. In this state of things the supreme government of the country whose subjects have established the factory prepare laws for its control and administration, and treat it in fact as if it were its dependency, though the sovereignty of the native government is undisputed.

But in its usual acceptation, the word factory has now a different meaning. By the Factory Act of 1844, a factory means any building wherein steam, water, or other mechanical power is used to work any machinery employed in the manufacture of cotton, wool, hair, silk, flax, hemp, jute, or tow.

What is called the Factory System owes its origin to the invention and skill of Arkwright; and it is probable that but for the invention of spinning machinery, and the consequent necessary aggregation of large numbers of workmen in cotton-mills, the name would never have been thus applied. It is in the cotton-mills that the factory system has been brought to its highest state of perfection. The power of subdivision of employment according to strength and skill, and that of bringing to bear upon every distinct process exactly as much force as is necessary, without waste, are the two great and valuable advantages of the factory system.

The legislature has interfered to prevent children in factories being tasked beyond their strength, to the permanent injury of their constitutions. This abuse was the more to be apprehended, because a large proportion of the children engaged in cotton-spinning are not directly employed by the masters, but are under the control of the spinners, a highly paid class of workmen, whose earnings greatly depend upon the length of time during which they can keep their young assistants at work. A parliamentary committee sat for the investigation of this subject in 1832, and subsequently a commission was issued by the crown for ascertaining, by examinations at the factories themselves, the kind and degree of abuses that prevailed, and for suggesting the proper remedies. In consequence of these inquiries, an act was passed in 1833 for regulating factories. This act was amended by that of 1844.

On January 1, 1846, a new act came into operation, which brought print-works, or calico-printing establishments, within the operation of the factory regulations. By the terms of another act, passed in 1847, 'no children' or 'young persons' are to work in a factory more than 11 hours a day, from July 1, 1847; nor more than 10 hours a day from May 1, 1848. The same provisions were made in respect to all women of whatever age; so that at the present time the work-hours of women, boys, and girls, are limited: those of men unlimited by any enactment. By an act passed in 1850, a few minor changes were made, chiefly with a view to prevent night-work in factories. The 'Ten Hours' Bill,' advocated by many persons, would, if passed, limit the working hours of males in factories.

The United Kingdom is divided into four factory districts, presided over by four inspectors and several sub-inspectors. Each inspector presents a report half yearly to the Home Secretary, respecting the state of the factories within his district. These reports occasionally give such information as will show the number of factories and work-people. In 1845, Mr. Horner, whose district is very nearly coextensive with the county of Lancashire, gave the following as the state of his district in that year :—

	Mills.	Workers under 18.	Workers 18 & above.	Power Looms.
Cotton Mills	1,724	69,155	128,305	138,717
Woollen do.	241	5,456	6,485	3,237
Flax do.	71	2,255	3,336	,,
Silk do.	32	3,121	3,324	995
	2,068	79,987	141,450	142,949

The great strength of the woollen and worsted trades lay in another district, concerning which similar returns were not made.

In September 1848 the mills and works within the limits of the town of Manchester, subject to the factory laws, were as follow:

	Mills.	Hands.
Cotton . .	96	26,809
Silk . . .	8	2,850
Worsted . .	3	169
Small Wares	17	1,752
Print Works	4	1,172
Dye Works .	23	1,847

In 1850 a return was made to the House of Commons respecting factories, more detailed and instructive than any before prepared. We will give a few of the results, calculated to illustrate different aspects of the subject.

First, in respect to different parts of the United Kingdom we have :—

	Factories.	Spindles.	Power Looms.	Horse Power.	Children Employed.	Total Employed.
England and Wales	3,689	22,850,010	272,588	109,824	34,155	495,707
Scotland	550	2,256,403	23,811	19,861	929	75,688
Ireland	91	532,303	2,517	4,532	38	24,687
	4,330	25,638,716	298,916	134,217	35,122	596,082

In this table, the *horse-power* includes both steam engines and water-wheels employed in working the machinery in the factories; they are nearly in the ratio of four-fifths steam power to one-fifth water power. The term *children* is applied to those at and under 13 years of age; from 13 to 18 the term applied is *young persons*.

Taking the whole of the United Kingdom in one entry, and regarding only the ages and sexes of the persons employed, we find the following numbers :—

	Males.	Females.
Under 13 .	19,400	15,722 = 35,122
13 to 18 .	67,864	329,577 = 555,307
Above 18 .	157,866	
	245,130	345,299 = 590,429

In respect to females, one entry includes *young persons* and *adults*, as the same laws now apply to both classes. Of 100 persons working in factories 58 are females and 42 males. About 6 per cent of the workers are under 13 years old.

The next classification we shall notice is that which depends on the kind of operations carried on. There are four classes, as follows :—

Spinning factories	2,636
Weaving factories	454
Spinning and weaving factories ..	1,005
Not specified	505
	4,600

Next in regard to the five principal kinds of materials employed, we find the factories to be distributed as follows:—

Cotton factories	..	1,932	330,924
Woollen ,,	..	1,497	74,443
Worsted ,,	..	501	79,737
Flax ,,	..	393	68,434
Silk ,,	..	277	42,544
		4,600	596,082

The number of factories here given (4,600) is in excess of that given in the first table (4330); this probably arises from some of the factories being entered twice, in cases where they work *mixed fabrics* of cotton and woollen, or cotton and silk, or woollen and silk. The cotton factories are rather less than half the whole number, but employ more than half the entire number of operatives. The average number of operatives in cotton factories is 120; the average in all factories is 75. Out of the 1932 cotton factories, no less than 1235 are in Lancashire; out of the 1998 woollen and worsted factories, no less than 1298 are in Yorkshire. It will be seen that a remarkable parallelism exists in these numbers; 64 per cent of all the cotton factories are in Lancashire, and 65 per cent of all the woollen and worsted factories are in Yorkshire.

FAHRENHEIT, GABRIEL DANIEL, is noticeable here on account of one particular invention. He was born at Danzig, near the end of the 17th century, but the precise year of his birth is unknown. His taste inclined strongly to scientific pursuits, and having travelled through different parts of Germany in order to acquire information respecting the subjects of his studies, he came to Holland, and established himself at Amsterdam as a maker of philosophical instruments. He is chiefly distinguished for the invention of that particular scale which he applied to thermometers [THERMOMETER], and which has ever since been generally in use in this country. He was elected a Fellow of the Royal Society of London in 1724, and wrote some papers in the 'Philosophical Transactions' for that year. He died in 1740.

FAIR. Anciently, before any flourishing towns were established, and the necessaries or ornaments of life, from the convenience of communication and the increase of provincial towns, could be procured in various places, goods and commodities of every kind were chiefly sold at fairs; to which, as to one universal mart, the people resorted periodically, and supplied most of their wants for the ensuing year. Wharton, in his 'History of English Poetry,' has given us a curious account of that of St. Giles's hill or down, near Winchester. It was instituted by William the Conqueror, at first for three days, which were afterwards extended to sixteen. Its jurisdiction extended seven miles round, and comprehended even Southampton, then a capital trading town; and all merchants who sold wares within that circuit, unless at the fair, forfeited them to the bishop. As late as 1512, as we learn from the Northumberland Household-book, fairs still continued to be the principal marts for purchasing necessaries in large quantities, which are now supplied by the numerous trading towns.

The fairs of Frankfort-on-the-Main and Leipzig are still pre-eminent in Europe. A very large part of the book-trade of Germany is centered in the Easter fair at Leipzig.

The fair at Nischnei Novgorod, in Russia, between the river Oka and the river Volga, is the largest at the present day: 200,000 visitors are said to attend it, and commodities to the amount of 4,000,000*l.* sterling to be disposed of. There is also a singular fair held at Berbera, on the coast of Adel, in Eastern Africa. Throughout nearly the whole of the year the place is abandoned to the hyena and the jackall, and the huts are left open; but as the period of the fair approaches, caravans of camels, horses, mules, asses, and troops of warriors continue to arrive, and in a short time the desert is animated by the presence of many thousands of persons, who, having transacted their business, disperse, and the place resumes its desolate solitude. The great commercial fair at Beaucaire in France has been already described. [BEAUCAIRE.]

FALKLAND ISLANDS. These remote islands will in time acquire commercial importance. They are situated in the South Atlantic, and consist of two islands of considerable size, and many smaller ones. East Falkland is about 90 miles long, and on an average 40 miles wide; West Falkland is about 80 miles long, with a mean width of about 25 miles. The smaller islands, about two hundred in number, vary considerably, from 16 miles in length and 8 in width, to mere islets of half a mile in diameter. The area of the whole is about 6000 square miles.

The Falklands are moderately fertile, and contain several good harbours. Small colonies were formed there by the French and the English in the last century, but afterwards abandoned. When, however, it was found that the islands formed a convenient halting-place for southern whalers, the Republic of Buenos Ayres took possession of them in 1820. England protested against this step in 1829. Meanwhile the government of Buenos Ayres had formed a settlement at Port Louis in

1823, but Great Britain asserted its rights, and the colony was given up to the English in 1833. The islands have since assumed the condition of a regular British colony, and in 1844 a new town was laid out on the southern shore of Stanley Harbour, a land-locked inlet sheltered from every wind.

In a recent letter from Falkland it is said: 'The number of wild cattle now upon East Falkland is estimated at over 150,000 head, in addition to which there are herds of several thousand tame stock, and about 3000 wild horses, with several troops of tamed horses, some imported from South America, and some of the native breed, trained to assist in capturing and managing the cattle. This latter work is chiefly performed by a class of men called Guachos, natives of the Pampas of La Plata, whose occupation, from childhood upwards, is the pursuit and subjection of the wild herds which, in countless numbers, cover those vast plains; but latterly several English and Irish men have been initiated in the arts of the Guachos, and have proved themselves quite as skilful as the South American hunters, whilst they conduct their perilous occupation with more humanity and consequently with greater profit to their employers. It is found that all esculent vegetables, particularly carrots, parsneps, and turnips, thrive and grow to great perfection in these islands, the climate of which is remarkably salubrious. As a naval station, there can be no question that the Falklands are, at the present juncture, more than at any former period, a most important possession of the crown.'

FALLOW is a portion of land in which no seed is sown for a whole year, in order that the soil may be left exposed to the influence of the atmosphere, the weeds destroyed by repeated ploughings and harrowings, and the fertility improved at a less expense of manure than it would be if a crop had been raised upon it.

The practice of fallowing land is as old as the Roman Empire. It appears that, wherever the Romans extended their conquests and planted colonies, they introduced this mode of restoring land to a certain degree of fertility when exhausted by bearing grain. The attention of agriculturists has in later times been turned to lessen the necessity of fallows, and to substitute some other means of restoring fertility. It is acknowledged by all experienced farmers that manure alone is not sufficient for this purpose. The ground must be tilled and noxious weeds destroyed; and the only efficacious mode of doing so is to stir the ground at the time when their seeds have vegetated, their roots have made shoots, and before any new seed can ripen. Light sandy soils require only cleansing from weeds; and if this can be done without leaving them fallow for a whole summer, a great advantage will be obtained. This has been effected completely by the cultivation of turnips and clover, which was first practised in the light soils of Flanders, and afterwards introduced into the similar soils of Norfolk, from whence it has spread all over Great Britain, and is beginning to be adopted more generally in Ireland. On light lands the preparation for the turnips, the abundant manuring and subsequent hoeing, are as effectual in cleansing the land and bringing it into a fertile state as any complete fallow could ever be; and the clover smothers and destroys the weeds which may have come up amongst the barley or oats sown after the turnips. On heavy soils it is often impossible to keep the land clear of weeds, in wet climates and unfavourable seasons, without a complete fallow, and when this is the case it is best to do the thing effectually. Upon cold wet soils, which should always first of all be well underdrained, no pains should be spared to get the land perfectly clean.

The advice given by the late Mr. Rham was —Avoid fallows if you can keep your land clean; but, when you fallow, do it effectually, and improve the soil at the same time by chalk, lime, or marl, according to circumstances. Do not spare either ploughs or harrows in dry weather. In short, neither ploughing nor manuring alone will keep a soil in a good fertile state. There must be an occasional fallow for some soils, and turnips or similar husbandry for others.

FALMOUTH. The harbour of this Cornish seaport is an extensive bay, well protected by the surrounding highlands, and so conveniently situated, that vessels have frequently been able to proceed on their voyage from this port, while those from Plymouth and Portsmouth have been forced back by contrary winds before they could reach the mouth of the Channel. The exports consist principally of the produce of the tin and copper mines. The number of sailing vessels registered at the port is about 120.

Unfortunately for Falmouth, the non-existence of a railway through Cornwall has nearly deprived this town of its former importance as a packet station. Southampton has risen in its stead, on account of its admirable position in respect to communication with the metropolis. Nothing but a complete line of railway will restore Falmouth as a packet station; and even that could only occur after the expiration of existing contracts between the Government and the various steam-packet companies.

FALUN, a town in Sweden, the capital of the province of Dalecarlia, is celebrated for the great mine of copper, which is in the middle of the town, and which also yields small quantities of gold, silver, and lead, besides vitriol, ochre, and brimstone. There are a few manufactures of tobacco, linen, cotton, and wool.

FAN. This name is given to an instrument or machine for agitating the air by the wafting or revolving motion of a broad surface for the purpose of producing artificial currents. Large revolving fans, driven by machinery, are frequently used either to facilitate the cooling of fluids or the process of winnowing, or as blowing machines to urge the combustion of a fire, or to assist in ventilation. Another application of such an apparatus is for the purpose of regulating or checking, by the resistance of air to its rapid motion, the velocity of light machinery. A familiar example of such an use is afforded by the revolving fans of a musical snuff-box.

FAN MANUFACTURE. The manufacture of ladies' fans is a larger department of industry than many persons would suppose. After a considerable interval, during which fans were little used, they have lately come again into favour; and the manufacture is conducted in France on a considerable scale. The firm of M. Duvelleroy at Paris are preparing some magnificent specimens for the Great Exhibition. From an account of that establishment recently given in the 'Expositor,' we learn that M. Duvelleroy has prepared a whole set of fans displaying the stories of the 'Arabian Nights,' intended by the Grand Sultan as presents for the ladies of his harem; they are to be submitted to the lady of the Turkish Ambassador at Paris, before being transmitted to Constantinople. M. Duvelleroy manufactures fans for the courts not only of European countries, but for those even of Africa and Asia. It is said that we shall have submitted to our inspection at the Exhibition a fan now being made for the Emperor of Morocco, at a cost of more than 1000*l*. Another is now in progress for the Empress of Russia.

From the source above referred to we gather some curious details concerning the fan manufacture. Fans were known in the East from remote ages; but they are not supposed to have been introduced into western Europe until the time of the crusaders. About the 16th century fans came into very general use; generally made by fixing peacock or ostrich feathers in a handle of gold, silver, or ivory. As early as 1522 the fan manufacturers formed one of the industrial guilds of Paris. In the time of Louis XIV. the Jesuits who returned from China brought over specimens of the Chinese folding-fan, which at once superseded the former shape. When the Edict of Nantes drove so many artisans out of France, fan makers were among the number; they came to England, where the trade became established on a firm footing. Just a century afterwards, the French Revolution crushed the remains of the manufacture in France, and England became the chief emporium of fans. At the termination of the war the manufacture revived in France; and so congenial is it to the taste of that nation, that France now almost entirely monopolises the manufacture, very few fans being made in England.

It is said that Duvelleroy employs 2000 persons—a statement scarcely credible; he has made it a point to grasp the two extremes of the scale in costliness as well as all intermediate degrees, for he makes fans from one halfpenny each to one thousand guineas. Every halfpenny fan goes through no less than fifteen hands: a proof that the factory system must be thoroughly carried out in that establishment. Duvelleroy's fans are sent to all parts of the world, and are now competing in the East with those of China. Spain is trying to maintain a home manufacture, but all the best specimens come from Paris. America affords the best markets, for while the ladies of North America closely imitate the fashions of Paris, those of South and tropical America are passionately fond of gorgeous fans, on which the most exciting scenes are painted in the most dazzling colours. Duvelleroy has a large corps of intelligent artists, who study the peculiar tastes of every nation in respect to pictures and colours.

In the manufacture of fans, the chief parts are called the *handle*, the *brins*, the *panaches*, the *end*, and the *leaf*. The *handle* is the part at which all the rest of the fan is hinged together, and which is made of ivory, wood, or any hard material. The *brins*, or radiants, from twelve to twenty-four in number, radiate from the handle; they are about four inches long. The *ends* are elastic pieces which connect the brins with the handle, and which form with them the skeleton of the fan; they are made of mother-o'-pearl, tortoise-shell, ivory, horn, ebony, bone, citron-wood, sandal-wood, or plain wood, and are rivetted with diamonds, gold, pearls, or more cheap material, according to the price. The *panaches* are the two outermost brins, made wider and stronger than the rest for security. The *leaf* is the surface of the fan, cut into the form of the segment of a circle. It is made of paper, of cabretillo (very delicate kid-skin), vellum, parchment, satin, tulle, gauze, or crêpe, according to circumstances. There are as many folds or plaits given to this leaf as there are brins; and the brins govern the opening and closing of the leaf.

It is in the painting and decorating of the leaf that the costliness of the best fans chiefly consists. Duvelleroy has a number of highly paid and accomplished artists engaged in this department.

The Chinese workmen are not permitted by the Emperor, it is said, to send goods to England for the approaching Exhibition; but M. Duvelleroy is about to send some choice specimens of Chinese fans, as well as others of his own manufacture.

FARM. In the present state of agriculture, a man who takes a farm of 200 acres of arable land, or land partly arable and partly good pasture, will require from 1600*l.* to 2000*l.*; and it is not the interest either of the landlord or the tenant that he should take the farm unless he can command that sum. The amount of capital required depends in a great degree also on the quality of the land; very rich land requires less capital in proportion to the rent than poor land. Besides the quality of the soil, many other circumstances determine the value of a farm. The roads, especially those which lead to the neighbouring towns, whence manure may be obtained, are a most important object; and, if there is water-carriage, it greatly enhances the value of the farm. The roads to the fields, and the distance from these to the farm-yard; the convenience of having good pasture, or land easily laid down in grass, near the homestead; and especially the situation of the farm buildings with respect to the land, and the abundance of good water—are all circumstances which must be well considered, and which will greatly influence the probable profits, and consequently the rent which may be fairly offered.

Large straggling farm-buildings are inconvenient, and cost much in repairs. The yard or yards in a large farm should be sheltered on the north side by the barns, which need not be so extensive as used formerly to be thought necessary. Every farm which is so extensive as to require more than one floor to thrash the corn on ought always to have a thrashing-mill attached to it. A small yard, distinct from the other, with sheds for the cattle to shelter themselves under in wet and stormy weather, is a great advantage. The cart-sheds should be in the stack-yard, which properly occupies a space north of the barn. There should be a sufficient number of stands with proper pillars and frames to build stacks on. On each side of the yard should be placed the stables, cow-houses, and feeding-stalls, with a pump of good water near the last, and convenient places to put hay, straw, and turnips in, with a machine to cut them. An under-ground cistern near the cow-house and stables, into which the urine and washings of the cow-house may run by means of a sink or drain, is a most useful appendage. Light thatched roofs are sufficient for the sheds and smaller buildings, and even for the cow-houses and stables.

In the old system of agriculture a third of the gross average produce was considered as a fair rent for a farm, including all the direct payments for the occupation of the land, such as tithes, rates, and taxes; another third was supposed to cover the labour and expenses of the farm and interest of capital; and the remaining third was appropriated to the maintenance of the farmer and his family, out of which he had to save whatever he laid by as a clear profit. But this calculation is no longer applicable to the present state of agriculture. The expenses are greatly increased, and the produce is also greater. Rents in Scotland are higher than in England, not only for small occupations, but for extensive farms; and yet the tenants have complained less of the times than their neighbours in the south. One cause for this difference is, that the Scotch farm-labourer is more advantageously kept as a sort of in-door servant than in England; another is that the horses are better managed on a Scotch farm; and a third is that Scotch farmers are generally more alive to scientific improvements than those of England.

In the accounts of a farm there are many separate items to be taken into consideration. There may be a separate account kept for every field. There should always be one for every crop of which the rotation consists. There is an account of the labour of men and horses; of the produce of the dairy; of the stock purchased to be fatted, or sold again in an improved state. In short, the divisions of the general account may be increased without limit. M. de Dombasle, at his celebrated farm of Roville, in France, has all his principal servants and his apprentices assembled every evening after the day's work is over. Each man gives an account of the work done by him or under his superintendence, which is written down by the clerk. The orders for the next day are then given, and every one rereturns to his lodging or his home. In the course of the next day the clerk enters all that is in the journal into a book, where every person employed has an account: every field has one; every servant and domestic animal has one; and every item which can be separated from the rest is entered, both as adding to the account or taking from it.

FAT is of two different kinds, which differ as to their melting point: these are termed *olein* (or *elain*) and *stearin*. The substances to which these names are given are not however in all cases absolutely identical: they vary as to smell, taste, solubility in alcohol, &c.; but all fats agree in being insoluble in water, and in not containing any nitrogen, which is a common constituent of most other animal matter.

Human Fat varies a little according to the part of the body producing it; that from the region of the kidneys, after it has been melted, is yellowish and inodorous; it begins to concrete at 76° Fahr., and is solid at 64°. The *Olein* of human fat is a colourless, oily, sweetish fluid, and remains so at 40°. *Ox Fat*, when melted, begins to solidify at 98°, and the temperature then rises to 102°; it contains about three-fourths of its weight of stearin, which is solid, hard, colourless, not greasy, and of a granular crystalline texture. The olein of ox fat is colourless and nearly inodorous. *Sheep's Fat* (or *Mutton Suet*), by exposure to the air acquires a peculiar odour; after fusion it congeals at a temperature varying between 98° and 102°; the stearin is white, translucent, and after fusion but imperfectly crystalline. *Hog's Fat*, or *Hog's Lard*, is a soft colourless solid, which fuses between 78° and 86°; the stearin is inodorous, solid, and granular. *Goat's Fat* contains a peculiar fat, termed by Chevreul *Hircin*, to the presence of which its peculiar odour is owing. *Goose Fat* is colourless, and of a peculiar taste and smell.

The fluid fats, whether of animal or vegetable origin, are usually termed *oils*. [OILS.]

The olein and stearin of animal fats are highly useful and important substances in the manufacture of soap and candles; for the latter purpose stearin has been of late very advantageously employed, and to a considerable extent, as a substitute for wax. [CANDLE; SOAP.]

FEATHERS. The principal uses to which feathers are applied are for personal decoration, as plumes for ladies' head-dresses, or for the hats of military officers; as a soft and highly elastic material for filling beds, cushions and pillows; or, in the case of the larger quill-feathers, as writing-pens, or small tubes for the manufacture of hair-pencils, or similar purposes.

Of the various kinds of feathers employed as plumes for head-dresses the most important are those of the ostrich. They are first washed in a lather of white soap and water, and subsequently in warm clear water. They are bleached by three successive operations: first with water only, then with a little indigo, and then a little sulphur. The feathers are then dried by hanging upon cords, during which they are shaken from time to time to separate their fibres. To increase their pliancy, the ribs are scraped with a bit of glass cut circularly; and, to impart the requisite curly form to the filaments or fibres, the edge of a blunt knife is drawn over them.

Feathers have long been used as a stuffing for beds and pillows; goose feathers especially. Goose feathers are divided into white and gray, the former being deemed the most valuable. The less valuable kind of feathers, known by the general name of *poultry feathers*, are obtained from turkeys, ducks, and fowls. Wild duck feathers are both soft and elastic, but their value is impaired by the great difficulty of removing the disagreeable odour of the animal oil which they contain. Various methods are practised of cleansing feathers from their oil, principally by the use of lime or lime-water; but Mr. Herring has introduced a method of purifying feathers by steam, which is said to be very efficacious. The softest and finest kind of feathers employed for bedding are those from the breast of the eider-duck. [EIDER-DOWN.]

Of the quills of feathers employed for pens, those from the goose are most used. One among many modes of preparing them is the following:—A workman sits before a small stove fire, into which he thrusts the barrel of the quill for about a second. Immediately upon withdrawing it from the fire, he draws it under the edge of a large blunt edged knife, called a hook, by which it is forcibly compressed against a block or plate of iron heated to about 350° Fahr. By this process the barrel, which is rendered soft and elastic by the heat, is pressed flat, and stripped of its outer membrane, without danger of splitting. It springs back to its natural form, and the dressing is completed by scrubbing with a piece of rough dog-fish skin. The principal workman employed in this operation can pass 2000 quills through his hands in a day of ten hours. By whatever process the external membrane is removed, that inside the quill remains, shrivelled up in the centre of the barrel, until it is cut open to convert it into a pen.

Foreign feathers were imported to the following values, in four recent years, viz.:—5,279*l.* in 1846, 4,237*l.* in 1847, 4,689*l.* in 1848, and 5,096*l.* in 1849.

FELSPAR is a mineral which occurs both crystalline and massive. The primary form of the crystal is an oblique rhombic prism. Both the colour and the degree of transparency vary greatly. Felspar, which is a component of all granites, consists mainly of silica and alumina.

FELT; FELTING. Under HAT MANUFACTURE will be found a description of that peculiar process whereby woollen and fur fibres are felted into a material fitted for hats.

Woollen fibres are sometimes combined by the felting instead of the weaving process for carpets and various kinds of cloth. Among other manufacturing firms for the purpose, there is the 'Patent Felted Woollen Cloth Company;' by whom is made felt carpets, embossed and printed felt table-covers, felt polishing cloth for plate and other purposes, felt for veterinary purposes, felt waistcoatings, felt coach-cloths and railway carriage-linings, upholsterers' felt, and felt for pianofortes.

A material called *Asphalted Roofing Felt* has come rather extensively into use. The two principal kinds are Croggon's and McNeill's. The qualities of this material are stated by the patentees to be imperviousness to rain and snow, non-conductibility of heat, elasticity, lightness, durability, economy, and easy application. It may not perhaps possess all these desirable qualities, but it certainly possesses many of them. It is used for roofing churches, houses, cottages, verandahs, farm-buildings, cattle sheds, and other buildings; for lining granaries and stores; for protecting ceilings from damp; for lining the insides or outsides of wooden buildings; for covering conservatories and garden-frames; for thatching corn and hay ricks; and for many other purposes.

The felt for the above purposes is sold in large sheets at the rate of about a penny per square foot. Another kind, called Inodorous Felt, is saturated with waterproof material free from the smell of the ordinary felt, and is used to prevent wall-paper from being injured by damp. There is also a patent Felted Sheathing, for covering ships' bottoms; it is a felted mixture of hair and vegetable fibre, and is not intended as a substitute for copper sheathing, but to be used as a layer beneath it. Another variety, the Non-conducting Felt, is used as a covering for boilers and steam-pipes, on account of its power of confining the heat within the vessel enclosed by it; it is used for fixed, locomotive, and marine steam-engines, and in breweries and distilleries: it is said also to be a good protective of water pipes from frost.

The Asphalted Felt is made in long pieces, 32 inches wide by about 30 yards long, and is sold in any smaller or larger quantities. The fibrous material of which it is formed is saturated with asphalte or bitumen. Many sheds and other buildings at Devonport and Woolwich Dock Yards, Isle of Portland, and elsewhere, are now covered with this material.

FELUCCA is the name of a vessel or small craft used in the Mediterranean for coasting voyages, being propelled both by oars and sails. The feluccas carry two masts, main and fore, with lateen sails.

FENCES. When a park is inclosed to keep in deer and game, the best fence is a stone or brick wall, well built with lime mortar; but, as this is expensive where stone and lime are not at hand, the common *park paling* is more frequently met with. This is composed of posts and rails of oak morticed and pinned together, and split pales of the same material nailed upon these in an upright position. Sometimes the pales are nailed at a distance from each other, which makes the *open paled fence*, and the pales are then generally cut to a point at top. Wood fences on the continent are generally of ruder construction.

In wild mountain passes in Scotland and Ireland it is usual to separate the properties of different individuals or that of parishes by rough stone walls put together without any mortar. The materials are generally at hand, and a rough and efficient fence is made without much labour. Where stones are not at hand, a high bank of earth faced with sods of grass is substituted for a wall. Furze seed is often sown on it, and soon forms an excellent fence, which, by proper care and clipping, will last a long time. But the most common kind of fence for fields is the hedge and ditch, the bank being raised with the sods and earth taken out of the ditch, and the hedge planted in the side of the bank towards the ditch, or on the top. Where they are not required as drains, it is a great waste of land to have any ditches, and a simple hedge planted on the surface of the soil is much to be preferred. Of all fences, a live hedge, which is carefully planted, and kept properly cut and trimmed when it is grown up, is by far the best.

When a fence is required within sight of a dwelling, a deep ditch is sometimes dug, and a fence placed at the bottom of it. This is called a *sunk fence*. Sometimes a wall is built against a perpendicular side of a ditch, and some very light fence is placed obliquely outwards near the top of it, and level with the ground. This is called a *ha-ha fence*, a name given to it from the surprise excited in a person unacquainted with it, when he suddenly finds himself on the top of a wall with a deep ditch before him. A variety of *light fences of iron* have been invented for the same purpose: some of these are fixed, and others moveable: some have upright pieces of cast iron as posts let into oak blocks sunk in the ground, and rods of wrought iron passing through holes in the uprights: some have wire for the same purpose. But the most common iron fence is composed of separate wrought-iron hurdles, which may be moved at pleasure, and are kept together by screwed pins and nuts.

FERMENTATION. This is a general name for certain changes which occur in vegetable and animal matters, and by which there are produced new fluids and gaseous compounds. Fermentation is of three kinds: the *vinous*, producing alcohol; the *acetous*, yielding vinegar; and the *putrefactive*, of which the products are very variable, and usually fetid.

When the expressed juice of grapes is exposed in warm weather to the air, it soon becomes turbid; its temperature rises a few degrees, a motion occurs in the fluid, and minute bubbles of air form and break. As the process goes on, a thick froth, consisting of these bubbles and viscid matter, rises to the surface, and, when these bubbles have burst, a viscid substance falls to the bottom of the vessel: this possesses the property of causing fermentation to take place in other fluids which, without its presence, would not undergo such a change: this substance is called *yest*. The sugar of the grape has undergone by this fermentation a decomposition into alcohol and carbonic acid.

Although sugar yields alcohol by its decomposition, yet pure sugar suffers no fermentation. In the juice of the grape, there is some accompanying matter which acts as a ferment; and when yest is thus spontaneously produced it causes fermentation in sugar, without, as far as appears, adding anything important.

The fermentation of malt-extract is noticed under BREWING and DISTILLATION. Acetous fermentation is treated under ACETIC ACID and VINEGAR. The putrefactive fermentation is the spontaneous decomposition of vegetable and animal matter, which is unaccompanied with the production of alcohol or acetic acid. In vegetable putrefactive fermentation the principal product is carbonic acid, and probably water, both derived from the absorption of the oxygen of the air, which unites with the hydrogen and carbon of the vegetable matter. In the putrefactive fermentation of animal matter ammonia is formed by the union of the hydrogen and nitrogen of the substance.

FERNS. The properties and uses of the ferns are numerous. Many of them deposit starch in their rizomata, from which food may be prepared. The roots of *Nephrodium esculentum* are eaten in Nepaul; those of *Angiopteris evecta* are used in the same manner in the Sandwich Islands. *Diplazium esculentum*, *Cyathea medullaris*, *Pteris esculenta*, and *Gleichenia dichotoma*, all yield starch, and are employed as food in different countries. The *Adiantum Capillus Veneris* yields astringent and aromatic secretions. Some of the American polypodiums are said to possess powerful medicinal effects. The *Angiopteris evecta* yields an aromatic oil, which is used in the Sandwich Islands to perfume the fixed oils, as cocoa-nut oil. The stems of many species contain bitter principles, and have hence been used as tonics. Species of *Aspidium* and *Asplenium* have been used in European medicine. The Brazilian negroes form tubes for their pipes from the stems of *Mertensia dichotoma*. *Osmunda regalis* had once a great reputation in medicine.

FERO'NIA. The Elephant or Wood Apple of the Coromandel coast, is a species of the *Feronia* genus of plants. The fruit is fleshy, and extremely acid before it arrives at maturity; but, when ripe, it contains a dark brown agreeable sub-acid pulp. In appearance the fruit is large, spheroidal, rugged, and often warted externally. A transparent oily fluid exudes from the trunk of this tree when an incision is made into it, which is used by painters for mixing their colours. A clear white gum may also be obtained from the tree very much resembling gum arabic. The wood is likewise valuable on account of its durability, whiteness, and hardness.

FERROCYANIC ACID is composed of hydrocyanic acid, cyanide of iron, and water. It contains 23.27 per cent. of iron. This acid is decomposed by long exposure to the air, Prussian blue being formed and precipitated; this is also produced by adding it to a persalt of iron.

FERRO'L, a seaport town of Gallicia in Spain, has some manufactures of hats, and carries on a considerable fishery of herrings, and sardines, which are pickled and exported. It also carries on some trade with America, exporting wine, brandy, and corn.

FE'RULA. The drugs called *Sagapenum* and *Assafœtida* are yielded by species of the Ferula plant.

Assafœtida is said to be found only in two districts of Persia, that is, the fields and mountains round Herat, the capital of Khorassan, and the range of mountains in the province of Lar. The plant is said to arrive at as great an age as man himself, and in consequence its roots sometimes attain a considerable size. It is from wounds in this part that the drug is obtained. The roots are not wounded before they are four years old; the greater their age, the better the quality of their produce. There were four operations each year when Kæmpfer visited the country; the first in the middle of

April, the second at the latter end of May, the third ten days later, and the fourth in the beginning of July. The gatherers on the first occasion only clear the hard sandy or stony soil away from the root to the depth of a span or so, pulling off the leaves, replacing the earth about the roots, and then heaping the leaves on them, and pressing them down with a stone. On the subsequent occasions they slice the roots transversely, beginning a little below the top, and collecting the juice that flows from the wounds. After every operation they cover the root with the old leaves, to screen it from the sun. After the last gathering the roots are left to perish.

Various useful substances are yielded by other species of this genus of plants.

FIBRE, is one of the most elementary forms of vegetable tissue. It consists of excessively delicate threads twisted spirally in the interior of a cell or tube. The fibre is solid. It is this elementary fibre which, being turned spirally round a long delicate tube with its spires in contact, forms the elastic spiral vessel.

Without entering into minor differences, fibre is a general name for the cotton, flaxen, and hempen material which forms so important a class of our textile manufactures.

FIBRIN, is a substance contained in the bodies of animals both in a fluid and in a solid state; in the fluid state it exists in the blood, and in the solid state in muscular fibre, but the fibrin of venous blood differs from that of arterial blood. When separated from the other constituents of the blood, fibrin appears in the form of long white elastic filaments; it is inodorous, tasteless, and insoluble in water whether cold or hot, but by long-continued boiling a portion is dissolved. When dried at a gentle heat, it loses about four-fifths of its weight, which loss is water, and it becomes then horny and translucent, and very much resembles albumen which has been coagulated. Acetic acid and fresh fibrin, when kept for some hours in contact, form a transparent gelatinous mass which is soluble in water. Solution of potash dissolves fibrin. Its composition is precisely similar to that of coagulated albumen, and they have several properties in common.

That variety of fibrin which constitutes muscular fibre is so interwoven with nerves, vessels, and cellular and adipose tissue, that its properties are probably always more or less modified by foreign matters. To obtain the fibrin of a muscle, it must be finely minced, and washed in repeated portions of water at 60° or 70° till all colouring and soluble substances are withdrawn, and till the residue is colourless, insipid and inodorous. It is then strongly pressed between folds of linen, by which it is rendered semitransparent and pulverulent.

There is also a substance called *Vegetable Fibrin*, which is obtained from wheat flour by the following process:—Make the flour into a paste, and wash it on a fine sieve with a small stream of water. The gluten of the flour will remain, and a milky liquid will pass through the sieve, which when suffered to rest will in a few hours become clear by depositing the starch by which it was rendered turbid. If this clear liquor be boiled, a flocculent precipitate is formed in it, which, when washed, dried, and purified by boiling æther, has the same composition as animal fibrin. When heated, it coagulates, and possesses the properties of coagulated albumen.

FIFE, a very small flute giving acute piercing sounds. It is an octave higher than the flute, and in compass comprises two octaves. Fifes are of three sizes, named by the letters A, B, and C. The first is the lowest; the last, which is that in common use, is the highest.

FIFESHIRE is one of the best cultivated counties in Scotland. The soil is of various kinds. In the most fertile districts it consists principally of a rich loam: in the poorer tracts it is mostly a wet clay, resting on a cold bed of till. A level tract of deep, rich, and very fertile loam extends from east to west along the whole southern side, varying in width from three miles to one mile from the shore of the Frith of Forth; and there are in other parts very rich tracts of land. The extensive water-boundary gives the county many excellent ports and small harbours, from which steam communication is kept up with Edinburgh, Dundee, Perth, and other places. Most of the chief towns of the county will be shortly linked together by railways. Coal and limestone of the best description are found in abundance in almost every part of the county south of the Eden; but they are not found in the upper division, north of this river. The collieries are numerous, and some are very extensive, and employ a large number of hands. Limestone quarries are numerous in various parts of the southern district. Ironstone is plentifully obtained in several parts of the coal fields, especially near Dysart, and in the parish of Balgonie. Lead mines have been worked in the Lomond Hills. Freestone, whinstone, and many of the primitive rocks are abundantly met with. There are beds of rich marl, brick-clay, and peat. Gems are sometimes picked up in the beds of the rivers.

There are a few patches of natural wood in

Fife. The plantations are numerous, and the timber in them, which is mostly aged and valuable, consists of ash, elm, beech, fir of different kinds, limes, chestnut, sycomore, and oak. Flax is grown to a considerable extent, and is used in the linen manufacture at Dunfermline and elsewhere. The county of Fife has been long distinguished for the excellence of its breed of black cattle; when fat, they bring a much higher price at Smithfield market than any other kind. The Fife cows are also of high repute in the dairy.

Small breweries and distilleries for the manufacture of malt liquor and malt spirits, flour mills and pot-barley mills, salt-works and coal-works, tan-works and soap-works, and brick and tile works, are among the industrial establishments of the county. But the linen manufacture is by far the largest; it occupies a great number of hands, who spin and weave flax into damasks, diapers, checks, ticks, coarse sheeting, and many other kinds of linen fabrics. There are fisheries of salmon, cod, turbot, haddock, &c., off the coasts. There are a good many trading vessels belonging to the county.

At Dunfermline fine linens are largely manufactured. At Kirkaldy an excellent harbour has been formed, from which about 50,000 tons are annually shipped, chiefly to places on the coast of Scotland. Corn, potatoes, sheep, and pigs also form large items of exportation to London and various other ports. There are several flax-mills, extensive manufactures of coarse linen fabrics, an iron-foundry, tanneries, &c.

The factory-statistics of Fifeshire in 1850 presented the following results:—There were 2 factories for spinning and weaving woollens, with 26 power-looms and 1480 spindles. There were 40 factories for spinning flax, having 52,344 spindles, 1353 horse power for moving machinery, and employing 3980 persons. There were 3 factories for weaving flax, with 194 power-looms, and having 42-horse power.

FIGS. Figs belong to the *Ficus* genus of plants. The number of species of ficus is very considerable, perhaps as great as that of any arborescent genus. They are all either tropical or inhabitants of warm countries. Some are small plants creeping upon the surface of rocks and walls, or clinging to the trunks of trees like ivy; others are among the largest trees in the forest. They abound in a milky juice containing caoutchouc; and there is every reason to believe that the specimens of this substance which come from Java are exclusively procured by tapping different species of Ficus. The best known on the continent of India is yielded by *Ficus elastica*.

Although the fruit of *Ficus carica* (the common fig) and some others is eatable, yet the whole genus abounds in an acrid, highly dangerous principle, diffused among the milky secretion. This is perceptible even in the common fig, whose milk produces a burning sensation on the tongue and throat; but, when the fruit of that species is ripe, the acridity is destroyed by the chemical elements entering into new combinations. The common fig is a small tree, naturally inhabiting the temperate parts of Asia, and now commonly cultivated in Europe for the sake of its fruit. In the fertile islands of the Mediterranean, in Spain, Italy, and Greece, and even so far north as the south of France, the fruit is so well ripened as to form a valuable article of exportation in a dried state. The fruit is grown with some success even in the southern and milder parts of England, but it is seldom found in the northern parts or in Scotland, except under glass. The fig-tree is very apt to throw off its fruit before it ripens, and various methods have been suggested to prevent this. In the Levant, to insure a crop, the process of caprification is resorted to. [CAPRIFICATION.]

The figs imported in 1849 amounted to 39,516 cwts.; and in 1850, to 33,964 cwts.

FILBERT. This term was originally applied to those kinds of nuts which have very long husks; but, owing to the number of varieties that have of late years been obtained, this distinction, which was never scientific, appears to be nearly disregarded, and *nut* and *filbert* are almost synonymous terms, excepting that the wild uncultivated fruit, and those varieties which most nearly approach it, are never called filberts. The best sorts are the Frizzled Filbert, Red Filbert, White Filbert, Cob-Nut, Bond-Nut, Downton, and Northamptonshire.

About Maidstone, and in other parts of Kent, the management of the filbert is better understood than in any other part of this country; and, as the soil and other circumstances seem to suit its growth, immense quantities are grown for the London market. In order to preserve filberts in a fresh and plump state, it is only necessary to prevent their parting with their moisture by evaporation. Burying them in heaps in the earth, putting them in earthen jars in a wine-cellar, covering them with dry sand, are all very good plans, and many others equally efficient will suggest themselves.

FILE MANUFACTURE. A file, as every one knows, is a steel instrument having flat or curved surfaces so notched or serrated as to produce a series of fine teeth or cutting edges, which are employed for the abrasion of metal, ivory, wood, &c.

Steel for making files, being required to be of unusual hardness, is more highly converted than for other purposes, and is sometimes said to be *double converted.* Small files are mostly made of cast steel. The very large files, called smiths' rubbers, are generally forged immediately from the converted bars. Smaller files are forged from bars which are wrought to the required form and size by the action of tilt-hammers, either from blistered bars or from ingots of cast steel. These bars are cut into pieces suitable for making one file each, which are heated in a forge fire, and then wrought to the required shape on an anvil by two men, one of whom superintends the work, while the other acts as general assistant.

The next operation upon the blanks which are to be converted into files is that of softening or 'lightening,' to render the steel capable of being cut with the toothing instruments. This is effected by a gradual heating and a gradual cooling. The surface is then rendered flat and smooth, either by filing or by grinding.

The cutting of the teeth is usually performed by workmen sitting astride upon a board or saddle-shaped seat, in front of a bench, upon which is fixed a kind of small anvil. Laying the blank file across the anvil, the cutter secures it from moving by a strap which passes over each end and under his feet, like the stirrup of the shoemaker. He then takes in his left hand a very carefully ground chisel made of the best steel, and in his right a peculiarly-shaped hammer. If the file be flat, or have one or more flat surfaces, the operator places the steel chisel upon it at a particular angle or inclination, and with one blow of the hammer cuts an indentation or furrow completely across its face from side to side, and then moves the chisel to the requisite positions for making other similar and parallel cuts. If it be a half round file, as a straight-edged chisel is still used, a number of small cuts are necessary to extend across the file from edge to edge. So minute are these cuts in some kinds of files, that in one specimen about ten inches long, flat on one side and round on the other, there are more than 20,000 cuts, each made with a separate blow of the hammer, and the cutting-tool being shifted after each blow. The range of manufactures afford few examples more striking of the peculiar manual tact acquired by long practice.

Several highly ingenious machines have been contrived for superseding the tedious operation of file-cutting by hand; but, suited as the process may appear to be for the use of machinery, it has been found to present such great difficulties, that we believe no file-cutting engine has been brought successfully or extensively into operation. One very serious difficulty arises from the circumstance that, if one part of the file be either a little softer than the adjacent parts, or narrower, so as to present less resistance to the blow of the hammer, a machine would, owing to the perfect uniformity of its stroke, make a deeper cut there than elsewhere.

After the files have been cut, the steel is brought to a state of great hardness; this is effected in various ways, according to the purpose to which the file is to be applied: they are generally coated with a sort of temporary varnish, then heated in a stove, and then suddenly quenched. After hardening, the files are scoured, washed, dried, and tested.

We will here give, from a Sheffield newspaper, a description of a file intended for the Great Exhibition, the most elaborate perhaps ever produced. It was wholly made by a file-forger named Hiram Younge, in the employ of Messrs. Carr of Sheffield. The length is 54 inches, breadth 3¼ inches, thickness ⅝ of an inch, weight 28 lbs. With some small exceptions, the whole surface is covered with ornamental designs, all cut by hand with hammer and chisel. The tangs (it is a double-tanged file)—are sunk by filing, and are ornamented on one side with the national arms and the words "God save the Queen," on a shield; a front view of the cutlers' hall on the other, with the motto 'Pour parvenir a Bonne foy.' The other tang represents Atlas bearing the globe, with two lions couchant: beneath are the Sheffield arms, and a cornucopia on each side. On the reverse side appear the cutlers' arms with the emblem of industry—beehives and bees on the wing—on each side. On the moulding these words appear: 'Cut, designed, and executed by Hiram Younge, a member of the Sheffield file trade.' The centre or body of the file is ornamented on one side with an accurate, full-length view of the Great Palace of Industry, in perspective, forming an elegant and spirited sketch. The reverse side is occupied by a view of the Sheffield Infirmary; while on the ends, between the centre and the tangs, are four views, illustrating the processes of file manufacturing. 1. A file-forger's shop, exhibiting bellows and other appointments, and a file-forger and striker in working costume. 2. The interior of a wheel: grinders at work. 3. A file-cutting shop: three men cutting files, and one grinding his chisel. 4. A hardening shop:

hardeners at work, and two women scouring files. The edges of the file are occupied with an inscription. The remaining space is filled up with chequered work, half diamonds, &c. This unique file revolves on pivots, so that every part can be inspected in succession with ease, and the position varied to bring out the innumerable effects which light produces. The lighter parts possess that peculiar bright richness observable on highly ornamented silver plate. But the most remarkable feature in this elaborate ornamentation is a number of trees in full foliage, luxuriant as the work of the pencil. Each separate shade is effected by a distinct style of perfect tooth. Those practised in the delicate art of file-cutting can best appreciate this wonderful piece of work; but the uninitiated may judge of its merit by bearing in mind that if a single tooth were cut too deep or too shallow, too narrow or too broad, or the least awry, it would destroy the uniformity of the shade, and that nowhere is there such a defect discernible.

FILLET, a flat rectangular moulding, of very frequent occurrence in architecture. It is used to terminate or divide other mouldings, as in the cavetto, which is surmounted with a fillet, and in the flutings of columns, which are divided by a fillet. The fillet is much used in entablatures.

FILTER. The smaller kinds of filters are strainers used in chemical operations for rendering fluids transparent by separating the suspended impurities which make them turbid; or for separating and washing the precipitates resulting from chemical analysis. They are usually made of unsized or blotting paper; and they are used either spread out upon cloth stretched on a wooden frame, or folded and placed in funnels, and having consequently the form of an inverted cone. They are either single or double, according to the purposes to which they are to be applied.

Various forms of filter are employed for the purpose of filtering water, either for drinking or culinary purposes. These filters generally depend upon passing water through sand or small pebbles and charcoal. It is well known that the Thames water, though it contains but little saline matter in solution, is frequently turbid, owing to mechanical admixture of earthy matter, which the filters in question are well calculated to remove, so as to render the water, though not so agreeable as spring-water for drinking on account of its flatness, yet well adapted for other purposes.

A considerable portion of the river-water of Paris is filtered in large establishments where it is employed. The filters employed are small boxes, many in number, lined with lead, open at top, and having at the bottom a layer of charcoal between two layers of sand. If the water is foul, the upper layer of sand requires to be renewed daily. At the Hôtel Dieu the boxes are hermetically sealed, and the water is forced through the filtering layers by artificial pressure.

A very simple water-filter may be made of a common garden-pot, or similar vessel, with a bottom pierced with holes. Fill the lower part with round pebbles, then place a layer of smaller pebbles, then coarse sand, and lastly a layer three or four inches in depth of well-made pounded charcoal. The water, in percolating through these various strata, loses nearly all its mechanical impurities.

Murray's 'Self-cleansing Domestic Tubular Filter,' registered in 1850, is to be soldered to the end of the service-pipe. The enlarged part of the pipe contains a perforated tube with several folds of flannel and linen wrapped round it. The smaller tap communicates only with the outer casing, so that no water can reach it that has not passed through the filtering tube. The larger tap communicates with the interior of the tube; and by allowing it to run, the filter will clean itself.

In 'Bird's Hydrostatic Syphon Water Purifier,' also registered in 1850, the filtration is performed in two inverted cones containing filtering media, situated in the cylinder. When used, the instrument is immersed in the water to be filtered, and the pipe uncoiled so as to hang with its stop-cock below the bottom of the instrument. On drawing out the air from the pipe, it acts as a syphon and a stream of pure water flows.

Foster's Pressure Filter, recently patented at Liverpool, and recommended for use by the Sanitary Board of that town, consists of a porous stone, hollow in the inside, and contained in a metal jacket. This apparatus, when screwed on to the service-pipe, causes the water, forced through the stone by the pressure of the main, to lose all its pollutions, and come out pure and clear in the extreme. There are two taps, one of which draws the filtered water from the interior of the stone globe; the other the unfiltered from the exterior; and the apparatus is so arranged that the drawing of the unfiltered water cleanses the stone and increases its powers of filtration.

FINISTÉRE. This department of France, in Brittany or Bretagne, produces, besides the usual kinds of crops, flax, hemp, tobacco, and cider fruits. The cider produce is about 1,500,000 gallons annually. Eels, trout, salmon, lobsters, and oysters are plentiful; but the pilchard fisheries along the coast afford the most profitable occupation to the Breton fishermen. In this pursuit more than 1000 vessels of small size, and about 4000 men, are employed, and a gross annual value of 2,000,000 francs is obtained. This includes the value of the enormous quantities of the common pilchard (4,400,000 lbs.), the anchovy pilchard, caught off Concarneau in Forêt Bay (1,100,000 lbs.), and a large quantity of oil pressed from fish which are not cured. These fisheries form an excellent nursery for the French navy, which draws its best seamen from Bretagne.

Iron, coal, lead, bismuth, and zinc mines are worked. An excellent stone, easily worked, and capable of resisting the action of the weather, is found at Daoulas and one or two other places near the Brest Roads: it is of a light green colour, and when worked presents the appearance of bronze; it is called *Kersanton* stone, and of it several of the churches in the department are built. Granite, marble, building stone, and slates are quarried; potters' clay, kaolin, and whetstones are found. The manufactures consist of sailcloth, linen, soda, soap, seed oil, candles, ropes, pottery, paper, leather, refined sugar, litharge, and tobacco. Ship-building is carried on at Brest and in most of the large towns on the coast. The commerce of the department is composed of the various products already named, and of wine, brandy, beer, Dutch cheese, butter, salt, and colonial produce.

FINLAND. This cold Russian province, lying north-east of the Baltic, has extensive forests of firs and pines in the south, interspersed with oaks, elms, &c. In northern Lapland these trees are replaced by the birch, until, in the coldest districts, trees cease altogether. The chief crops are barley, rye, oats, wheat, peas, beans, hemp, flax, potatoes, carrots, parsnips, onions, hops, and tobacco; but the produce is seldom large. Of fruit there is scarcely any. The forests yield much timber, pitch, and potash. The streams are well provided with fish, which form the chief food of the people. The mineral produce met with is chiefly bog-iron, lead, copper, marble, slate, and chalk.

Agriculture, the breeding of cattle, and in some parts the fisheries constitute the principal occupations of the people. There are few manufactures except in the large towns, and these are principally of iron-ware, sailcloth, and stockings. The navigation and trade are inconsiderable.

FIR. [Abies; Pine-Tree.]

FIRE-ENGINE. In Rome under the emperors there were bands of trained firemen kept. Ctesibius is believed to have invented some engine for the extinction of fires in the time of the Ptolemies; and a few indications of similar inventions are met with in other quarters. But the first fire-engine which has been distinctly described was made by Hautsch of Nürnberg about 1657. Duperrier received a patent for making fire-engines for France in 1699. None of these earlier engines had either a flexible hose or an air-chamber: the first of these was introduced by Jan Vanderheide in 1672; and the latter by Leupold in 1720. It was about the beginning of the same century that fire-engines came generally into use in England.

A fire-engine of the common construction consists of an oblong wooden chest or cistern, along the lower part of which runs a metallic pipe, into which the water flows from a feed-pipe connected at the other end with the street plug. The water having entered the interior pipe is elevated and forced into an upright air vessel by two pumps which are worked by manual power, by means of long handles or levers on the outside. From the air-vessel the water is forced into a pipe connected with the leather hose; and from the latter it is forcibly impelled on the burning buildings. If there were no air-vessel the water would not flow out in an equable continuous stream, but would gush forth at intervals at every successive movement of the pump-handles; but by the aid of the air-vessel the stream is rendered continuous by the elastic pressure of air within the vessel.

Numerous improvements have been introduced in almost every part of the fire-engine, whereby it has been rendered much more efficient than formerly. In 1830 Mr. Braithwaite introduced an ingeniously constructed steam fire-engine, which has occasionally been employed. The same engineer has also introduced a steam floating fire-engine, in which the power of the engine can be transferred from propelling the vessel to working the pumps when requisite.

Mr. Tilley, the fire engine maker, has recently contrived a small fire-pump, calculated to be useful before the larger engines arrive. It is well suited for warehouses and shops, as it can be worked from a single bucket of water. It consists of a sort of double cylinder, one within another, the inner one being the barrel, and the outer the air-vessel. In the barrel works a piston, the rod of which ends at the top in a nob, which serves as a handle. The lower end of the instrument being placed in a bucket of water, and the piston being worked vertically, water is drawn into the barrel, and is forced by the air pressure through a hose screwed to one side of the air-vessel. The pump can discharge six gallons of water per minute, to a height of thirty feet.

Down to the year 1825 all the Fire Insurance Companies of London had their separate establishments of fire-engines; but in that year the Sun, the Union, and the Royal Exchange Companies joined their fire-engine establishments, which were placed under one superintendence. Soon afterwards the Atlas and the Phœnix Companies joined the association. The advantage of this combined system of action having been proved, most of the remaining companies joined in 1833, and formed a new association, which was to be managed by a committee, formed of one member from each of the associated companies. London was divided into a certain number of districts, in each of which were two or more stations, provided with engines.

The plan has worked well: more companies have joined the association; and it is found that all are benefited. The firemen are formed into a corps, called the *fire-brigade*, which is under the efficient control of Mr. Braidwood, superintendent of the establishment. The men are clothed in a uniform; and a certain number of them at each station are ready at all hours of day or night. Each company pays its quota towards the expenses of the fire-engine establishment.

A fire engine of great power was made for the London Docks a few years ago, with working barrels eight inches diameter. It would throw a jet perpendicularly to a height of eighty feet; at an angle of 45° the jet would reach to a distance of 130 feet.

The West India Dock Company employ a steam tug to move the vessels using the docks; and their assistant engineer, Mr. P. Clark, has designed a simple method of making the power of the engines of the boat available in case of fire. A large Downton's pump is fixed on deck, and connected by gearing to the engines, so that they can be readily disconnected from the paddle-wheels, and their power applied to the pump. The power of the engines is 30 horses, which, nominally, would be equal to 240 men, or 10 of the ordinary fire-engines, but in reality to a much greater number. Without using the whole power of the engines, a stream of water equal to 600 gallons, or 3 tons, per minute, is projected 20 feet higher than the highest warehouse in the docks. As the fires in the boilers are never allowed to go out entirely, this machine is always in readiness, and in the event of a ship taking fire could tow her out of danger, and extinguish the fire at the same time.

In the year 1850 there were 247 premises totally destroyed by fire in the metropolis, 621 partially destroyed, and 18 lives lost. Nearly 100 houses were more or less injured by explosions of fire-works.

The employment of saline substances for extinguishing fires has been long known. Dr. Clanny suggested, a few years ago, the employment of water for fire-engines, containing five ounces of muriate of ammonia to each gallon of water. Mr. Phillips's apparatus, now occupying a good deal of public attention, is briefly noticed under the heading of ANNIHILATOR, FIRE.

The engines employed in gardening and agriculture partake a good deal of the character of fire-engines in their construction. [GARDEN ENGINE.]

FIRE-ESCAPE. Numerous contrivances have been brought before public notice from time to time for saving the lives of persons who may be in a building while it is burning. Mr. Meseres devised a kind of chair of straps, by which a person could lower himself from the window. Mr. Davis proposed the use of three ladders, which might draw out like a telescope, and might reach from the ground to the upper windows of a house. Mr. Young contrived a sort of rope-ladder, with iron rounds of very flexible construction. Mr. Braby invented a sort of a long pole, down which a car or chair might travel from a window to the ground. Mr. Witly introduced a sort of bag or case, which may be lowered from the sill of a window by ropes governed by the person who might be seated in the bag. Mr. Ford recommended the use of a long pole, at the upper end of which is tackle for lowering persons from a window. Mr. Merryweather has contrived a series of short ladders, which fit on to each other end to end, and can be elevated to a considerable height quickly.

But the fire-escape which has come most into use in London is a wheel-carriage supporting a lofty canvas shoot or trunk, attached to a ladder or frame; when placed up against a house, a person can get into this trunk from a window, and slide safely down to the bottom, with the aid of some ingenious mechanism attached to the frame. Many such machines are kept in public places in London during the night, attended by men whose business it is to wheel these machines to any spot where life is endangered by fire.

A Report was presented to the city corporation in 1840 from the police commissioners, descriptive of thirty plans for fire-escapes, which had been proposed by different parties. They were of three classes: 1st. Machines intended for domestic use only, to be resorted to by inmates of houses in cases of fire; 2nd. Machines to be used from the outside, and made to combine the security of property with the protection of persons; 3rd. Machines exclusively for the protection of life from fire, to be used out of doors under the responsible direction of the police. Among the thirty were Davies's effective but rather ponderous machine; Wivell's, with the canvas trunk; and Gregory's sliding ladders on a carriage. Whichever may be the best form in wide thoroughfares, it is thought that the common fire ladders of the London Brigade are the most generally useful in courts and confined situations.

FIRE, GREEK, an invention of the middle ages which was often employed in the wars of the Christians and Saracens. According to Gibbon, this combustible was used at the sieges of Constantinople in the 7th and 8th centuries. It was afterwards employed by the caliphs against the Crusaders; but the invention of gunpowder changed the nature of military tactics. There is much uncertainty as to the nature of this Greek Fire. It is supposed to have been a compound of naptha, sulphur, and pitch; and Gibbon thus describes its effects:—'From this mixture, which produced a thick smoke and a loud explosion, proceeded a fierce and obstinate flame, which not only rose in perpendicular ascent, but likewise burnt with equal vehemence in descent or lateral progress; instead of being extinguished, it was nourished and quickened by the element of water; and sand, urine, or vinegar, were the only remedies that could damp the fury of this powerful agent, which was justly denominated by the Greeks the liquid or the Maritime Fire. For the annoyance of the enemy it was employed with equal effect by sea and by land, in battles or in sieges. It was either poured from the ramparts in large boilers, or launched in red-hot balls of stone and iron, or darted in arrows and javelins, twisted round with flax and tow which had deeply imbibed the inflammable oil: sometimes it was deposited in fire-ships, the victims and instruments of a more ample revenge, and was most commonly blown through long tubes of copper, planted on the prow of a galley, and fancifully shaped into the mouths of savage monsters, that seemed to vomit a stream of liquid and consuming fire.'

FIRE-PROOF BUILDINGS. The most obvious method of rendering houses and other buildings indestructible by fire is to construct them entirely of incombustible materials, such as stone, brick, and iron. Such a mode of construction, however, is of very limited application. The use of iron, and especially of cast iron, in buildings, has indeed increased very much, and many plans for the construction of dwelling-houses almost entirely of that material have been brought forward.

Brickwork forms in this country the chief material of the external walls of houses, and it is occasionally employed without any admixture of timber for the partition walls also,—a plan which, in conjunction with other precautions, tends greatly to limit the damage done by a fire to the apartment in which it may happen to break out. Cast-iron pillars and brest-summers are very extensively employed in modern London shops and warehouses, where the whole front on the ground floor is left open for shop-windows and doors. Fire-proof floors are now often adopted, not only in public buildings, but also in the larger and better sort of private houses; the beams being either of cast or wrought iron, and the brick vaultings, which abut upon the ledges of the beams, being often only half a brick thick. In Farrow's patent method of fire-proof building, the floors are supported upon joists of wrought iron, formed with a projecting flange on each side, upon which are laid, stretching from joist to joist, a series of flat stones the upper surfaces of which lie flush with the upper edges of the joists. These produce a level stone floor, interlined with iron, which may either be used as such or be covered with planks. Mr. Frost has invented a mode of constructing floors and roofs of hollow square earthenware tubes, laid in strata crossing each other in direction, and united with cement in such a way that the whole floor becomes one solid flagstone. In one mode of construction, hollow earthen pots are employed to form a sort of vaulted roof.

The great use of timber in building renders very important any method by which it may be rendered incombustible. Solutions of muriate of ammonia, muriate of soda, sal-ammoniac, borax, alum, and several other salts and alkalies, with which wood may be impregnated, or which may be applied to its surface, possess this quality in a limited degree; and by Payne's wood-preserving process timber is made, for all practical purposes, completely incombustible. The non-conducting power of earth and sand, or of a layer of sand placed over timber, has been the basis of many plans for preventing fires.

FIRE-SHIP is a vessel laden with combustible materials, which is sent or left in a burning state among the ships of a hostile fleet for the purpose of setting them on fire. Such vessels have been used in various countries, at different times. Those now constructed have between decks, on both sides, a stage containing a groove, in which the train of powder for firing the combustibles is deposited in a hose or tube. The stage is covered with a tarpaulin on which is strewed loose powder; and on this are placed faggots of wood and bundles of hemp steeped in a mixture of resin, turpentine, saltpetre, and mealed gunpowder, billets of wood dipped in saltpetre and pitch, casks filled with chips of wood mixed with pitch and turpentine, and loaded shells and carcasses. Faggots soaked in pitch are also fastened to the sides of the ship; and around the ship are grappling-irons to enable it to cling to the ill-fated vessel to be destroyed. When the crew has brought the fire-ship close to its prey, they fire the combustibles, and escape by a boat as quickly as possible.

FIRE-WOOD MANUFACTURE. The manufacture of such an article as fire-wood would only be thought of in a large and populous city, far distant from woodland and copses. The neat appearance of our London bundles and net works and wheels of fire-wood has to this day an air of strangeness to country people.

The bundles of fire-wood, largely used in London, and having a cylindrical shape, are made with simple apparatus. The pieces of wood, well dried, are cut by saws into blocks about six inches long, and these blocks are chopped up to the requisite degree of thinness. A sufficient number of small sticks to form one bundle are placed within a kind of hoop, and confined there until a piece of tarred string is firmly bound round them.

The *Patent* fire-wood of recent times assumes two forms—the *wheel* and the *gridiron*. In the first form a number of small pieces are arranged somewhat like a wheel, and bound into that form by string. In the gridiron form the pieces are first notched or dovetailed, by a machine, and made to fit very tightly into each other. Both forms have a few fragments of shavings, and a slight coating of resin on one side, to facilitate their ignition.

The manufacture of the cylindrical bundles of fire-wood is deemed sufficiently important to warrant the erection of an extensive factory at Bow, where steam-power is employed to work an ingenious series of machines recently patented by Messrs. Thompson and Elms. There are two machines, for cutting and for binding. The cutting-machine has a large wheel, on the periphery of which are eight equi-distant cutters. An endless band passing over the rollers, acts as a feeder to these cutters. The billets of wood are cut by the saw into blocks, about six inches long; and these blocks are ranged, side by side, on the feeding-band, with the grain of the wood perpendicular. As the feeding band travels on, these blocks are brought one by one to a spot where the cutters may act upon them: and they are speedily cut up into slices or flat pieces. These slices are re-arranged on the feeding-band, side by side, but in such a position that they may be cut up into splints or square sticks. These splints are much more regular in form than those produced by the old method of chopping. The splints are next taken to the binding-machine. They are placed in a kind of hopper, through which they descend into a horizontal cylinder, and a plunger or piston here compresses them, retains them at one end while the bundle is being bound with string, and then forces the bundle out of the cylinder.

FIRKIN is a measure of ale, beer, and some dry commodities, now disused. Eight gallons of ale, soap, or herrings, made a firkin, and nine gallons of beer made a firkin.

FISH. Of the varieties of fish eaten in this country, those that are the whitest and most flaky when cooked, such as whiting, cod, flounders, sole, haddock, turbot, hake, &c. are the most easily digestible; but those which abound in oily matter, such as salmon, eels, herrings, &c., contain more nourishment.

Fish may be preserved in a dry state, Mr. Cooley informs us, by sugar alone. Fresh fish may be thus kept for some days, so as to remain as good as when first caught. The sugar gives no disagreeable taste. This process is very useful in making what is called *Kippered Salmon*. A few table-spoonfuls of brown sugar are sufficient for a salmon of five or six pounds weight: and a little salt or saltpetre may be added. Salmon kippered in this way preserves its natural flavour better than if salted or smoked.

FISHERIES are localities frequented at certain seasons by great numbers of fish, where they are taken upon a large scale. Of the British fisheries, some are carried on in rivers or their æstuaries, and others in the bays or along the coasts. Our principal cod fishery is on the banks of Newfoundland: and for whales our ships frequent the shores of Greenland, Davis's Straits, and the South Seas. Of late, whale fisheries have also been carried on near the shores of Australia, New Zealand, and the Cape of Good Hope.

In the reign of Queen Elizabeth and afterwards, various associations were formed and orders in council issued, having for object the encouragement of British fisheries; but the trade did not flourish under these protections. Every attempt to encourage the fisheries by means of bounties failed, and the impolicy of granting these bounties was at length seen and acknowledged. In 1821 the tonnage bounty of 60*s*. per ton on fishing vessels was repealed; the bounty of 4*s*. per barrel, which was paid up to the 5th of April, 1826, was thereafter reduced 1*s*. per barrel each succeeding year; so that, in April 1830, the bounty ceased altogether. This alteration of the system was not productive of any serious evil to the herring fishery.

In 1849 the white herrings *cured* in Great Britain amounted to 770,698 barrels; the number *branded* by the commissioners was 213,286 barrels; and the number *exported* 340,256 barrels. Including those cured and those sold for immediate consumption, the number was 1,151,979 barrels. In the cod and ling department, there were 98,903 cwt. cured dried, and 6,580 barrels cured in pickle. In that year there were 14,962 boats and 59,792 fishermen under the control of the commissioners.

The removal of the bounty has been attended with an improvement in the condition of the fishermen generally, and in Scotland the fishermen have been able, from the fair profits of their business, to replace the small boats they formerly used by new boats of larger dimensions, and to provide themselves with fishing materials of superior value.

The facilities of communication with populous inland districts have greatly extended the market for fish, and the rapid means of transport by railways enables the inhabitants of Birmingham and London to consume cod and other fish caught in the Atlantic by the fishermen of Galway and Donegal. The fishermen who supply the London market, instead of returning to Gravesend or other ports of the Thames and Medway, put their cargoes, already packed in hampers, on board the steam-boats which pass along the whole eastern coast as far north as Aberdeen: or they sometimes make for Hull or some other port in the neighbourhood of the fishing-ground, and there land their cargoes, which are conveyed rapidly inland per railway. Fast-sailing cutters are sometimes employed to take provisions to the boats on the fishing-ground, and to bring back the fish taken by each.

One branch of fishing wholly different in its object from all other branches is the *Stow-Boat Fishery*. This fishery prevails principally upon the Kentish, Norfolk, and Essex coasts; and the object is the catching of sprats as manure for the land, for which there is a constant demand. This branch of fishing gives employment on the Kentish coast alone to from 400 to 500 boats.

Vessels and boats employed in fishing are licensed by the Commissioners of Customs; and they are required to be painted or tarred entirely black, except the name and place to which such vessel or boat belongs. The licenses thus granted specify the limits beyond which fishing vessels must not be employed: this distance is usually four leagues from the English coast.

The *Pilchard Fishery*, which is carried on upon parts of the Devon and Cornish coasts, employs about 1000 boats, 3500 men at sea, and about 5000 men and women on shore. As soon as caught the pilchards are salted or pickled and exported to foreign markets, chiefly to the Mediterranean: the average exports amounts to 30,000 hogsheads per year.

Our chief *Salmon Fisheries* are carried on in the rivers and æstuaries of Scotland, but the annual value of this fishery is not exactly known. The produce of the fishings in the rivers Tay, Dee, Don, Spey, Findhorn, Beauly, Borriedale, Langwell, and Thurso, and of the coasts adjacent, are conveyed in steam-boats and small sailing-vessels to Aberdeen, where they are packed with ice in boxes and sent to the London market. London is the great market to which Scotch salmon are sent. The quantity which arrives during one season is about 2500 tons, and the average price is from 10*d*. to 1*s*. per lb.

Mackerel visit every part of our coasts in the spring and early part of the summer, and are taken in great abundance. As mackerel will not keep, it may be hawked about on Sunday for Sale.

The fisheries of Ireland, by the Act of 1842 have been placed under the regulation of the Board of Public Works, the commissioners of which prepare an annual report concerning them. In 1845 the commissioners registered 19,883 vessels and boats, and 93,073 men and boys as engaged in the Irish fisheries. The whole coast of Ireland is divided into 28 fishing districts.

The *Cod Fishery* at Newfoundland was carried on as early as 1500 by the Portuguese, Biscayans, and French, but it was not until 1585 that the English ventured to interfere with them. The French and English have still continued to fish there. The principal fisheries of Newfoundland are prosecuted on the banks which nearly surround that island: the object of these fisheries is solely cod-fish. These fisheries may be said to be the sole pursuit of the settlers in Newfoundland, and of the traders who frequent the island.

In 1818 a convention was concluded between the United States' government and that of

Great Britain for regulating the fisheries on the coasts of the British American provinces. Conventions are also in force relating to the British and French fisheries in the English Channel.

The *Whale Fishery* will form the subject of a separate article. [WHALE FISHERY.]

The fish imported in 1848, and paying import duty, were

Anchovies......	161,100 lbs.
Eels	76 ship loads.
Salmon	1,344 cwts.
Turbots and soles	41 cwts.
" " of British taking	99,147 cwts.

FLA'GEOLET, a small musical instrument, played on by means of a mouth-piece. Its compass is two octaves, from F, the first space in the treble clef, to F in altissimo. The scale of the *Quadrille Flageolet* is rather more limited; and that of the *Patent Octave Flageolet* is an octave higher than the ordinary instruments. The *Double Flageolet* consists of two instruments, united by one mouth-piece, and producing double notes.

FLAME is the combustion of gaseous or of volatilized matter. It is attended with great heat, and sometimes with the evolution of much light; but the temperature may be intense when the light is feeble: this is the case with the flame of burning hydrogen gas, it being scarcely visible by day-light, though its heat is intense.

In the burning of a candle, the wax or tallow being first rendered fluid by heat, rises in the wick, and although the wick supplies some hydrogen and carbon, by far the greater portion of these is yielded by the wax or tallow, which burn by the assistance of the oxygen of the air. The supply of hot vapour diminishes as it ascends, and eventually fails, and hence the flame of a candle gradually tapers to a point, and then ceases.

That flame is merely a thin film of white hot vapour, and that this combustion is entirely superficial, while inflammable matter is contained within which cannot burn for want of oxygen, is proved by inserting one end of a small glass tube into the dark central portion of a flame; the inferior unburnt vapour or gas will escape through it, and may be lighted at the other end of the tube. For various illustrations of flame, see BUDE LIGHT; DRUMMOND'S LIGHT; LAMP, SAFETY.

FLANDERS. There are two provinces of this name in Belgium, East and West.

East Flanders, is low and level. In many parts of the province there are beds of peat. The chief productions of the earth are wheat, rye, barley, oats, potatoes, flax, hemp, hops, madder, and tobacco. There is but little wood of large growth in the province. The chief manufactures are lace, linen and woollen cloths, bobbin net, silk, cordage, bricks, hats, soap; and there are also cotton-factories, potteries, sugar-refineries, distilleries, and breweries. GHENT is the chief town. The manufactures are carried on chiefly at Ghent, Eecloo, Grammont, Lokeren, St. Nicholas, Ninove, Oudenarde, and Renaix.

West Flanders is admirably accommodated by inland navigation; the most important of these are the canals between Ghent and Bruges, Bruges and Ostend, Dunkirk, Furnes, and Nieuport. The production and industrial occupations of the people are similar to those of East Flanders. The agriculture of this province, as well as that of East Flanders, is of the most perfect kind. The chief manufacturing towns are BRUGES and COURTRAI; and besides these, various branches of industry are carried on at Iseghem, Menin, Poperingen, Roulers, Thielt, Thourout, Ypres, and other towns.

The most fertile land, in both provinces of Flanders, is that of the low districts which have been reclaimed from the sea by embankments: it is chiefly composed of a muddy deposit mixed with fragments of marine shells and fine sea-sand. These lands are called *polders*, and their great natural fertility causes them to be cultivated with less art and industry than those lands which are much inferior. The usual rotation of crops in the polders consists of—1, Winter barley after a fallow;—2, Beans;—3, Wheat;—4, Flax;—5, Clover;—6, Potatoes. The polder farmer seldom thinks of purchasing manure; and even the ashes made by burning weeds are usually sold, to be sent to the poorer sandy soils, where their effects are more perceptible. In the tillage of the land the Flemings use few and very simple instruments. The common plough for light lands is a small light foot plough, which has no wheels and is drawn by one or two horses. In the stiffer soils the turn-wrest plough is sometimes used, made much smaller and lighter than the heavy Walloon plough. An instrument peculiarly Flemish is the *traineau;* this is a wooden frame of a triangular shape, covered with boards, which is drawn over the ground to smooth the surface and press in the seed. The *mollebaert* is another Flemish instrument for levelling ground. The Hainault scythe and hook are generally used for reaping corn. The most important instrument in Flemish agriculture is the spade, which is used to a much greater extent than in England, and in some instances is the only instrument of tillage. Flax is everywhere a most important crop, for it much exceeds all other crops in value. In most agricultural crops, the Flemish farmers contrive to do with a smaller amount of seed than the English.

In respect to the Industrial Exhibition of 1851, out of 509 intending exhibitors from the nine provinces of Belgium, 138 are from East and West Flanders. The products and manufactures to be exhibited comprise almost every possible variety.

FLANNEL. [Woollen Manufactures.]

FLAX MANUFACTURE. Flax is an annual plant, cultivated from time immemorial for its textile fibres, which are spun into thread and woven into linen cloth. It has a green stem from a foot and a half to two feet high, and a blue flower, which is succeeded by a capsule containing ten flat oblong seeds of a brown colour, from which an oil is expressed, which is extensively used in manufactures and in painting. There are several varieties of flax cultivated. The best seed comes from Riga and from Holland. There is a very fine long variety which is cultivated in the neighbourhood of Courtrai, in Flanders. The most common variety of flax is of a moderate length with a stronger stem. There is a small variety which does not rise above a foot, grows fast, and ripens its seed sooner. Another variety has a perennial root, and shoots out stems to a considerable height.

The soil best adapted to the growth of flax is a deep rich loam in which there is much humus or vegetable mould. It thrives well in the rich alluvial land of Zeeland and the polders. It is also raised with great success in the light sands of Flanders, but much more careful tillage and manuring are required. The land on which flax is sown must be very free from weeds, the weeding of this crop being a very important part of the expense of cultivation. In southern climates flax is sown before winter, because too great heat would destroy it. It is then pulled before the heat of summer. In northern climates the frost, and especially the alternation of frost and thaw in the early part of spring, would cause the flax to perish; it is consequently sown as early in spring as may be, so as to avoid the effect of hard frost. In Flanders the ground is prepared for flax more carefully than in any other country. The seed which is used is generally obtained from Riga, it being found that the flax raised from home-grown seed is inferior after the first year.

When the flax is full grown (and this depends on whether coarse or fine fibres or seeds for oil are the chief commercial object), the pulling begins, which is done carefully by small handfuls at a time. These are laid upon the ground to dry, two and two obliquely across each other. Soon after this, they are collected in larger bundles and placed with the root end on the ground, the bundles being slightly tied near the seed end; the other end is spread out that the air may have access, and the rain may not damage the flax. When sufficiently dry, they are tied more firmly in the middle, and stacked in long narrow stacks on the ground. This is the method adopted by those who defer the steeping till another season. Some carry the flax as soon as it is dry under a shed, and take off the capsules with the seed by *rippling*, which is drawing the flax through an iron comb fixed in a block of wood. The flax is then immediately steeped: but the most experienced flax-steepers defer this operation till the next season. In this case it is put in barns, and the seed is beat out at leisure in winter.

Steeping the flax is a very important process. The object is to separate the bark from the woody part of the stem, by dissolving a glutinous matter which causes it to adhere. The usual mode of steeping is to place the bundles of flax horizontally in shallow pools or ditches of stagnant water, keeping them under water by means of poles or boards with stones or weights laid upon them. The method adopted by the steepers of Courtrai, where steeping flax is a distinct trade, is different. The bundles of flax are placed alternately with the seed end of the one to the root end of the other, the latter projecting a few inches: as many of these are tied together near both ends as form a thick bundle about a foot in diameter, and these are placed in an oblong wooden frame. The frame is sunk in the river Lys, low enough to keep all the flax under water, and is kept there till the steeping is effected. The bundles are now untied, and the flax is spread evenly in rows slightly overlapping each other on a piece of clean smooth grass which has been mown or fed off close. It is occasionally turned over, and is allowed to remain spread out upon the grass till the woody part becomes brittle. It is then taken up, and as soon as it is quite dry it is tied up again in bundles, and carried into the barn.

In the domestic manufactures the flax is broken or scutched at home, when the weather prevents out-door work. The common brake consists of four wooden swords fixed in a frame, and another frame with three swords, which play in the interstices of the first by means of a joint at one end. The flax is taken in the left hand, and placed between the two frames, and the upper frame is pushed down briskly upon it. It breaks the flax in four places, and by moving the left hand, and rapidly repeating the strokes with the right, the whole handful is soon broken. It is then scutched by means of a board set upright in a block of wood so as to stand steady, in which is a horizontal slit about three feet from the ground, the edge of which is thin. The broken flax held in handfuls in the left hand is inserted in this slit, so as to project to the right and a flat wooden sword of a peculiar shape is held in the right hand; with this the flax is repeatedly struck close to the upright board, while the part which lies in the slit is continually changed by a motion of the left hand. This operation beats off all the pieces of the wood which still adhere to the fibre, without breaking it, and after a short time the flax is cleared of it and fit to be heckled. On a larger scale the breaking, scutching, and, and subsequent heckling, are effected by more efficient machines.

Flax is found in every quarter of the globe, and has been cultivated for its fibrous stalk from the very earliest period of which we have any record. England has never grown a sufficient quantity of flax for its own use, although it has been attempted to give encouragement to the cultivation by public rewards or bounties. A considerable quantity of land is now sown with flax seed every year in Somersetshire, Lancashire, and Yorkshire: it is largely grown in Scotland, and still more so in Ireland.

There has perhaps never been a period when the flax culture and manufacture occupied a larger share of public attention than at present. Many circumstances have combined to bring about this state of things. We will briefly glance at the chief aspects which the subject presents.

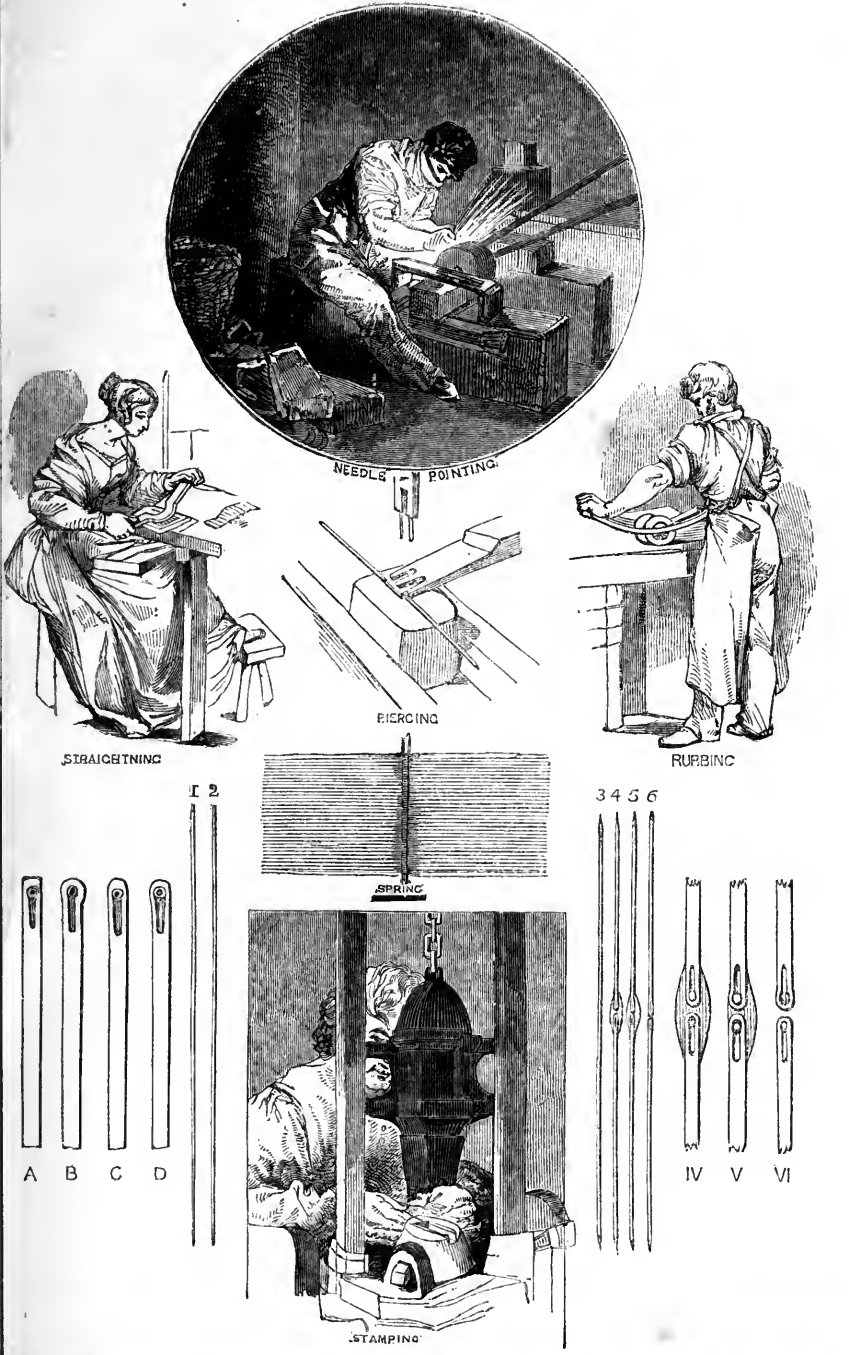
Cotton forms a larger item of our textile manufactures than all other fibrous materials combined: and the United States supply an overwhelming proportion of the cotton which we work up. We imported 775 million lbs. of cotton in 1849, of which four-fifths were brought from the United States. Hence our manufactures are almost wholly at the mercy of any fluctuations of crop which may occur in America; for the market-price depends chiefly in the abundance or scarcity of the United States supply.

If therefore we could increase the quantity of any fibrous material capable of being grown in our own country, and use it as a partial substitute for cotton, it would give our manufactures greater independence of America. Besides this, Great Britain and Ireland would be benefited if a good sale were commanded for home grown flax. Ireland and the Highlands of Scotland since the failure of the potato crops, and England since the repeal of the Corn Laws, have been in a position to seize eagerly on any new culture which promises moderate success; and landowners in all three countries are at the present time encouraging their tenants to direct attention to the flax culture.

Mr. G. R. Porter, in an able paper read at the Edinburgh Meeting of the British Association in 1850, said—'Hitherto we have in this country been greatly dependent upon our foreign importation for supplies of flax. While the law imposed restrictions upon the importation of grain for human food, there existed a kind of impediment in the way of increasing our home growth of articles for any purpose not of equal primary necessity. That impediment is now removed; and there can be no reason given why our fields should not be henceforth used for the production of any article that promises an adequate profit to the farmer.' These words have had considerable effect in urging agriculturists to attend to this matter.

It is admitted that much has yet to be learned before the English and Irish farmers will equal those of Belgium in the flax culture. Great care must be shewn in selecting the seed; and Sir Robert Kane has lately shewn how, by applying the steep-water to purposes of manure, and the woody or stalky refuse to purposes of fuel, greater profit may be realized than heretofore. It is not only the flax fibre which we largely import, but flax-seed for sowing, flax seed for making linseed oil, and flax oil-cake for feeding our cattle. In addition to many minor improvements recently suggested, Mr. Donlan has introduced a mode of pickling or chemically preparing the seed before sowing; which (unless the accounts are greatly exaggerated) seems to be a very important improvement.

But improvements in *culture* are not the only object of attention; improvements in *manufacture* are equally undergoing enquiry. The reader will have observed, in the earlier paragraphs of this article, that whatever the mode of steeping may be, *cold* water is always employed. Now it has occurred to Mr. Schenk that if *hot* water were substituted, the process might be expedited. The method has been tried by the Royal Flax Society of Belfast, who placed the flax in long troughs, filled the troughs with cold water, and heated the water by steam. The experiments tried seem to bear out the assertion that the process is not only more quickly conducted by the new method than by the old, but that more flax fibre can be obtained from a given weight of flax plant.



NIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 22.

While this hot water process has been under examination, Mr. Donlan has introduced a *dry* process, by which the fibre is separated from the stalk without any steeping whatever. The mode of proceeding is not yet made public, as it is not yet patented; but its advocates assert that it is as much superior to the hot water process as that is to the old mode of steeping in cold water. The experiments which are now being carried on will speedily determine the relative merits of all the three systems.

To shew how remarkably this subject is calling forth the energies of different persons, we need only state that the Chevalier Claussen is carrying out improvements in a direction differing from all those hitherto noticed. He takes the flax fibre after it has been prepared to a certain stage, and so modifies its substance as to make it susceptible of being spun by the usual cotton machinery. It is known that flax or linen goods have a *coldness* which other textile fabrics have not. M. Claussen has tried to give to flax, instead of this coldness, the *warmth* of woollens, the *softness* of cottons, and the *glossiness* of silks; and hence he has prepared four kinds, which he calls *flax fibre*, *flax cotton*, *flax wool*, and *flax silk*. The flax fibre is fit to be spun into beautiful linen thread or yarn; the flax cotton is intended to be combined with cotton, and to be spun with it into a mixed yarn; and so in like manner the flax wool with wool, and the flax silk with silk. The processes comprise, among others, the bursting or opening of the cylindrical tubes which form the minute fibres of flax, by exposing them to carbonic acid gas.

Application has been made to the Crown for a trading charter to a Flax Company; by the terms of which, the company engage to give for Irish flax a price better than can now be obtained under any other arrangement; which flax is to be prepared up to a certain stage by Donlan's process, ready to be carried forward to its ultimate results by Claussen's process. This charter has not yet been granted; but the application is receiving the favourable consideration of the government.

The reader will hence see that flax culture and manufacture are now in a highly interesting phase of their history. In Ireland especially the subject is being favourably taken up. Besides the culture, the spinning is there on the increase. There were 41 flax mills in Ireland in 1841, and 73 in 1850.

Further details will be found under LINEN MANUFACTURES. The flax imported in 1850 amounted to 97,982 cwts., of which more than two-thirds were from Russia. The flax seed imported in the same year amounted to 132,343 quarters.

FLEXIBILITY; FLEXURE. Flexibility is a property of bodies by which they yield transversely, on the application of some power: this property is distinct from elasticity, as it does not necessarily follow that the bodies acted on recover their original figures when the power is removed. [MATERIALS, STRENGTH OF; ROPES.]

In intimate connection with this subject is the flexure of columns, which has undergone much investigation since the prevalent use of iron for columns. The fibres of wooden pillars are generally of serpentine forms, and they adhere together laterally, with comparatively a small force: hence, when such a pillar is compressed longitudinally by a weight, the latter acts obliquely on the fibres; and thus a pillar of wood becomes bent sooner than one formed of the other materials.

The valuable series of experiments carried on by Mr. Hodgkinson, and of which a full account is given in the Philosophical Transactions for 1840, have thrown much light on the flexure and strength of columns. In these experiments the columns, which were placed in vertical positions, were of various lengths, from a few inches to seven feet six inches, and all were subjected to pressures acting vertically; some were cylindrical and others were rectangular prisms, and the former were either solid or hollow: in some cases the ends of the columns were planes perpendicular to the lengths, in order that the pressure might be diffused uniformly over those ends; and, in the others, the ends were hemispherical, in order that the pressure might be transmitted almost wholly in the direction of the axis. From his experiments Mr. Hodgkinson has obtained the following conclusions:—All the pillars whose lengths exceeded four times their diameters became bent before they broke; and, when the pillars were of uniform dimensions, both ends being plane or both hemispherical, the greatest flexure was near the middle of the length, and the fracture was at that place; but when one end was plane and the other hemispherical, the fracture was at a distance from the rounded end equal to about one-third of the whole length. Pillars of cast-iron with plane ends, and having their lengths about thirty times their diameters, were broken by weights equal to one-third or one-fourth of those which would crush them if they had been made short enough to be crushed without bending. In some of the experiments the cast-iron columns were formed with discs at their ends, the diameters of the discs being about twice as great as those of the columns; and it was found that these sustained a greater pressure before breaking than the simple columns. When the columns were thicker in the middle than at either end, their strength was thereby increased, if compared with cylindrical columns, by about one-eighth. In the prismatic pillars, the flexure always took place in the direction of a diagonal.

In all such buildings as the Crystal Palace, where the entire weight is supported on iron columns, the due appreciation of these various properties of columns is of the highest degree of importance.

FLINT. The true native place of this well-known mineral is the upper bed of the chalk formation, where it occurs in regular beds. Gravel consists principally of flints which have been rounded by attrition, and, by exposure to air and moisture, have acquired a yellowish red colour.

Flint is usually of a gray colour. It is rather harder than quartz; thin fragments of the black varieties are translucent; it is fragile, and, being rarely laminated, it is broken with equal facility in almost every direction. Specific gravity, 2.594. It is infusible, but becomes opaque and white by the action of heat. Flint is almost wholly pure silica.

The true origin of flint—as it occurs in the chalk of Europe especially—has been, and still is, the subject of much discussion among microscopists and geologists. Mr. Bowerbank believes generally in the origin of flints (and some allied minerals) from sponges. Ehrenberg, finding in some flints abundance of infusorial animalculæ, suggests the origin of flint from aggregations of these silicious-shielded microzoaria.

Flint is an important article in many departments of manufactures. In the making of glass and porcelain it is almost indispensable; it is the ingredient which gives hardness and strength to those substances. Flint glass, called by the French *crystal*, owes its English name to the large proportion of flint which it always contains.

Since percussion caps have been largely used in the army, gun-flints have been to the same extent abandoned; but they used in former years to be an object of some importance. The best chalk-flints were selected: those which occur in nodules from 2 lbs. to 20 lbs. each. Hammers of various shapes were employed in the manufacture. The workman began by holding a flint on his left thigh, and breaking it with a hammer into several broad flattish pieces. He next held one of the pieces in his left hand, and chipped off the white envelope by a pointed hammer. By means of other hammers and a peculiar form of chisel he brought the pieces to the requisite size and shape for gun-flints. The gun-flint makers prided themselves on keeping their modes of proceeding secret, at least in France and Germany.

FLINTSHIRE. In this Welsh county, coal-measures occupy the coast of the æstuary of the Dee, and the coal-field, which has several seams of various thickness, extends across the county. Many pits are worked. Extensive lead mines are worked in the limestone, especially in the neighbourhood of Holywell. Copper, iron, zinc, and calamine are also found. At the town of *Flint* the neighbouring lead and coal mines, and the works for smelting the lead, give employment to a great number of persons, and furnish the principal articles for export. *Holywell* was formerly an inconsiderable village, but the minerals of the neighbouring country, and the manufactures connected with them, have rendered it a flourishing town. The mines supply lead, copper, calamine, and other ores, and there are smelting furnaces, copper works, brass works, wire works, &c. Steam power is used as well as the stream which issues from the well of St. Winifrede, from which the town derives its name.

FLINTY-SLATE, or *Silicious Schistus*, is a substance which is found of various colours, gray, blueish gray, and red; its structure is rather slaty; it contains about 75 per cent. of silica, the remainder being lime, magnesia, and oxide of iron. It is employed, when polished, for trying gold by a comparison of colours, and has thence obtained the name of *Touchstone*.

FLOOR-CLOTH MANUFACTURE. This useful production is made partly of hemp and partly of flax, the former being the cheaper of the two, but the latter better fitted to retain the oil and paint on the surface. As a means of avoiding the necessity for seams or joinings in the cloth, looms are constructed expressly for the weaving of the canvas of the greatest width likely to be required. As brought to the floor-cloth factories, the pieces of canvas have generally one of these scales of dimensions: a hundred yards long by six wide, a hundred and eight yards by seven, a hundred and thirteen yards by eight. The flax and hemp are spun, and the canvas woven, almost entirely in Scotland, chiefly at Dundee; and the degree of fineness is generally such as to present about 16 threads to the inch.

The canvas is cut into pieces varying from sixty to a hundred feet long: each of these pieces is stretched over a frame in a vertical position; and in most of the factories there is a large number of such frames, some a hundred feet long by eighteen or twenty high, others sixty feet long by twenty-four high. A wash of melted size is applied by means of a brush to each surface; and, while this is yet wet, the surface is well rubbed with a flat piece of pumice-stone, whereby the little irregularities of the canvas are worn down, and a foundation is laid for the oil and colour afterwards to be applied. The paint employed consists of the same mineral colours as those used in house-painting, and, like them, mixed with linseed oil; but it is much stiffer or thicker in consistence, and has very little turpentine added to it. The canvas receives many coatings on the back as well as the front, and is well dried and smoothed at intervals.

The printing of floor-cloth is conducted much on the same principle as that of paper-hangings for rooms, and that of 'colour-printing,' viz., the successive application of two or more blocks or engraved surfaces, each one giving a different part of the device from the others, and being supplied with paint of a different colour. As at present conducted, the pattern is engraved or cut upon blocks of wood, formed of pear-tree on one side and deal on the other: they are about fifteen inches square; and each block is to give the portion of the device which is to be in one particular colour.

The blocks (which we will suppose to be four for one pattern, red, yellow, blue, and green) being ready, and the prepared canvas spread out on a flat table, the printing commences. The paint (say red) is applied with a brush to the surface of a pad or cushion formed of flannel covered with floor-cloth; the block, held by a handle at the back, is placed face downwards on this cushion, and the layer of paint thus obtained is transferred to the surface of the canvas by pressing the block smartly down on the latter. A second impression is made in a similar way by the side of and close to the first; and so on throughout the length and breadth of the canvas; each impression being about fifteen inches square. The proper junction, or 'register,' of the successive impressions is aided by pins at the corners of the blocks. When the whole surface is thus printed with one colour, all the other three are similarly applied in succession. Such would likewise be the case if the number of colours was more than four: but the greater the number the greater would be the care necessary in adjusting the numerous partial impressions so as to insure a proper arrangement of the whole.

There will be some splendid specimens of floor-cloth at the approaching Exhibition; some made on the usual commercial principles, and some as curiosities.

FLORENCE. This beautiful city is more distinguished in fine arts than in industrial arts. In the province of Tuscany to which it belongs, the valleys produce corn, wine, oil, silk, and abundance of fruit; and the mountains are adorned with chestnut trees, and timber trees. The chief manufacture is straw plat. The other manufactures are pottery and china-ware, cloth, paper, leather, &c., mostly for home consumption.

A few details bearing indirectly on the industry of Florence, will be found under Leghorn and Tuscany.

FLO'RIDA. The productive and commercial features of Florida will be briefly noticed under United States.

FLOTSAM, or FLOATSAM, in relation to the laws of shipping, are barbarous terms for such portion of the wreck of a ship and the cargo as continues floating on the surface of the water. *Jetsam* is goods which are cast into the sea, and there sink and remain under water. *Ligan* is goods sunk in the sea, but tied to a cork or buoy, in order that they may be found again. Flotsam, jetsam, and ligan belong to the king, or his grantee, if no owner appears to claim within a year after they are taken possession of by the persons otherwise entitled. They are accounted so far distinct from legal wreck, that by the king's grant of wreck, floatsam, jetsam, and ligan will not pass. Wreck is frequently granted by the king to lords of manors, as a royal franchise; but, if the king's goods are wrecked, he can claim them at any time, even after a year and a day.

FLOUR; FLOUR DRESSING. When corn is ground to the state of a powder, it becomes *meal;* and the particular kind of meal which is produced from wheat constitutes *flour.* The term flour is sometimes applied to other kinds of meal, but not usually.

The mode in which wheat is ground into flour by the crushing action of two circular stones is explained under Windmill; but we may here briefly speak of the mode of *dressing* flour by a smaller machine. Nearly all the flour dressing machines used in farm houses and for domestic purposes, comprise either a revolving fan or a perforated cylinder; a handle protrudes through the machine; and ground corn being placed inside, the centrifugal action occasioned by the rotation separates the flour from the husk or bran.

In the Board of Trade returns, wheat flour is converted from cwts. into qrs. at the rate of 392 lbs. per qr. In most of those returns the wheat and wheat flour are entered under one heading, so that we cannot separate them. [Corn Trade.]

ring at one end on a rope may, by being kept in an oblique position, in like manner be *sheered* across the river.

On broad rivers, and when objects of great bulk and weight, as horses, carriages, or artillery, are to be conveyed across, two boats or barges placed in parallel positions, and carrying a platform extending between their exterior gunwales, are employed. Each vessel is provided with a mast, which may be from 20 to 30 feet in height.

In military manœuvres, flying bridges will continue to be frequently useful; but for general inland purposes steam-bridges are now coming into use over broad rivers.

FLYING MACHINES. All that need be said in this work on these hitherto futile contrivances, will be found under BALLOON.

FOILS. Very thin leaves of metal are often called by this name; they are placed under artificial gems to heighten the brilliancy. They are made of tin, copper, tinned copper, or silvered copper. They are left white for imitation diamonds, but are coloured for imitation rubies, sapphires, &c. The coloured foils are prepared by coating the white foil with coloured varnish. The best white foil is made by coating a plate of copper with a layer of silver, and then rolling it into sheets in the flatting mill. The principal colours used by artists are employed, mixed with mastic, spirit, and drying oil, to form the coloured varnishes.

FONT. The form of the font in churches is usually hexagonal, similar to the form of the baptistery, in which fonts were originally placed. Fonts also occur both of a circular and a square form. They are usually shaped like a cup, with a solid stem, or supported on columns; the top is hollowed out for the water, and the sides and stem are often highly enriched with ornaments, sculptured figures, and with colour and gilding. In many instances a flight of steps forms a base, and even the sides of these steps are carved with pannels, having quatrefoils and rosettes sunk within them. It was usual to cover the basin of the font with a wooden lid, and there are some of these remaining of a pyramidal or spire-like form, richly carved and designed, with a profusion of shafts, buttresses, and tracery piled up to the apex.

Among the fonts especially worthy of note may be mentioned those of Porchester church, which is like the circular stone mouth of the well in the atrium of a Roman house; of Lincoln cathedral, which is square, on five columns, one being in the centre: of Lowestoff in Suffolk, and Loddor in Norfolk, both remarkable for their richness of decoration; of Winchester cathedral, very curious and ancient; and of East Dereham in Norfolk.

FOOD. All organized bodies are nourished by the introduction into their internal structures of materials from without, which form the numerous kinds of *food* so familiar to us. Although man derives his food from both the vegetable and animal kingdoms, it is found that the animals which are consumed by man derive their nourishment from the vegetable kingdom alone, so that plants are the true source of all the food both of man and the lower animals. The principal constituents of the human body, as well as all other animal bodies, are the organic elements, carbon, hydrogen, oxygen, and nitrogen; and it is the waste of these substances which is constantly going on that it is the object of food to supply. Plants, however, do not supply the animal with carbon, hydrogen, oxygen, and nitrogen, in a simple form, but as secretions of the vegetable tissues known to chemists under the names of gluten, fibrin, albumen, casein, &c. The plant itself does not derive its food from the organic elements in a pure form, but combined with each other: thus, carbonic acid gas, consisting of carbon and oxygen; water, composed of oxygen and hydrogen; and ammonia, of hydrogen and nitrogen, are the great sources of vegetable nutrition, and consequently of the various secretions used as the food of man and animals. Not only do these secretions serve to build up the fabric of the human body, and to supply the daily waste of tissue which is going on, but they also supply materials for keeping up animal heat within the system.

The reader will find a familiar exposition of this subject, and of the relative value of albumen, fibrin, casein, starch, sugar, fat, oils, acids, spices, condiments, &c., in Dr. Lankester's 'Food of Man.'

FORCE, in mechanical and scientific matters, is a term employed to denote the unknown cause of any mechanical effect. Thus the cause of motion and the cause of pressure are both *forces:* again, difference of effects must be attributed to difference in the producing causes: thus, greater or less velocity, and greater or less pressure, are both attributed to differences in the causes of velocity or pressure. But, on the other hand, effects which are the same in one point of view may differ in another; thus, bodies of different weights, let fall from the same heights above the ground, will strike the ground with the same velocities, but with different degrees of effect upon the substance which they strike.

When force, in the sense of pressure, is considered as the cause of motion, we must take into account both the element *time*, and also the *quantity of matter* which is moved. The connection of pressure, velocity created by pressure, and time which pressure takes to create velocity, as deduced from experiment, are contained in the following results :

1. The same pressure continually acting upon a given mass for different times produces velocities which are proportional to the times, and augments velocity by equal portions in equal times.

2. The same pressure applied to different masses of matter (that is to different weights of matter), during the same time, produces velocities which are inversely proportional to those masses.

3. The velocities of falling bodies is accelerated by 32.19 feet in every second: and in that proportion for all other times.

Very exact calculations and experiments on all these points are of great importance to machinists and engineers, who have to provide force adequate to the kind and quantity of the work to be done.

FORESTS; FOREST-SCIENCE. A forest is a large tract of ground overgrown with trees and underwood. As civilization and population advance, forests lessen in every country. It has been notably so in Great Britain. Ireland has few forests. In Norway the mountains are covered with wood; birch, maple, pine, and fir, forming immense forests. The fir sometimes attaining a height of 160 feet, is in great estimation for masts and building timber. In the regions of moderate elevation are aspens. The good lands have some fine forests of oaks. The forests of Sweden are similar to those of Norway. In Denmark the existing forests cover but a small area. The timber of Holland consists of beech, fir, poplar, and ash; willow grows along the canals, and the coppices are of maple, ash, hornbeam, birch, and beech, with a slight portion of oak-bushes. In Germany the forests are estimated to cover nearly one-third of the whole surface; they comprise most of the usual varieties of timber-trees. Switzerland is abundantly wooded, particularly with the cone-bearing trees. France has many fine forests, though hardly sufficient for the consumption of a country where wood is the chief combustible. Italy, Spain, and Portugal, are all rather deficient in forests. European Turkey has fine forests of oak, elm, pine, plum, apple, pear, cherry, apricot, maple, sycamore, walnut, chestnut, and beech trees.

Of all the countries of Europe, Russia is the most abundantly provided with timber; and her forests would be an almost inexhaustible source of wealth, if it were possible for the government effectually to protect them from destruction. In 1802 regulations for the preservation of the forests were established; but such is their extent and that of the country, that it is next to impossible wholly to prevent the waste of wood. There are 200,000,000 of acres exclusively covered with pine and other cone-bearing trees, without counting oaks, maples, beech, poplar, hornbeam, and birch. Poland is, for its size, nearly as well supplied with forests as Russia.

In Asia Minor, Mount Taurus is covered with forests of cypress, juniper, and savines. Oaks and fir abound in the forests along the Black Sea. Trees of all these kinds occur in the Caucasus. Persia has few forests, except amongst the mountains near the Caspian. Arabia has none. Central Asia is too little known to yield us much information respecting its forests. Siberia has some vast forests of the harder kinds of trees. China, Japan, and Corea, all possess immense forests in their more mountainous districts. India, both within and beyond the Ganges, is rich in wood. There are whole forests of the bamboo, which sometimes attain a height of 60 feet. Cocoa-nut and palms of all kinds cover large tracts. Here are woods of oak, fir, cypress, and poplar; there of mangoes, banyan-trees, uvarias, robinias, sandal-wood, &c. Nearly all the eastern islands seem to be tolerably rich in forests, Australia perhaps excepted.

In Africa there are some spots in which vegetation is rich beyond description. Thus Senegambia, Guinea, and Congo, are covered with forests, which consist of the baobab, of palms, robinias, sycamores, sandal-wood, tamarinds, bananas, oranges, limes, and pomegranates; there are also cocoa-nut trees in great abundance. The tamarind and cedar, which grow in the greatest profusion on the borders of the Congo, furnish timber of the finest quality. Abyssinia has abundant woods. The Atlas Mountains are covered with magnificent forests, producing a variety of oaks, the mastic tree, the cypress, &c. The kingdom of Bornou has immense forests, and the date-palm abounds there.

America is, of all parts of the world, the most thickly covered with wood. Canada contains immense forests, as do most of the British North American territories. The United States are abundantly wooded, the cleared land even in some of the Atlantic states being inconsiderable when compared with that still covered with the primitive forests. Oregon, Mexico, and Texas, have all splendid forests. The West India islands are for the most part only moderately wooded. In South America the Caracas possesses inexhaustible forests; and so indeed do most of the South American states. The forest region of the river Amazon and of the upper Orinoco, according to Humboldt, covers an area of about 719,000 square miles.

There are no laws respecting the forests of England among the laws attributed to the Conqueror; but after the Norman Conquest the royal forests were guarded with much greater strictness. In later times these forests gradually sunk in importance; and our government department of 'Woods and Forests' shews how little benefit the royal forests produce to the state generally.

In Germany a distinct branch of education has become established, called 'Forest Science.' In the Forest Academies are taught botany generally, including vegetable physiology, mineralogy, zoology, chemistry, surveying, mensuration, mechanics, the methods of resisting the encroachments of sands, draining and embanking, together with the care and chase of game; and also the laws and regulations of forest administration. In Prussia and other German states, in France, and in Russia, similar studies are carried on. The wood from forests is applied to the various purposes of house-building, ship-building, mill and wheel work, turnery, ornaments, fuel, &c.; and the study of its fitness for these purposes forms a part of forest science.

In England, where no such schools exist, knowledge has accumulated from out-door experience, rather than school education. In English timber plantations, as crooked pieces of large oaks are of value in ship-building, the side branches are not taken off higher than fifteen or twenty feet from the ground, and where trees have plenty of room, as in hedge-rows or parks, this may be judicious, but in close plantations it is of advantage to have a long stem without branches. In France and Germany the branches are always cut off to the height of 30 or 40 feet.

FORFARSHIRE. The Grampian Hills, in this Scottish county, are of granite, having frequently topazes and rock crystal in its cavities and fissures. There are also limestone slate, porphyry, and lead ore. In the Strathmore district there is a shell-marl, which is procured in large quantities from beneath beds of peat-moss at the bottom of several ancient lochs which have been drained chiefly for this purpose; it is dragged up by means of iron scoops, worked from boats, and is used for manure. Iron and pipe-clay occur in this district. The maritime district contains beds of sandstone and extensive quarries of limestone. Fragments of granite from the Grampians lie strewed about the lower ground. Coal of an inferior quality has been traced a little to the west of Aberbrothwick. The poor, who cannot obtain coal without difficulty, procure for fuel peat, brushwood, broom, and furze.

It may in general be stated that almost every useful improvement has been adopted in the modes and implements of agriculture in this county. Inclosures are made chiefly by stone dykes in the highlands, and by quick thorn hedges in the plains of Strathmore and towards the sea. The chief crops are oats, barley, and wheat. Much of the oat crop is consumed by horses and exported from the county. Oatmeal porridge, eaten with milk or beer, forms the breakfast and supper of the labouring classes, among whom oat cakes are still much used as bread. Considerable quantities of wheat are annually exported to London and other ports, and some American, Danzig, and other foreign wheats are imported to mix with that produced in the county. Barley is much used in the county for broth, porridge, and cakes. There are about 40,000 acres of natural pasture. The grazing and stall feeding of cattle are prosecuted to a much greater extent than the rearing, large numbers being brought into the county to be fed and prepared for the butcher.

The deep-sea fishing off the eastern coast is very productive, and large quantities of salmon and smaller fish are taken in the Frith of Tay, and at the mouths of several streams from thence to the North Esk. Cod, ling, herring, haddocks, turbots, sole, skate, sprats, smelts, lobsters, crabs, mussels, and fresh water fish are all abundant. The chief manufactures of the county are represented by those of its busiest town. [DUNDEE.]

FORK. The manufacture of this useful implement is briefly noticed under CUTLERY.

FOSSIL COPAL occurs in irregular pieces in clayey soils. Its colour is yellowish or dull brown; nearly opaque; specific gravity 1.046. When heated it yields an aromatic odour, and melts into a limpid fluid.

FOSSILS. The time may arrive when fossils or organic remains will be largely employed in the arts. At present they are chiefly objects of scientific geological investigation, and as such they do not come within the range of this work.

FOUNDATION, the lower part or courses of the basement walls or piers of a building. In foundations it is of the utmost importance to prevent the settlement of the walls in an unequal manner; this can only be done by making the earth on which the foundation is set equally solid throughout its whole extent. Concrete composed of gravel or shingle and hot lime is often used to form a solid bearing for the footings of foundations. The greatest care and judgment are required in making foundations for heavy superstructures, for if the piles should be of a bad quality, and the ground in which they are driven of a very loose and boggy nature, the same catastrophe which occurred at the New Custom House in London may be expected to take place. In this building it was found necessary to remove the piles and loose earth, and form a solid concrete foundation.

FOUNDING. This important mechanical art embraces all the operations of reducing ores, and of smelting and casting metals. There are various branches of the art, and some difference prevails in the minor details of the processes, as in iron, brass, and bronze founding, in casting guns and cannon, types for printing, and bell founding. The art has been known and practised from the earliest ages.

The preparation of the principal ores is described under the names of their metals, such as COPPER, IRON, &c. The furnaces are described under FURNACE.

Founding is practised either in casting any quantity of metal in the solid, or with a core (by means of which the metal is preserved of a determined thickness or substance), or in plain casting. Before any article can be cast in metal it is necessary that a *model* of it be prepared. The models must be made of various substances; clay or wax, or sand with clay, are those usually employed, but they may also be made of wood, stone, or any other material. Upon those models *moulds* must be made. These are commonly composed of plaster of Paris, mixed with brick-dust, sometimes sand, or sand with a mixture of cow-hair. For moulds for iron and brass work a yellowish sharp sand is preferred, which is prepared by mixing it with water and then rolling it on a flat board till it is well kneaded and fit for use. If the article is cylindrical, or of a form that admits of it, it is moulded and cast in two pieces; these two parts are then carefully joined together, and the edges or seams carefully cleaned. For the smaller class of works, instead of running the metal at once from a large furnace, earthen crucibles are used, into which the metal is thrown in small pieces: the crucible is placed in a strong heat in a close stove, and as the metal is melted and sinks more is added till the vessel is full. It is then lifted out by means of iron instruments adapted to the purpose, and the metal is poured from it into the moulds, in which channels or ducts for receiving it have been previously made.

In noticing the different ways of casting, mention has been made of one in which a core is used. The *core*, as its name denotes, is a part or portion situated within the body of the cast; and its purpose is to form a centre to the work by which the thickness or substance of the metal may be regulated. In coring, the mould is first made complete; into this, clay or wax, or any other fit substance or material, is then squeezed or pressed in a layer of uniform thickness; in large works it is usually from half an inch to an inch thick. This layer represents the metal. The mould, if in parts, is then put together, the above-mentioned layer being left within it, and into the open space in the centre a composition (usually of plaster of Paris with other substances mixed with it) is introduced, and made to adhere to the clay or wax, or rather is filled up to it. This is the core, and it is often made to occupy the whole interior of the mould. When this is *set*, or dry, the mould is taken to pieces, and the material which has been made to represent the metal removed. The mould is then again put carefully together ronnd its core or nucleus, the two portions being secured from contact by stops and keys properly arranged for that purpose. The mould and core are dried to dissipate moisture; and large moulds are strengthened with iron hoops. Channels or ducts are made for the entrance of the melted metal; and others are also made for allowing the air to escape as the melted metal enters the mould; these are called vents. With respect to placing the mould, it is only important to secure a sufficient inclination of plane from the mouth of the furnace to the mould that the metal may run easily and uninterruptedly, and not have time to grow cool and therefore sluggish. The usual method in bronze works of large size is to bury the mould in a pit a little below the level of the furnace, and by ramming sand firmly round it to ensure its not being affected by any sudden or violent shock, or by the weight of the metal running into it. When everything is ready and the metal found to be in a state fit for running, the orifice or mouth of the furnace (which is usually plugged with clay and sand) is opened, when the metal descends, and in a few minutes the mould is filled. The metal is allowed to run till it overflows the mouths of the channels into the mould. The work is then left to cool, after which the mould is scraped or knocked off and the cast undergoes the necessary processes (such as cleaning, chasing, &c.) to render it fit for the purpose designed.

Large bells and *statues* are cast in the way first described. *Brass ordnance* is always cast solid. The model is made round a nucleus of wood called a spindle, and the mould of loam and sand made over it. When this is perfectly dry, the model and spindle within are removed, and the mould is well dried or baked. When ready for casting, it is placed upright in the pit, and the metal is allowed to run into it till filled. What is called a dead head is left at the upper and smaller or mouth end of the gun, which presses the metal down, and prevents its becoming porous as it settles and cools. After a few days the mould is knocked off, and the gun is ready for finishing. The dead head is turned off, and the boring, which is an operation requiring great care is effected. [BORING.]

After the founding, the metal cast is often finished by chasing, burnishing, lacquering, plating, or gilding.

One of the largest cylinders, cast and bored in iron, is that employed at the Mostyn colliery in Flintshire. It was made at the Haigh Foundry at Wigan in 1848. It is 17 feet long, by 8 feet 4 inches in diameter; it weighs 22 tons; and the quantity of metal brought to a liquid state for the purpose of casting was 30 tons.

A silver statue was cast at Paris in 1850. In the preceding year M. Pradier exhibited at the Luxembourg a bronze statue of Sappho, which was much admired for its beauty; and a silver copy of this statue was prepared in 1850, as a prize for a sort of Art Union lottery. The founding was entrusted to M. Simonet, who has produced many beautiful specimens in this department of Art. The weight of silver used was about four thousand ounces.

The largest cast statue of recent times is the allegorical figure of *Bavaria*, placed in front of the Rühmeshalle on the Theresien meadow near Munich. The figure is 63 feet high, and stands on a granite base 30 feet high; so that the wreath held in the uplifted hand of the figure is nearly 100 feet from the ground. A winding staircase leads entirely up the interior of the statue. It is said that no fewer than 26 musicians were placed within the head of the statue, on the occasion of the inauguration. The length of the fore-finger, 38 inches, will give an idea of the size of the statue. The statue was modelled by the great sculptor Schwanthaler, who hastened his death by his intense application to it. The founding or casting was entrusted to Stiglmayer; but as he also died, the work was carried out to a successful completion by his pupil Ferdinand Miller. The statue was cast in many pieces, one of which required 380 cwt. of molten bronze!

FOUNTAIN. A fountain is a jet or jets of water, flowing either naturally out of the earth, or from structures formed by art. Artificial fountains consist of water flowing from statues, vases, or architectural buildings combined with sculptured figures and other ornamental decorations. At Pompeii not only the streets but even the private houses were decorated with fountains. At Rome, the proper distribution of the rivers which flowed through her aqueducts was a matter of great importance, intrusted to the care of an officer of very high rank. The aqueducts were each charged with a certain number of pipes of supply; and no new pipe could be inserted without a special application to the emperor. Those whose means of interest were insufficient to obtain a private pipe, were obliged to fetch water from the public fountains.

Some of the cities of Italy and the East are adorned with fountains, which are no less agreeable to the eye than useful to the inhabitants. Many of the fountains of Rome are highly decorated, of great magnitude, and very varied in their mode of ejecting the waters with which they are supplied from the existing aqueducts.

The city of Paris is well supplied with fountains, many of which are elegantly designed. The fountains of Versailles and St. Cloud in France, and the fountains at Wilhelmshöhe near Cassel, are the largest in Europe. London has no fountains worthy of notice except the two large ones in Trafalgar Square, which are supplied from a very deep artesian well; and these have been severely criticised as works of art.

The great fountain, planned by Mr. Paxton for the Duke of Devonshire at Chatsworth, is in all probability the loftiest in the world. It presents one single jet that rises to a perpendicular height of 270 feet. The pressure is derived from a previous descent of water from a height of 380 feet. A reservoir has been formed at that height, in some hills which bound the eastern side of the park; and more than half a mile of piping is employed to convey the water from the reservoir to the fountain.

FOURCROY, ANTOINE-FRANCOIS DE. This eminent French chemist deserves our grateful notice for the aid which his discoveries afforded to many practical arts. He was born in 1755, and died in 1809, after having filled many important offices. Among his other discoveries, Fourcroy shewed that the salts of magnesia and ammonia have the property of uniting together and forming double salts. His dissertation on the sulphate of mercury contains some good observations. The same remark applies to his paper on the action of ammonia on the sulphate, nitrate, and muriate of mercury; and he first described the double salts which are formed. We may mention the process of Fourcroy and Vauquelin for obtaining pure barytes, by exposing nitrate of barytes to a red heat, as a good one. They discovered the existence of phosphate of magnesia in the bones, of phosphorus in the brain, and in the milts of fishes, and a considerable quantity of saccharine matter in the bulb of the common onion, which, by undergoing a kind of spontaneous fermentation, was converted into manna.

FRAMEWORK KNITTERS. [HOSIERY MANUFACTURE.]

FRANCE. This important country has a varied though perhaps not very rich supply of mineral wealth. Granite, sienite, porphyry, variolites, and serpentine are quarried in some of the departments; lava in others; marble, limestone, and slate in others; while various parts of France yield lithographic stone, porcelain clay, brick clay, pipe clay, gypsum, chalk, millstones, and sandstone. Of metals, the chief ores are those of iron, manganese, antimony, lead, and copper. Minute traces of gold and silver are met with. Thirty-three of the departments contain excellent coal. Anthracite, asphaltum, bitumen, petroleum, alum, rock-salt, and lime, are also obtained. There are about 500 coal-pits in France, from which four to five million tons of coal are annually extracted.

France has always been considered one of the most agricultural countries in Europe, chiefly on account of the numerous publications relating to this subject; but in most parts of the country, the progress towards a general adoption of improved methods of cultivation is very slow. The northern part of France, on the confines of Belgium, and the part in the immediate neighbourhood of Paris, are the best cultivated. In most other parts, except where maize is cultivated, the old system of two or three crops of corn and a fallow is generally adopted.

The arable land of France is now estimated at 23,000,000 hectares, which (taking the hectare =2.47 acres nearly) are about equal to 56,810,000 acres English measure. In recent years there have been about 14,000,000 hectares under corn culture, yielding 180,000,000 hectolitres (a hectolitre = about 22 gallons, or 2¾ bushels) of wheat, oats, rye, meslim, and maize; the wheat being ⅔ and oats ¼. The corn culture has not increased much during the present century; but the cultivation of the vine, of the artificial grasses, of pulse, and, above all, of potatoes, has much increased. Beet-root is extensively grown for the manufacture of sugar. The esculent roots and table vegetables are common. Flax and hemp are cultivated in various parts of the country, and to a considerable extent; hops, tobacco, and madder, in a small degree; and colza and rape, for oil, are grown in the north.

The vine is one of the most important objects of cultivation in France. The amount of land occupied by this culture is about 5,000,000 English acres. The average yearly produce is nearly 1,000,000,000 of English gallons, of which about one-sixth is converted into brandy. The annual produce of the vineyards is estimated at about 30,000,000*l.* sterling, of which at least nine-tenths are consumed in France. Of fruits and of timber-trees France has a very fair supply.

The coasts abound in fish of various kinds, the taking of which occupies a number of hands: the oyster, the herring, the mackerel, and especially the sardine or pilchard, are the chief objects of attention to the fishermen of the coasts of the Channel and the Atlantic: the tunny and the anchovy to the fishermen of the Mediterranean.

Every branch of industry in France has undergone vast improvement since the peace of 1815. The energies of the nation being turned from war to domestic employments, speedily repaired the evils which France had suffered from so long a struggle. The woollen manufacture has increased materially: the increased quantity of wool used is partly furnished by the increased number of sheep bred, partly by the importation of foreign wool. The quality of the home-grown wool has been improved by the introduction of foreign breeds, and the Cashmere goat has been naturalized on the slopes of the Pyrenees. The cotton manufacture has increased since 1812 in a greater proportion than that of wool, and the process of manufacture and the fineness and excellence of the fabrics have undergone great improvements. The north and east of France are the chief seats of this manufacture. Printed calicoes are made at Rouen and Bauvais; but especially at Colmar, Mühlhausen, and other places in the department of Haut Rhin, the printed cottons of which are much approved in the German markets for the vividness of their colours (especially the Turkey red), and their other qualities. The silk manufacture is carried on chiefly in the south. The brilliancy of the French silks has been increased by the substitution of Prussian-blue for indigo as a dye.

A part of the raw silk required for these various fabrics is grown in France. Linens, damasks, sail-cloth, and lace, are made to some considerable extent.

The working of the metals has much increased, especially iron. The quality and appearance of the steel and wrought-iron goods have much improved; yet the quality of the French iron is inferior, and it maintains its ground against the Russian and Swedish iron only by means of protecting duties. In the manufacture of clocks and watches France is almost equal to Switzerland; and for chronometers and instruments for scientific purposes it is not surpassed by any country. The inventions of the French chemists and the improvement of chemical science have done much in producing with economy and expedition the many chemical agents employed in the various branches of manufacture, and particularly dyeing. The commoner sort of French earthenware has much improved in beauty of design. Fine porcelain is made at Sèvres, Paris, and Limoges. The cut-glass is nearly equal to that of England in beauty of workmanship, and it is perhaps superior in elegance of form.

The means of internal communication in France are much inferior to those of Great Britain. The roads are divisible into those maintained by the central government, and designated *Routes Royales* and those which are kept up at the cost of the several departments to which they belong, and designated *Routes Départementales.* Besides these there are *Chemins Vicinaux*, or bye-roads. The *Routes Royales* extend about 22,000 miles. Posting and the mail service along these roads are under the control of the government. Diligences run on all these roads. The departmental roads are rather greater in length than the royal, but are mostly in bad condition. The inland water communication is carried on by means of the great rivers and by the canals which have been formed. Many of the rivers have been improved for navigation; and the artificial canals are rather numerous. The canals present a united length of about 1,600 miles. The railway system of communication has not made considerable progress in France; but lines have been laid out along most of the great travelling routes in the kingdom.

The following important statistics of French commerce, shipping, and manufactures have recently appeared—mostly referring to the year 1850. There exist in France 5,607 manufactories of various denominations in which steam machinery is employed. This machinery is worked by means of boilers, the number of which is 9,288, and of which 8,776 were made in French establishments. These boilers represent a force of 65,120 horses' power, calculating the horse-power as 75 kilogrammes (180 lb.) raised one metre (1 yard) per second; they represent the force that would be produced by 195,361 draught horses and 1,367,530 labourers. The length of railway now open for traffic is 2,171 kilometres (1,300 miles), on which are employed 725 locomotives. The number of steam trading vessels is 279; their tonnage amounts to 40,098 tons; and they are propelled by 502 engines, constituting a total power of 22,893 horses. The merchandise transported by these vessels amounted to 730,948 tons. The progress of steam navigation in France is indicated in the following facts:—In 1835 there were 75 steamers, by which 1,038,916 passengers were carried, and 88.140 tons of merchandise; in 1840 there were 211 steamers, 2,547,116 passengers, and 485,539 tons; in 1845, there were 259 steamers, 3,461,336 passengers, and 696,066 tons; and in the last year there were 279 steamers, 2,808,886 passengers, and 730,948 tons. The total number of steam engines employed by land or sea in France amounts to nearly 7,000, and they constitute together a force of 110,178 steam horses, or 330,535 draught horses.

In 1850 there were 12,335 vessels engaged in the import trade, and 11,587 in the export. About 513 kilometres of new railway are expected to be opened in 1851. In 1849 the iron foundries produced 700,000 tons of iron.

In 1848 we imported the following among other commodities from France:—

Corn	390,000 qrs.
Flour and meal	370,000 cwts.
Gloves ..	3,000,000 pairs.
Madder ..	54,000 cwts.
Prunes ..	34,000 cwts.
Clover seed ..	29,000 cwts.
Silk	1,350,000 lbs.
Silk goods ..	720,000 lbs.
Skins and furs	640,000
Brandy ..	2,360,000 gallons.
Wine ..	660,000 gallons.

In the same year Great Britain sold to France:—

Brass and copper goods ..	150,000*l.*
Coals	570,000 tons.
Hardware and cutlery ..	51,000*l.*
Machinery	35,000*l.*
Silk goods	57,000*l.*
Wool and woollens ..	194,000*l.*

and other goods to the aggregate value of 1,024,521*l.* The amount was more than double this in 1846 and 1847; for 1848, being a year of revolution, presented unfavourable commercial results.

Of the important Expositions of Industry which have been held in France in past years, a brief account has been given in the INTRODUCTION. Everything affords ground for believing that France will hold a distinguished position at the approaching display in Hyde Park. All the goods from all the departments have been collected at one spot in Paris, where they have been inspected by a jury, who would not suffer any specimens to be exhibited but such as will reflect credit on the manufacturers. From Paris they have been forwarded by railway to Dunkirk, and thence by sea to London. The following has been announced to be the number and distribution of the exhibitors. Of the eighty-six departments of France nine only are without intended exhibitors. In the department of the Seine there are 1,730 exhibitors; Rhone, 96; Nord, 56; Seine Inférieure, 53; Marne, 47; Loire Inférieure, 33; Gard, 25; Bas Rhin, 23; Haut Rhin, 22; Ardennes, 20; Gironde, 18; Oise, 18; Seine et Oise, 18; Haute Vienne, 17; Pas de Calais, 16; Loire, 14; Seine et Marne, 14; Ardêche, 12; Aube, 12; Haute Garonne, 12; Hérault, 12; Jura, 12; Maine et Loire, 10; Sarthe, 10. The following is the analysis, according to the classification decided on by the English committee, of the 2,481 persons declaring an intention to exhibit above mentioned:—Section 1. Raw materials, 485; 2. Machinery and tools, 554; 3. Manufactured productions, 1,088; 4. Plastic arts and models 354. Even Algeria will take part in this industrial display.

FRANKFORT. With the exception of Sachsenhausen and its 5000 inhabitants, who are principally agriculturists, gardeners, and day-labourers, the citizens of Frankfort-on-the Main derive their subsistence from commerce, money operations, and manufactures. It is a place of considerable transit for German and foreign produce. The chief articles of trade are wines, English, French, and Italian goods, Bavarian timber, German wools, colonial produce, and German manufactures. The chief manufactures are carpets, galloon, tobacco, cards, cottons, silks, printer's black, &c.

An establishment formed here for the sale of Bohemian glass, contains some of the best examples of that manufacture. The works which supply the stock are situated at Hayda, and the activity with which they are conducted here and elsewhere is necessarily a means of many improvements and novelties. Some of the examples of verre perruche are very beautiful; this is a production in which glass of different colours is joined together. There are also many examples of enamel on colourless glass, presenting forms and designs of much taste. There is in this city an establishment for the extensive sale of the productions of the iron-foundry of Hanau, comprehending a very extensive assortment of objects of utility and ornament—as candlesticks, branches, paper-weights; vases, tazzas, and every other ornamental object which the French artists and manufacturers produce in bronze. The finest manufacture, that in gray iron, is also brought to a high degree of excellence; this class of productions comprehends every ornamental article in which iron filligree is in anywise available, and so fine is the workmanship in this hair wire material, that iron, equivalent in value to 1*l.* sterling, may be manufactured into a variety of articles amounting in value to 1000*l.*

Many curiosities from Frankfort will appear at the forthcoming Exhibition.

There is another Frankfort, called *Frankfort on the Oder*. The manufactures of the town consist of wines, mustard, brandy, tobacco, sugar, gloves, stockings, linen, leather, &c.: its trade is extensive, and the three periodical fairs, instituted in 1253, are well frequented, particularly by Polish dealers.

FRANKINCENSE is the produce of the *Abies excelsa, Pinus abies*, or common Spruce Fir, from which it either exudes spontaneously or more abundantly from incisions in the bark. When it first flows out it is liquid, but on exposure to the air concretes, and is collected during autumn and winter. It occurs in two states, in tears, and in large irregular lumps or compressed cakes. When recent, the colour should be white, or only inclining to yellow, subdiaphonous, soft, tenacious, and glutinous: by the action of time it becomes hard, and even friable, the colour having deepened into an orange hue. By the heat of the hand it softens, and by a higher temperature liquefies. It possesses a turpentine-like odour and taste. It is insoluble in water, but completely soluble in alcohol with the aid of heat. Frankincense consists of two kinds of resin mixed with oil of turpentine. By melting it in water, and straining it through strong cloths, it is deprived of much of its oil, when it is termed *Pix arida* or Burgundy Pitch.

It is scarcely now used internally, but is irritant and diuretic. Externally it is useful in the composition of plasters.

FRAXININ is a neutral principle obtained from the bark of the *Fraxinus excelsior*. It is obtained in slender hexagonal prisms, which are unalterable in the air. Fraxinin is very soluble in water and in alcohol, and only slightly so in æther. It has a very bitter taste and has neither an alkaline nor acid reaction.

FREEZING MIXTURES. Freezing is the solidification of fluid bodies by the abstraction of the heat necessary to their fluid form. Freezing mixtures are such as produce cold by the liquefaction of their solid ingredient. Such mixtures reduce the temperature of substances immersed in them on the principle of the transfer of heat, which always takes place from hotter to colder bodies when exposed to each other.

The process used by confectioners for producing cold is by the mixture of ice and common salt, both of which in liquefying absorb so much heat, or, in other words, produce as much cold, as will reduce the thermometer from the usual temperature to zero of Fahrenheit, or even rather below it. If however freshly fallen snow be used instead of ice, then the fluidity is more suddenly produced, and the cold is more intense. It is found that ice or snow, though exceedingly convenient substances for the production of artificial cold, are by no means necessary to it. Any salts which dissolve rapidly in water, finely powdered, are powerful freezing mixtures. Mixtures of muriate of ammonia and nitrate of potash, and of these with phosphate of soda, act strongly in this way; and so do various other salts.

The following are useful freezing mixtures, with the temperature which they produce :—

—Salt 1 part, snow 2 parts...... — 5° Fahr.
—Salt 2, mur. of ammonia 1, snow 5—12° „
—Salt 10, snow 24, mur. of ammonia 5, nit. of pot. 5 .... —18° „
—Snow 3, dilute sulph. acid 2 .. —23° „
—Snow 5, concen. mur. acid 8 .. —27° „
—Snow 4, concent. nit. acid 7 .. —30° „
—Snow 5, chloride of calcium 4 . —40° „
—Snow 2, chloride of calcium 3 . —50° „
—Snow 3, fused potash 4...... —51° „
—Snow 8, dilute sulphuric acid 10—91° „

These negative temperatures indicate so many degrees below zero of Fahrenheit. In some cases they depend on the temperature of the substance before the freezing process. Solid carbonic acid is an agent in producing still greater degrees of cold.

In order to produce the congelation of water by a rapid evaporation from its own surface under the exhausted receiver of an air-pump, Sir John Leslie introduced in the receiver a shallow vessel containing highly concentrated sulphuric acid, above which was placed the vessel containing the water. The air being extracted as quickly as possible, the vapour, which, in consequence of the removal of the pressure, escaped continually from the water, was absorbed by the acid as fast as it rose; and the remainder of the water was speedily frozen. Dry potash, muriate of lime, or powder of basalt, will do instead of sulphuric acid. Leslie succeeded in freezing mercury by the absorption of caloric from a coating of ice in which the bulb of a thermometer was immersed.

FREIGHT, in commercial matters, is the charge made for the carriage of merchandise in a ship. The amount of the freight is generally specified in the bill of lading. It frequently happens that the whole ship is hired by a merchant for a voyage, and a certain amount is paid without reference to the quantity of goods put on board. In such cases the mode of payment is part of the matter of agreement between the shipowner and the merchant, and the terms of the agreement are stated in an instrument called a *charter-party*. Where the shipper of goods does not stipulate for the use of the whole ship, the amount of the freight, as well as the mode of payment, may be inserted in the bill of lading. Where this is not done, the freight is due from the merchant on the delivery of the goods, and the owner or master of the ship may demand payment of the same, package by package, as the same are delivered. In London where the greater part of the merchandise brought from foreign countries is delivered into the custody of one or other of the incorporated dock-companies, there is a custom of arresting the goods in their hands, so that they cannot pass away from the original importer until the shipowner, or some person acting on his behalf, has signified in writing that the freight has been paid. If goods are damaged on board the ship, through the carelessness or neglect of those in whose charge she and her cargo are placed, so that the owner of the ship is liable for the amount of the damage, this cannot, without the consent of the owner or master, be set off against the amount of the freight, which must under all circumstances be paid, and the merchant must afterwards substantiate his claim to compensation for the amount of the damage.

FRENCH BERRIES are the berries of the *Rhamnus infectorius*, which are gathered before they are ripe. They afford a pretty but fugitive yellow dye.

FRESCO PAINTING. A painting is said to be a *fresco*, or painted in fresco (*sul fresco intonaco*, upon the fresh coat), when it is executed in water-colours upon wet plaster. Fresco is the most noble and imposing of all methods of painting. *Colouring* in fresco was practised by the ancients, though it has not yet been shown that they *painted frescoes*. Vitruvius explains the mode of preparing the walls for this species of colouring, and describes a method of varnishing them when coloured to preserve them. The earliest Italian frescoes are in the church of Assissi, in the cathedrals of Orvieto and Siena, in the Campo Santo at Pisa, and in San Miniato and Santo Spirito at Florence. These and other later frescoes are painted on different kinds of walls: in the old Gothic buildings, on ashlar walls covered with a thin coat of plaster; in more recent buildings, on brick and rubble walls; and, in some of the most recent edifices, on lath covered with various thicknesses of plaster. The best preserved of these frescoes are on brick. There are many frescoes at Pisa, Florence, and Venice, on lath, and all are in tolerable preservation.

The method of plastering the walls for painting has been nearly uniform in most ages. The walls of the baths of Titus at Rome are covered first with a layer about half an inch thick of coarse sand and lime; above this, a thick layer of lime and pozzolana with an admixture of sand and pounded brick; the third and upper coat is of lime and pounded marble. The third loggia of the Vatican, painted by Giovanni da Udine, is much the same as this. Cennino Cennini, Alberti, and various other Italian writers, give instruction as to the mode of preparing the walls and the materials for them. The selection of the limestone to be employed in fresco-painting, both for the ground and for the white, is a matter of great importance; it should be nearly pure carbonate of lime, and should contain as few foreign materials as possible. Modern fresco-painters recommend the lime to be kept a much longer period than Cennini and other early writers direct. If it is used too fresh, it blisters, and sometimes turns the colours to a brownish red. The lime for the *intonaco* in fresco painting must not be entirely carbonated, or it would not set; a certain degree of causticity is necessary. The picture must be executed while the *intonaco* is wet or soft; no more work therefore ought to be commenced than can be completed within the time (a few hours) that the plaster requires to harden. Numerous joints are thus necessary in a large fresco; and a judicious painter contrives that these joints shall be identical with the inner outlines of the parts of the figures and their draperies, or any other object, so as to be no disfigurement to the work. Before laying on the *intonaco* the prepared ground is repeatedly wetted, until it will absorb no more; then a thin moderately rough coat of plaster of sand and lime, is laid over as much of the wet surface as can be painted in one day; as soon as this coat begins to set, in about ten minutes or so, another thin coat is laid on with a wooden trowel, both layers together being scarcely a quarter of an inch thick. Upon this coat the fresco is painted. This *intonaco* will be fit to paint upon in about a quarter of an hour.

The colours used in fresco painting are all ground and mixed in water, boiled or distilled; they are chiefly earths. Lime, ochres, siena, vitriol, Verona green, cobalt, chrome, ultra marine, and vermilion are the chief colouring substances employed. Sufficient of each tint is kept ready for the whole picture. The brushes and pencils are made of hog's hair and otter's hair.

The method of *fresco-secco*, or dry fresco, is thus practised:—The plastering of the wall having been completed, the whole is allowed to dry thoroughly. Before painting, the surface of the *intonaco* is rubbed with pumice-stone, and on the evening of the day before the painting is to be commenced it is thoroughly washed with water mixed with a little lime; it is wetted again the next morning, and is then ready for pouncing or tracing the outline, and painting; the wall must be kept constantly moist by means of a syringe.

Frescoes are sometimes cleaned by dry bread; sometimes by pure water, by vinegar, and by wine. Ingenious modes have been devised of removing frescoes from walls, and transferring them to canvas.

FRET, in musical instruments of the stringed kind, is a wire or ridge so placed as to mark the exact part of the finger-board to be pressed for the purpose of producing certain sounds. Frets are now never applied to any instruments except guitars, lutes, &c.

FREYBERG, the centre of administration for the Saxon mines, stands about 20 miles from Dresden. The Berg Academie or Mining Academy was opened in 1767, and comprises class and lecture rooms, a museum, in which are rich collections in mineralogy, &c., a geographical and a geognostic cabinet, a museum of models of mining machines and philosophical and chemical apparatus, and an extensive library. The manufactures consist principally of articles in imitation of gold and silver ware, brass wares, white lead, gunpowder, iron and copper wares, linen, woollens, gold and silver lace, ribands and tape, leather and laces.

FRICTION. All surfaces have certain degrees of roughness arising from the innumerable small asperities with which they are covered; and from these, when two surfaces move upon one another, there arises a force acting in a direction opposite to that in which the surfaces move. This is *friction*, which is therefore a retarding force capable of destroying but incapable of generating motion, and capable of acting powerfully as a mechanical force, of which the tendency is to bestow stability.

The following are a few of the laws which govern friction, useful in all considerations respecting moving machinery:—1, Friction is increased by *time;* thus it requires the application of a greater force to move a weight along a horizontal plane from its position of rest than to keep it afterwards moving on the same plane. 2, Between substances of the same nature the friction is proportional to the *pressure;* thus, if a block of oak be double the weight of another, and both, having equal surfaces of contact, are placed on one plane of uniform nature, the force necessary to move the first will be double of that requisite for the second. 3, The amount of friction is independent for one and the same body of the extent of the surface of contact. 4, When the fibres of two substances are parallel, friction has a tendency to increase; thus, when a rectangular block of oak is placed on an oak table so that the fibres in both lie parallel, the friction is greater than in the case where the fibres of the block lie transversely to those of the table. 5, The friction is independent of the velocity, at least when the velocity is neither very small nor very great.

Mr. Rennie made many valuable experiments on friction a few years ago, with various substances drawn on a horizontal plane. He found that metals moving upon each other produced friction in the following order:—

Brass on wrought iron.
Steel upon steel.
Brass upon cast iron.
Brass upon steel.
Hard brass upon cast iron.
Wrought iron upon wrought iron.
Cast iron upon cast iron.
Cast iron upon steel.
Cast iron upon wrought iron.
Brass upon brass.
Tin upon tin.

Amongst the conclusions which Mr. Rennie draws, the following are perhaps the most important. With fibrous substauces, such as cloth, &c., friction is increased by surface and time, and diminished by pressure and velocity. With harder substances, such as woods, metals and stones, the amount of friction is simply as the pressure, without regard to surface, time, or velocity. Friction is greatest with soft, and least with hard substances. The diminution of friction by unguents depends on the nature of the unguents, without reference to the substances moving over them.

M. Coulomb and M. Morin have made valuable experiments on the friction produced by one kind of wood moving over another.

FUEL is any combustible matter employed for the purpose of creating and maintaining heat. In the early ages of the world, *wood* must have constituted, as indeed in many countries it does to this day, the principal fuel employed. *Charcoal*, another kind of fuel, is merely wood that has undergone imperfect combustion, so as to expel its hydrogen and oxygen, and to leave the greater part of the carbon. *Peat*, or *turf*, which is a congeries of vegetable matter, in which the remains of organisation are more or less visible, is used in many countries as fuel. In this country *coal* furnishes the great supply of fuel. *Coke* bears nearly the same relation to coal that charcoal does to wood. In the East, dried camel's dung is often used for fuel.

The number of substitutes for coal introduced within the last few years has been surprisingly large. Oram's patent fuel was planned with a view to make use of the small coal which is so extensively left to waste at the mouths of the pits; this coal to be mixed with earthy substances, such as sand, marl, clay, or alluvial deposit; or with some bituminous substance, such as mineral tar, coal tar, gas tar, pitch, resin, or asphaltum; or with saw dust, coke dust, or breeze. In short this was one of those vague patents which defeat their own purpose by the wideness of their grasp.

Mr. C. W. Williams, managing director of the Dublin Steam Packet Company, has patented three or four inventions for artificial fuel in which peat shall be one of the ingredients. The peat, after being dried, is pressed with great force, to expel the moisture with which it is saturated; and it is then mixed with some bituminous substance. By different modes of treatment Mr. Williams produced a very dense brown combustible solid, a charcoal twice as compact as hard wood charcoal, an artificial coal, and an artificial coke.

All the more recent patent fuels consist of various combinations of the substances noticed above. Bessemer's, Buckwell's, Cowper's, Snowden's, Reece's, Green's—all have a certain family resemblance, however they may differ in details. Warlich's patent fuel has been found to possess certain favourable qualities for use in steam-boats. See also CARBON; CHARCOAL; COAL; COKE; PEAT.

FULGURITES are vitrified sand-tubes, supposed to have originated from the action of lightning. These tubes are nearly all hollow, and vary in diameter from a fraction of an inch to two or three inches. All the evidence goes to show that they are produced by the action of lightning on the silicious particles of sand. They serve to illustrate in a pleasing manner how sand or flinty particles may be converted into a kind of glass by intense heat.

FULLERS' EARTH, a mineral product, was formerly much used in the fulling of cloth. It occurs massive, and is usually of a greenish brown or dull gray colour; sometimes it is nearly of a slate colour. It occurs in many parts of England, between beds of sand or sandstone.

FULLING. [WOOLLEN MANUFACTURE.]

FULTON, ROBERT, the first to establish steam navigation on the American seas and rivers, was born in 1765, in Pennsylvania. In 1786 he embarked for England, and projects for the improvement of canals began to occupy the chief share of his attention. In 1794 he took out a patent for an inclined plane, which was intended to set aside the use of locks; he invented a machine to facilitate excavation, and wrote a work on canals, in which he first styled himself a civil engineer. He also invented a mill for sawing marble, and took out patents for spinning flax and making ropes. These projects failed to enrich him; and he went to Paris, where he studied languages, invented a sub-marine boat, projected a panorama, and made experiments in the Seine with small steam-boats. After trying in vain to introduce his sub-marine boat into England, he went to America in 1806, and soon afterwards commenced the construction of a steam-vessel of considerable size, which began to navigate the Hudson in 1807. He afterwards built others of large dimensions, one of them a frigate, which bore his name. His reputation became established; but lawsuits in reference to certain patents kept him poor, and anxiety and excessive application shortened his days. He died in 1815.

Henry Bell in Scotland, and Robert Fulton in America, both died poor; after enriching —each his own country—by the decisive introduction of steam-navigation.

FUMIGATION. The vapours of hot vinegar, burning sulphur, and of aromatic vegetable matters, have been long used to counteract unpleasant or unwholesome smells: this is effected chiefly by the formation of such as are stronger. The most important kind of fumigation is that which consists in the employment of such vapours or gases as do not merely destroy unhealthy odours by exciting such as are more powerful, but which by their chemical action prevent the decomposition of animal and vegetable matters.

The fumigation of the first kind, that which is intended to produce a healing effect, is now much less employed than formerly. In the last kind of fumigation several substances have been employed in the gaseous state; such as the vapour of burning sulphur, or sulphurous acid gas, muriatic acid gas, nitric acid gas, and chlorine gas. Chlorine which is undoubtedly preferable to any disinfectant, was first recommended by Dr. Rollo, the gas being liberated by the usual method of mixing sulphuric acid, binoxide of manganese, and common salt. When it is desirable to produce a great effect in a short time, this is still unquestionably the best mode of proceeding.

Where unpleasant smells or effluvia are produced only in small quantities, the chloride of lime or soda, and especially of the former, has been within a few years successfully employed. The chloride of lime is a substance well known and extensively employed under the name of bleaching powder. It is used in solution, and is obtained by dissolving one part of Bleaching Powder in about 100 times its weight of water, and allowing the solution to become clear. This is to be exposed to infected air, or, in rooms which have any unpleasant odour, in flat vessels, in order that a sufficient surface may be acted upon. If it should be required, the operation may be quickened by the addition of a little vinegar, or of muriatic acid largely diluted.

Where it is necessary to diffuse a gas, vapour, or smoke over a given space, the usual plan is to place some easily evaporable substance on or near the spot; but in fumigating plants some difficulty arises. To remove this difficulty is the object of Brown's *Fumigator*, an ingenious apparatus patented in 1849. It comprises a cylinder, a fan, a funnel, a handle, a winch, and a spout. The cylinder is a metallic chamber, across the centre of which an axle extends; and to the middle of this axle a fan of several vanes is attached. The winch, outside the cylinder, affords the means of giving a rapid rotatory movement to the vanes; while a handle on one side of the cylinder enables the apparatus to be conveniently held in any desired position. The funnel is fixed into the top of the cylinder, and has a diaphragm of perforated metal about its centre. The action of the apparatus is simply as follows. Tobacco or other substance whose fumes are required, is put in the funnel and ignited, and the top of the funnel closed; the winch is turned, and the draught thereby occasioned within the cylinder sucks in the smoke, and then forces it out through the spout. This spout is so formed as to act easily on any part of a plant.

FUNGIN, the fleshy substance of mushrooms, purified by digestion in a hot weak solution of alkali: it is whitish, soft, insipid, and but little elastic. It is a highly nutritious substance, and in many of its properties it strongly resembles lignin.

FUNICULAR MACHINE is a name given by some mechanicians to a cord or chain attached at one extremity to an immoveable point, the other end passing over a fixed pulley or friction wheel, and having a weight suspended from it; a weight being also suspended from the cord or chain in some part of its length between the fixed extremity and the pulley. The cord or chain becomes thus a mechanical agent, since unequal weights, applied as has been said, may be in equilibrio.

FUNNEL is a hollow conical vessel with a small pipe issuing from its apex, much used in domestic life for conveying fluids into vessels of small apertures, and in chemical operations not only for this purpose but for that of filtering.

FUR TRADE; FUR DRESSING. The use of furs appears to have been introduced into civilised Europe by the northern conquerors.

The fur trade was taken up by the French colonists of Canada; and, through the ignorance of the Indians, the traders at first made very great profits. When the hunting season was over, the Indians came down the Ottawa in their canoes, with the furs, and encamped outside the town of Montreal, where a kind of fair was held until the furs were all exchanged for trinkets, &c. At a later period, European settlers under the name of *Coureurs des Bois*, or wood-rangers, set out at the proper season from Montreal in canoes loaded with various articles, and proceeded up the river to the hunting grounds, where they conducted their traffic with the hunters, and returned with the furs or peltries.

The Hudson's Bay Company, established for the express object of procuring furs, was chartered by Charles II. in 1670. This association founded several establishments. In 1783 a rival association, called the North West Company, was established by some British settlers in Canada; and from that time till 1821 great jealousy and enmity existed between the agents in the two companies. An amalgamation took place in 1821: and the Company have recently added Vancouver Island to their territories. The clerks, agents, &c., of the United Company are very numerous. All the furs collected by the Hudson's Bay Company are shipped to London, some from their factories of York Fort, and on Moose River, in Hudson's Bay; other portions from Montreal, and the remainder from the Columbia River.

The fur trade is prosecuted in the north-western territories of the United States by an association called the North American Fur Company, the principal managers of which reside in New York. The Company employs steam-boats for ascending the rivers, which penetrate with ease to regions which could formerly be explored only through the most painful exertions in keel boats and barges, or by small parties on horseback or on foot. There is also a Russian Fur Company, in the extreme north-west of America.

The following are the principal skins taken for the sake of the fur:—The *ermine*, called by way of pre-eminence 'the precious ermines is found almost exclusively in the cold region,' of Europe and Asia. The fur of the ermine is of a pure whiteness throughout, with the exception of the tip of the tail, which is black; and the spotted appearance of ermine skins, by which they are peculiarly known, is produced by fastening these black tips at intervals on the skins. The *stoat* is an inferior kind of ermine. The *sable* is a native of Northern Europe and Siberia; those of the darkest colour are the most esteemed. *Martens* are found in North America as well as in Northern Asia; the American skins are generally the least valued, but many among them are rich and of a beautiful dark brown olive colour. The *fiery fox*, so called from its brilliant red colour, is taken near the north-east coast of Asia, and its fur is much valued, both for its colour and fineness, in that quarter of the world. *Nutria* skins are chiefly used by hat-manufacturers as a substitute for beaver. *Sea-Otter* fur, of the young animal, is of a beautiful brown colour, but when older the colour becomes jet black. The fur is exceedingly fine, soft, and close, and bears a silky gloss. *Fur-Seals* are found in great numbers in the colder latitudes of the southern hemisphere. Bears, foxes, beavers, racoons, badgers, minks, lynxes, musk-rats, rabbits, hares, and squirrels are procured in North America.

Furs may be classed as *felting furs* and *dressed furs*. The first includes all such as are employed in hat-making, and are principally the skins of the hare, the rabbit, the beaver, and the neutria.

The mode of preparing beaver fur for the hatter will sufficiently illustrate the treatment of furs generally. The pelt or skin is so greasy, that it requires to be scoured with fuller's earth and whiting before it attains a sufficient state of cleanness. The coarse hairs are pulled out by the knife and thumb, and, being of no use to the hatter, they are sold as a stuffing for cushions. Then comes the cutting or cropping, which is at the present day, and in the largest establishments, effected by a very beautiful machine. There is a long broad and sharp blade, so adjusted as to fall rapidly with a chopping action against or near the edge of another blade beneath. The fur falls down in a light flocculent layer on an endless apron beneath, whence it is removed when the pelt has been shorn. [HAT MANUFACTURE.]

The term *dressed furs* is given to those furs which are retained on the original pelt, and in that state worn as garments or trimmings, in the forms of cloaks, tippets, cuffs, collars, &c. The fur-hunters, when they have captured a beaver or other fur-bearing animal, strip off the skin, and hang it up to dry, either in the open air or in a dry and cool room. When the skins are brought to England and placed in the hands of the furrier, he examines them minutely to see that the drying has been properly effected, and the pelt in a firm state. He then washes the skin, to extract all greasiness from the fur, and gives the pelt a sort of slight tanning, or tawing, by means of alum or other ingredients. The skins are then ready to be worked up into materials for garments. In order to give the surface of the fur a uniform length and colour of fibre, it is often necessary to cut up many skins, and sew them edge to edge; for it is rarely if ever the case that every part of the same skin is of one uniform colour.

FURNACE. The common grate is the most familiar example of a furnace; and in the smaller chemical operations various contrivances are used, midway in character between a grate and a furnace; but the furnaces usually so called are the following:—

The *Wind Furnace* gives a very high temperature by the aid of a powerful draught. It is from 12 to 15 inches square, and is furnished with moveable bars and a cover. The air is conveyed by pipes directly from without doors to the ash-pit, and the chimney is narrow and high. Such a furnace is much employed in the reduction of metals, and in the assaying of copper and various other ores. The fuel used is either coke or a mixture of coke and charcoal.

The *Assay* or *Cupelling Furnace* is a small furnace made of iron, lined with refractory clay, and containing a muffle; it is used principally for the cupellation of gold and silver, which is placed upon a cupel in the muffle, previously heated to redness. The interior of the furnace contains merely the muffle resting upon two bars of iron; it is put about two-thirds into the furnace, and there is consequently left a space between it and the back part of the furnace. Charcoal is used in this furnace.

For metallurgic operations on a large scale, as well as in making alkalies, red lead, &c., the *Reverberatory Furnace* is much used. There is a space furnished with a grate or bars, to contain the fuel, which is either coal, coke, or wood, according to circumstances. Beyond and behind this is a large low vacant space, so shaped that the flame may reverberate from the brick roof, and strike down upon the substance to be heated, which is placed upon a flat brick surface. There is a very high chimney that produces the draught, and which may be closed by a damper.

The *Smelting Furnace*, for iron works, is a large structure of brick, having a small square receptacle for the fuel beneath, a large interior space for the ore to be smelted, a wide-mouthed chimney at the top, and air-holes at the bottom to admit either the hot or cold blast. Some of the South Wales furnaces have an internal cavity of 5000 cubic feet.

In scarcely any department of machinery or manufacturing apparatus are there more numerous patented inventions than in the construction of furnaces. Newton, Grist, Jukes, Pollock, Burrows, Holcroft, Baker, Coad, Clarke, Bramwell, Homersham, Barker, Deeley, Williams, Newcome, Hall, Mackintosh, White, Howard, Wilson, Pidding, Robinson, Lee, Knowlys, Prideaux, Bessemer, Galloway, Johnson, Cliffe, Dalton—all these names, and many others, are connected with improvements in furnaces within the last two or three years. Some of these improvements relate to the furnaces of locomotives, some to those of marine engines, some to those of stationary engines, and some to furnaces in general. In one case the patentee seeks to economize space, in another fuel, in another to avoid the 'smoke nuisance.' Some relate to metallic furnaces, some to fire-brick furnaces. In some the object is to raise steam in great quantity; while in others it is to substitute rapidity for quantity.

An important principle has just been put in operation by the Ebbw Vale Iron Company of South Wales. It is no less than the application of blast-furnace gases to heating purposes. After a furnace has performed the work for which it is intended, various gases escape with the smoke, at the upper orifice; and these gases carry with them a large amount of valuable heat. If the heat could be abstracted and usefully applied, without lessening the power of the furnace, an economical benefit would result. The above named company have 11 blast furnaces, five engines to produce the blast, and twenty-five boilers to supply the engines with steam. The greater number of these boilers are wholly heated by the waste heat from the blast furnaces; and various ovens and stoves in the Works are heated by similar means. It is said that 1000 tons of coal per week are saved by this admirable contrivance. The heated gases are arrested near the top of the furnace, carried out by a horizontal tube, mixed with atmospheric air which enters in thin sheets or layers, and ignited by a small fire. It forms a true gas-light; and this gas-light heats a large flue, which is surrounded by a boiler containing water; and thus is a supply of steam obtained.

FURNITURE MANUFACTURE. It is supposed that there are about 50,000 workers in wood in the metropolis, and 350,000 in the kingdom, of whom a very large number are employed in making articles of household furniture. There has also been a rough estimate that about 160,000 average timber trees are required to make the furniture for the new houses built annually in England and Wales. There are about 30,000 sawyers in England, to cut up timber for various purposes. The carpenters and joiners are about 180,000; carpenters construct all the rough portions, and joiners all the more finished details, in the timber-work of houses. The cabinet-maker engages on such timber-work only as is connected with household furniture; but there are many departments, such as the chair maker, the bedstead maker, the carver, the general cabinet maker (who makes tables, drawers, sideboards, wardrobes, &c.), the fancy cabinet maker (who uses veneers of costly woods, and makes workboxes, teacaddies, desks, dressing cases, and other highly finished articles). The upholsterer does what is called the 'soft work,' that is, all that relates to curtains, hangings, cushions, and so forth; he is also responsible for the due finishing and fittings of carpets and beds.

The general furniture or cabinet makers require tools which cost from 30*l.* to 40*l.* per set. A portion of the journeymen in this trade in London belong to trade societies, by whom the rate of wages is to a considerable extent determined. Those employed at the west end of London generally receive higher wages than those of the east; but a much larger number are free of the trade-societies, and make their own bargains with employers concerning the rate of wages. There has been a large increase, in this trade, in what are termed 'garret masters,' who bear in manufactures a position analagous to that which 'peasant proprietors' bear in agriculture: that is, they supply both capital and labour. The garret master buys just so much wood as he can pay for at a time, works it up into tables and other articles of household furniture, and takes those articles to furniture dealers, to whom he sells them for the best prices he can obtain. A very large per-centage of the showy French-polished furniture now to be seen marked at low prices in the London shops, is manufactured in this way; and on a Saturday evening, in the busy districts, the garret masters and their apprentices may be seen carrying such commodities to the shops of the dealers, or conveying them in a hired vehicle.

It is one of the features attendant on any extra demand for accommodation for visitors, that furniture makers share in the increased activity. It is known that the cabinet or furniture makers of London, both garret masters and others, are at present busily engaged in making furniture for houses about to be finished for our expected visitors to the Great Exhibition.

FUSTIAN is a cotton fabric similar in the mode of manufacture to velvet, having in addition to the warp and weft, common to all woven goods, a *pile* consisting of other threads doubled under the weft, and 'thrown in' at intervals so close together that when the goods are finished the interlacing of the warp and weft are concealed by them. While in the loom, the pile forms a series of loops, which are afterwards cut and sheared; the shearing is effected by very beautiful machinery.

There are different varieties of fustians, known by the names of cotton velvets, velveteens, beaverteens, moleskin, corduroy, and cords. Different patterns are produced by different dispositions of the pile threads.

Ingenious machines have been patented within the last two or three years, for facilitating the production of the nap in fustians.

FUSTIC is the name of two kinds of yellow dye-wood. *Young Fustic* is the produce of *Rhus Cotinus*, a native of Italy, France, and Greece. The root and the wood of this shrub are both imported, deprived of their bark, and employed for dyeing a yellow colour approaching to orange, upon wool or cottons. *Old Fustic*, the 'bois jaune' of the French, is the produce of *Morus tinctoria*, a native of tropical America and the West India Islands. The wood is yellow, hard, and strong, but easily splintered, and is imported in the form of large logs or blocks. The yellow colour which it affords with an aluminous base, though durable is not very bright.

FUZE, is a short tube made of metal or of well-seasoned beech, and fixed in the bore of a shell. It is filled with a composition, which is fired by means of a small piece of quick-match inserted for the purpose. The length of a fuze is regulated by the intended range of the shell or by the intended time of its flight.

Mr. Loam, mining engineer in Cornwall, patented in 1849 a new kind of fuze for blasting. It is made of calico or some similar material. In making the fuze, a strip of calico is unwound from a reel, and made to assume the shape of a trough; it passes under a hopper filled with gunpowder, and a train of powder becomes deposited on it during the passage. The calico is then drawn through a hollow axis, whereby the trough-like form is exchanged for that of a tube. The tube passes through another piece of apparatus, by which it becomes closely bound round with yarn or thread. When the tube has been thus far completed, it is coated with any of the usual water-proofing materials.

G

GABION, a hollow cylinder of wicker-work, resembling a basket, but having no bottom. It is formed by planting slender stakes vertically in the ground, at intervals from each other, on the circumference of a circle, and interweaving with them osiers or other flexible twigs. The most usual kind of gabion is about two feet in diameter, and two feet nine inches in height, but the stakes, whose extremities are pointed, project beyond the basket work about three or four inches at each end. Such gabions are used during a siege in executing trenches by the process of sapping.

GA'LBANUM. The plant usually believed to yield this medicinal gum resin is *Bubon Galbanum*, a native of the Cape of Good Hope; but there is some doubt on this point. Three sorts of Galbanum are distinguished:—1, galbanum in grains or tears; 2, galbanum in masses; and 3, Persian galbanum. The first two come from Africa, especially from Ethiopia; the third sort from Persia. *Galbanum in tears* is most likely the spontaneous exudation from the plant; and that in masses, obtained by incision. The first occurs in irregular generally oblong grains, mostly distinct, but sometimes agglutinated together, about the size of a lentil or small pea, of a colour verging from whitish into yellowish brown, more or less diaphanous, opaque, or shining with a resinous lustre. The odour is strongly balsamic and disagreeable. The taste is resinous, sharp, bitter, and disagreeable. *Galbanum in masses* consists of irregular pieces of a yellowish or dark brown colour: the odour is stronger than that of the preceding kind, which, in its general characters, it much resembles, except that it can be powdered only during the low temperature of winter. *Persian galbanum*, being very soft and tenacious, is sent in skins or chests; it often contains many fragments of plants.

Galbanum is largely employed in making pills, plasters, and other medicinal preparations.

GALI'CIA, a province in the north-west of Spain, produces wine, fruits, flax, wheat, barley, maize; good pastures, which feed a vast quantity of cattle; and abundance of chestnuts, which constitute a common food of the peasantry. The forests supply plenty of fuel and timber. The principal manufacture of the country is linen. The town of *Betanzos* has a few manufactories, and some trade in wine and pickled anchovies and pilchards, which are taken all along this coast. *Vigo*, on the Bay of Vigo, which forms one of the largest and safest natural harbours in Spain, carries on a considerable trade with America, exporting wines, sardines, linen cloth, and stockings, and other articles of native industry.

GALIPE'A is the name of the plant which yields *Angostura Bark*. It is found in the neighbourhood of Angostura. Angostura Bark is obtained both from the stem and branches. The specimens from the stem are flat, while those from the branches are often quilled. Some specimens have the surface covered with a thick, fungus-like, whitish yellow or clay-coloured crust, which may be more or less easily scraped off, and beneath which is a yellowish red smooth bark, often exhibiting small cracks. Other specimens have this covering much thinner and closely adhering to the bark. The internal surface is generally smooth, of a tawny or reddish yellow colour. The bark is easily broken, and the recent fracture is of a brownish red colour, smooth, with a resiny shining surface. The shining appearance is best seen when a transverse section is made with a sharp knife. The smell is disagreeable: the taste pleasantly bitter, warm, aromatic, and causing a flow of saliva. The powder has the colour of rhubarb. The infusion is of an orange-yellow colour; the decoction, a clear light brown.

Angostura Bark is a valuable medicinal agent; but there is a spurious kind which requires to be guarded against.

GALIUM is the botanical name for a genus of plants which comprises many useful species. One, called *Wild Madder*, is a native almost throughout Europe and the Caucasus, and is found in Britain. The roots are creeping, and yield a red dye like the true madder, but of a brighter colour; they also have the property of colouring the bones of animals red that feed upon them. This plant has been extolled as an effectual cure for epilepsy. The *Dyer's Bedstraw* is another species. From the roots of a third species the Indians extract the red dye with which they colour their feathers and the ornaments of their dress. The Cree women use the roots of the *Northern Bedstraw* to dye red. Of the *Ladies' Bedstraw* or *cheese rennet*, the stalks and flowers have been used in the cheese counties for the purpose of curdling milk, and also for colouring it. Mathiolus says it produces an agreeable flavour, and makes the cheese 'eat sweeter.' The French formerly used to prescribe the flowers in hysteria and epilepsy. The roots afford a rich red dye, superior in colour to madder. All the other species yield a red dye.

GALIZIA. The produce and industry of this country have been briefly glanced at in connection with the empire to which it belongs. [AUSTRIA.]

GALLERY, in its most extended sense, is used synonymously with corridor. In England however it is understood to be either a long narrow passage-way, or an open space, generally longer than wide, raised above the floor of a building, and usually supported by columns. Such galleries are met with (among other places) in English churches, in some courts of justice, and in theatres. The long external wooden passage-ways, formed something like a balcony, such as are occasionally seen in old inns, are called galleries.

Gallery is also a name of distinction given to a room either on account of its extent and proportions, or to one or more rooms especially appropriated to pictures and other works of art, whence the term Gallery is extended to the collection itself, without any reference to the building.

In mining operations, a gallery is a horizontal passage, excavated to facilitate the progress of the miners.

GALLEY; GALLEON; GALLIOT. These are the names of three kinds of vessels. The *Galley*, a large-sized long and narrow vessel propelled by oars and sails, was much in use in the Mediterranean until the end of the 18th century for coast navigation, and for making the shore in shallow water. The oars were a great advantage in the dead calms so frequent in the Mediterranean, until the introduction of the steamboat. The largest galleys were 166 feet long, and about 32 wide, with 52 oars. The rowers, who were generally convicts or Turkish prisoners, with chains to their feet, sat on benches on the deck. The ship carried a 24 pounder and two 8-pounders. The Venetians had a sort of large galleys, with a very lofty poop, called 'Galeazza.'

The *Galleon* was the name given to very large ships, with three or four decks, which the court of Spain used to send to the coasts of Mexico and Peru, to receive on board the gold and silver bullion extracted from the mines, and bring it to Spain.

The *Galliot*, is a strong-built flat-bottomed vessel of a peculiar construction, used as a bomb-ship to fire against forts or batteries on the coast. Galliot is also a kind of small galley or large fellucca, used chiefly in the Mediterranean. The Dutch, Swedes, and other northern nations have a sort of merchant ship which they call Galliot, rounded both fore and aft, heavily and clumsily built, but strongly timbered, and of the burthen of from 200 to 300 tons.

GALLIC ACID exists in most astringent vegetables, but principally in the gall-nut, and hence its name. When obtained from the plants, it appears as slender prismatic colourless crystals. The taste is slightly sour and astringent. Gallic acid, in the form of *tincture of galls*, is much employed as a chemical reagent.

GALLON. Distinct gallons for wine, ale and beer, and corn and dry goods, continued in use until the act of 1825. By statutes of 1689 and 1697, the wine gallon was declared to contain 231 cubic inches. The ale gallon was measured in 1700 or thereabouts, and found to contain 282 cubic inches. The corn gallon was thought, in the middle of the last century, to contain exactly 272¼ cubic inches: but the statute of 1697, which declares that a round corn-bushel must be 8 inches deep and 18½ inches wide, had in fact fixed the gallon at 268 $\frac{8}{10}$ cubic inches. The imperial gallon, as settled by the Act of 1825 is to contain 10 pounds avoirdupois of distilled water, of which it is declared that 252.458 grains fill a cubic inch; consequently the imperial gallon contains 277.274 cubic inches.

GALLS are the result of a morbid action excited in the leaf-buds of several species of

No. 23.

the oak, occasioned by an insect depositing its ova in the bud. Such buds, instead of elongating and becoming branches, undergo a peculiar transformation, and enlarge into a globular figure, so as to constitute a fit nidus for the future larva. The galls of commerce are chiefly those which occur on the *Quercus infectoria*. They vary in size, from that of a pea to that of a nutmeg. The surface has irregular elevations or lines, with the interspaces generally smooth. The colour is white or yellow in one variety; green, gray, or black in another. The white variety, which is the largest, often has a hole in the substance of the shell, by which the larva has escaped. This kind is the least powerful and least esteemed. The best galls come from Aleppo and Smyrna, but are often mixed with those from Syria and Cypress.

The infusion and other preparations of galls are used in medicine. But the most extensive use is made of them in the arts, and as a chemical test.

Gall is also the name given to the bitter fluid secreted by the liver. Ox-gall is largely employed in scouring cloth, and in other manufacturing arts. Refined ox-gall is used by artists to fix chalk and pencil drawings before tinting them, and to remove the greasiness from ivory and tracing paper.

GALVANISM. The chief points of interest which connect galvanic or electric agency with the arts of life are noticed under ELECTRO-METALLURGY, ELECTROTYPE, &c.

GALWAY. The greater part of this Irish county is comparatively flat, and much of it encumbered with bogs. The whole district west of Lough Corrib and Lough Mask is known by the general name of Connamara, and has of late years attracted much attention by its capabilities of improvement. Westward from the town of Galway, and round the entire coast of Iar-Connaught and Connamara to the boundary of Mayo, there is a succession of harbours for vessels of the largest class, unequalled perhaps on any similar extent of coast in Europe. These harbours are at Galway, Costello Bay, Casheen Bay, Greatman's Bay, Kilkerran Bay, Birterbuy Bay, Roundstone Harbour, Mannin Bay, Clifden Bay, Cleggan Roadstead, Ballynakill Harbour, and Killeries Bay. Some of these harbours have piers or jetties. On the whole, there is no part of this district more than four miles from existing means of navigation. The harbours fit for vessels of any burthen are upwards of twenty in number. There are twenty-five navigable lakes of a mile or more in length, and hundreds of smaller size. Lough Corrib and Lough Mask alone have upwards of seventy miles of navigable coast; and all these waters abound with fish. The sea-shore affords a constant supply of red and black sea-weed, which can be used either as manure or in the manufacture of kelp. Banks of calcareous sand and beds of limestone are of frequent occurrence, and there is an inexhaustible supply of peat fuel and of water power.

The attempts made to improve the fisheries on the coast of Galway have been beneficial to the county generally; and roads have been gradually formed from the interior to the coast. There is an extension of the Grand Canal from Shannon Harbour to Ballinasloe. A railway from Dublin to Galway is rapidly approaching completion.

In respect to geology, the mountains of the primitive district are highly metalliferous. Copper, lead, iron, and manganese are met with; and there are also abundant quarries of black, green, and variegated marbles, mill-stone grit, yellow ochre, and potter's clay. In 1847 the land under culture was thus appropriated:—Corn and beans, 141,318 acres; potatoes, 12,876; turnips, 14,788; meadow and clover, 37,146; all other crops, 3460; total under crops, 209,588 acres. The fisheries off the coast yield a very considerable produce. Nearly 100 million herrings have been caught in one year. Besides the herring fishery, there is an excellent take of cod, ling, whiting, and turbot, from December to March; and of gurnet, mackerel, bream, and pollock, from May to August, together with a copious supply of oysters, lobsters, and crabs. The sun-fish deep-sea fishery is peculiar to this coast. The manufactures comprise scarcely any but a few coarse friezes, linens, and hosiery.

In the chief town, *Galway*, there are many flour-mills, and other mills driven by the water-power of the river. Wheat, oats, and flour are exported, and a good deal of black marble from the neighbourhood. Timber, iron, slates, wines, &c., are imported. The retail trade is large. A wet-dock, comprising 9 acres, and admitting vessels drawing 14 feet of water, has been formed on the south side of the town. At *Ballinasloe* a very large sheep, cattle, and horse fair is held annually.

The Galway merchants are making praiseworthy exertions to have their port selected as a mail-packet station for the American route.

The beautiful black marble of Connemara will, it is to be hoped, find a place in the approaching Exhibition.

GAMBOGE. [CAMBOGE.]

GARD. In this department of the South of France, iron, coal, and silver-lead mines are worked. Silver, copper, and calamine are found; but the working of the mines has been abandoned. Sulphate of iron, manganese, kaolin, antimony, fuller's and potter's clay, plaster of Paris, building stone, &c., are also found. The sheltered hills and the plains are devoted to the cultivation of the vine, the olive, the mulberry, and the almond. The vine is extensively cultivated all through the department, which yields annually 25 to 30 million gallons of good strong wine, one-fourth of which is consumed at home, one-sixth is distilled into brandy, and the remainder is exported through Cette, chiefly for the purpose of mixing with the poorer wines of more northern departments. The olive, too, is carefully cultivated in sheltered spots, and on the southern slopes of the hills; the oil of the department is in high repute. The cultivation of the mulberry, which here becomes a large and beautiful tree, is very extensive.

The industrial products of the department are varied and important. The principal are silk textures of all kinds, the chief seat of which is Nîmes; cashmere shawls, made of a mixture of Tibet wool, silk, and cotton; silk and cotton hosiery of every description; table-covers, carpets, &c.; woollen cloth, swanskins, blankets, shoe and glove leather; silk hats; ribbons and gloves; iron, steam machinery, wine casks; pottery, tiles, and bricks; glass, paper, cards; nails, plaster, and lime; cotton and woollen yarn; salt, soda. The commerce of the department consists of the various products already mentioned. The number of wind-mills and water-mills amounts to nearly 800; iron forges and furnaces about 150; factories and workshops, of different kinds, 500 to 600.

At *Calvisson* a good deal of cream of tartar is made, and the town gives name to a delicious claret. *Roquemaure* has silk-reeling factories, brandy distilleries, hydraulic saw-mills, and a great manufacture of wine-casks, of which 20,000 are made annually.

GARDENS. A garden, as distinguished from a farm, is a piece of ground designed for the cultivation of plants not actually indispensable to man for food. While corn for flour, various roots and herbs for the sustenance of cattle, or tracts of pasture land on which animals destined for slaughter are maintained, constitute the essential features of a farm,—a garden, even when exclusively occupied by culinary vegetables, is still a source of objects of luxury, not of first necessity; in a more extended sense, and as it usually exists at the present day, it is chiefly intended to gratify the senses, and to minister to the more refined enjoyments of social life. The possession of a garden is one of the earliest indications of civilization in man: it may be fairly considered that the taste for gardens has been at all times commensurate with the wealth of nations generally, their peaceful habits, and advance in the social relations of life.

The first great step that was made by gardeners to advance their art beyond mere mechanical operations was the invention of glass-houses, in which plants might be grown in an artificial climate, and protected from the inclemency of weather. Until this was effected, it is obvious that the cultivation of exotic plants in Europe, especially its northern kingdoms, must have been much circumscribed. Mr. Loudon, in his 'Encyclopædia of Gardening,' gives valuable descriptions of all the most famous gardens in the world. The repeal of the glass duties in England is likely to be very beneficial to gardening, in respect to the construction of green-houses, hot-houses, palm-houses, &c.

A little information on the supply of London with vegetables and fruit will be found under MARKET GARDENING.

GARDEN ENGINES. The engines employed for watering plants in gardens are very similar in principle to fire-engines. The water is either poured into them from buckets, or drawn in by a suction-pump; while it is expelled in a continuous stream by a forcing-pump, easily worked by one or two handles.

At the various agricultural and cattle shows, garden-engines are usually exhibited among other apparatus. One such, exhibited at the Smithfield cattle show in 1850, is placed on a light platform drawn on four low wheels; it is worked by six men, and will discharge 60 gallons per minute; it is therefore fitted to act as a fire-engine, and as a garden-engine on a large scale. Read's patent garden-engine has two wheels and two handles; it will contain 28 gallons, and a jet can be forced by one man to a distance of 50 feet; it is adapted for watering both wall trees and standard plants. A slight modification in an instrument of this kind renders it workable by two men, with a power to force a large stream of water on any distant object. Mr. Warner has lately registered an ingenious *spreader*, by which the jet from a garden-engine can be readily spread out into a fan-like form. The same inventor has introduced a 'fire-engine, force-pump, drainer, and irrigator,' for farming purposes. It consists of an engine supported by a kind of barrow with two wheels and two handles; it can be worked by one or two men; it draws in its own water from a tank or reservoir, and it forces out a stream of considerable power.

GARNET. There are many varieties of

this well-known precious stone. Some of them are probably distinct species; but, agreeing in form and some other properties, they are classed together. This mineral occurs crystallised, massive, and granular. The primary form is a cube, but it occurs in the form of a rhombic dodecahedron. The crystalline varieties, according generally to their colour, have received various names. Precious garnet, *Almandine;* black, *Melanite; Pyreneite;* greenish yellow, *Grossularia;* yellow, crystallised, *Topazolite;* granular, *Succinite;* brownish yellow, granular, *Colophonite;* greenish, compact, *Allochroite;* red, *Pyrope, Carbuncle;* reddish brown, *Essonite, Cinnamon-stone, Romanzovite;* magnesian, *Rothoffite.*

GARONNE. The mineral treasures of this French department are iron, copper, lead, antimony, bismuth, zinc, coal, rock-crystal, slates, gypsum, marble, jet, and granite. Gold is found in the sands of the Garonne and the Salat. There is a salt-spring at Salies. Mineral waters are found at various places; those of Bagnères-de-Luchon are the most celebrated.

The quantity of wine grown in the department annually is 14 to 15 million gallons, one-third of which is used for home consumption; the quality is generally inferior. The commerce of the department is composed of its agricultural products and of its manufactures, the chief of which are scythes, files, copper utensils, mathematical instruments, porcelain, pottery, tiles, coarse woollens, canvas, blankets, calico, tape, brandy, tin-ware, and leather of various kinds. There are about 80 iron furnaces, and about 350 factories of different kinds, including glass works, copper foundries, cannon foundries, gunpowder mills, tobacco factories, distilleries, marble sawing works, &c.; together with more than 1000 wind and water mills. The department has considerable commercial intercourse with Spain, whither many handicraftsmen annually emigrate to exercise their callings.

The commerce and industry of the chief town, Toulouse, are briefly noticed elsewhere.

GAS. The main difference between *vapours* and *gases* is, that vapours are reduced to solids or liquids when the heat is withdrawn; while gases preserve their aëriform state at common temperatures. This difference is one of degree only, but it is usefully retained. The number of gaseous bodies is great, and they possess in many respects such different properties that it would be impossible to give a general description of them.

Gay-Lussac found that, when 100 volumes of gas or air are heated from 32° to 212° F., they become 137½ volumes; or the increase is $\frac{1}{480}$ for each degree of Fahrenheit. This law has supplied a simple rule for determining what the known bulk of a gas at any temperature will be at any other temperature. Suppose, for example, it is desired to know what the bulk of 100 cubic inches of air at 32° will be at 60°: subtract 32 from 480, the remainder is 448; to which add the degrees above zero indicating the temperature of the air; these are 32° and 60°, making 480 and 508. Then say 480 : 508 :: 100 : 105.832 the volume of the air at 60°.

Air suffers diminution of volume in proportion to the pressure to which it is subjected, and the same law holds good with all the more incondensible gases.

The solubility of gases in water is extremely various. Dr. Henry ascertained that the volume of each gas absorbed by water is the same, whatever be the pressure to which the gas is previously subjected. 100 volumes of water will absorb 450 volumes of cyanogen; whereas the absorption of hydrogen is only 2 volumes. In general, the more easily a gas is condensable by cold and pressure, the more soluble it is in water. Gases are also absorbed by charcoal and other porous bodies, the absorption being in ammonia 90 times the volume of the absorbent, and in hydrogen 1.75 times.

Some gases are more soluble in water than others; and some are more readily absorbed than others by porous substances. Dr. Faraday has liquefied some gases and solidified others. The method which he employed consisted in combining the condensing powers of mechanical compression with that of very considerable depression of temperature. The first object was attained by the successive action of two air-pumps. The tubes into which the air, thus condensed, was made to pass were of green bottle-glass, and had a curvature at one portion of their length adapted to immersion in a cooling mixture: they were provided with suitable stopcocks, screws, connecting pieces, and terminal caps, sufficiently air-tight to sustain a pressure of 50 atmospheres. Cold was applied to the curved portions of the tube by their immersion in a bath of Thirolier's mixture of solid carbonic acid and ether. The degree of cold thus produced, when the mixture was surrounded by the air, was − 106° Fah., by an alcohol thermometer; but when placed in vacuo, the thermometer indicated 166° below zero. Without the aid of mechanical pressure, Faraday liquefied sulphurous acid gas, cyanogen, chlorine, ammoniacal gas, hydro-sulphuric acid gas, carbonic acid, hydrochloric acid, and nitrous oxide. With the combined aid of cold and pressure he liquefied sulphuretted hydrogen, arseniuretted hydrogen, hydriodic acid, hyrobromic acid, nitric oxide, fluosilicon, and olefiant gas. Alcohol, ether, and chlorine have not yet been solidified; oxygen, hydrogen, nitrogen, and carbonic oxide have neither been solidified nor liquefied.

GAS-LIGHTING. When coal, oil, wax, wood, or any other organic inflammable substance is exposed to destructive distillation in close vessels, an inflammable gas is the result. This gas is some compound of hydrogen and carbon: more or less brilliant when ignited, according to its constitution. That the gas obtainable from coal is inflammable has been known for more than 200 years; and so long ago as 1691 Dr. Clayton made and used inflammable gas as a philosophical experiment. In 1733 Sir James Lowther brought before the notice of the Royal Society the existence of inflammable gas in one of the Whitehaven collieries; and some years afterwards Dr. Watson further drew public attention to the subject.

But, although the properties of coal gas were known to so many persons, no one thought of applying it to a useful object until the year 1792, when Mr. Murdoch, an engineer, residing at Redruth in Cornwall, erected a little gasometer and apparatus, which produced gas enough to light his own house and offices. In 1797 he erected a similar apparatus in Ayrshire, where he then resided. In the following year he was engaged to put up a gas-work at the manufactory of Boulton and Watt, at Soho. This was the first application of gas in the large way; but, excepting in manufactories or among scientific men, it excited little attention until the year 1802, when the front of the great Soho manufactory was brilliantly illuminated with it on the occasion of the public rejoicings at the peace. Soon after this, several manufacturers, whose works required light and heat, adopted the use of gas. Mr. Winsor, a German, brought the subject forward in London, and formed a 'National Light and Heat Company,' in 1804, which failed. In 1807 however he lighted up Pall Mall, and this continued for some years to be the only street in London in which gas was used. In a few years afterwards a Gas Company was chartered; and London gradually became better lighted. The business of the company steadily increased; and in the year 1823 it was shown that this company alone consumed annually 20,678 chaldrons of coals, which produced on an average 680,000 cubic feet of gas every night; this was distributed by means of 122 miles of pipe, which supplied more than 30,000 burners, giving a light equal to as many pounds of tallow candles. Several other companies were established in London. The provincial towns followed the example, and continental cities one by one availed themselves of this useful system, until at length it has become one of the best known and extensively used of modern improvements.

Various substitutes for coal in gas-making have been proposed from time to time, such as resin, wood, and peat, but with little success. Oil yields a brilliant gas, which is easily manufactured; but coal excels them all in cheapness, and is almost universally employed.

Although in the large way there are many practical difficulties to be surmounted in the manufacture of coal gas, the operation is easily understood; it is merely a process of distillation. A quantity of coal is put into a retort, which is well closed, and placed upon the fire; the temperature is raised to redness, which decomposes the coal, and drives the gas resulting from the decomposition through a pipe leading from the retort to the receptacle prepared for it. A mass of coke remains, of greater bulk though less weight, than the coal first put in. Such is the theory of gas-making; the manner of putting it into practice remains to be described.

The *retorts* now in use are generally long cast-iron vessels, semi-cylindrical in shape, with the flat side placed lowermost, and each holding from two to three bushels of coals. They are placed in ovens, in groups of three, five, seven, or more; and their mouths, where the coal is put in, stand out in front of the ovens. Just behind the mouth of the retort a pipe leads from it perpendicularly several feet; then, taking a sudden turn, it descends again, and enters a much larger pipe technically called the *hydraulic main*, which runs through the whole building, and receives the gas produced from all the retorts. This great main is generally about half full of the tar and water which leave the coal with the heated gas, and rise with it in the state of vapour, but are condensed by the coldness of the main. Into this mixture the end of the pipe dips, and is thus closed against a return of gas, which would take place if the supply should slacken. The gas is now made; but it is very impure, being mixed with water, tar, sulphuretted hydrogen, and other impurities. The tar and water are easily got rid of, little more being required for this purpose than to cool the gas and to allow the deposit to run off. The separation of the sulphuretted hydrogen can only be effected by some substance for which it has a chemical attraction, but which has no influence on coal gas. Such a substance is lime. The lime is used by being mixed up with water into a thin pasty mass, which is placed in a cylindrical vessel, and is constantly stirred by machinery. The gas as it comes from the condenser passes into the lime, and comes from it partially purified; it then enters another purifier, made and furnished precisely in a similar way; after that another; and often a fourth, in large works. When it leaves the last vessel, it may be considered pure.

In the manufacture of oil gas it is only necessary to project a small stream of oil into a red-hot retort, in which pieces of brick or coke are inclosed; the gas immediately passes off through another pipe, and may be at once received into the gasometer.

The *gasometer* employed in gas-works is a very large cylindrical vessel, closed at the top and open at bottom; it is suspended by a rope or chain, and weight, in a tank filled with water, in which it rises and falls freely, being kept in its place by guide-wheels. Two tubes pass under and through the water, reaching above its surface into the hollow of the gasometer; one of them comes from the purifiers to admit the gas into the gasometer, the other carries it off when wanted for use. The action of this part of the apparatus is simple; when the gasometer is near the top of the water, it is full of gas, which has no communication with the air, because the edge of the gasometer is under water. If now it be pressed downwards, which is effected by lessening the counterbalancing weight, the gas will be forced through the pipe which is to convey the gas out, and which must be left open for the purpose. When the gasometer reaches the bottom, it will be full of water, and ready to receive gas again, which is admitted through the other tube; the gasometer then rises to the top as the gas goes in, and may be pressed down again. In this way it is alternately filled and emptied. In most establishments there are many gasometers, some filling and others emptying. Some gasometers are now made so large as to have a capacity of 100,000 cubic feet. Some of them have the telescope construction; that is, there are two gas-holders, one within another, and both within the tank; the inner gas-holder is filled first, and then, by an ingenious contrivance, it elevates the outer one as the gas continues to enter.

Many other contrivances are used before the gas is carried to its destination: a *meter*, to measure it; a *governor*, to equalise the flow; a *pressure-gauge*, to indicate the resistance offered to its passage; and a *tell-tale*, to show the quantity manufactured during every hour.

The tubes which convey the gas to the streets are of course larger or smaller, according to the number of burners which they supply. The largest in use are about 18 inches in diameter, the smallest about a quarter of an inch. The street gas-pipes are laid in slightly inclined planes, and a vessel is placed at the bottom of each descent to receive and carry off any deposition which would otherwise clog the pipes.

The burners are of many different forms, and each has its technical name; such as the argand, the fan, the cock-spur, and the bat's wing. The arrangement and management of the burners in practical use are exceedingly varied.

It was estimated in 1848 that at that time there were 6,000,000 tons of coal consumed in England for gas-making; that one-twelfth of this, or 500,000 tons were used in London alone; that the production in London was 500,000 cwts. of coke, and 4,500,000 cubic feet of gas; and that the length of the gas-mains in London was upwards of 1500 miles. The length of gas mains must now be much greater, owing to the operations of rival companies.

The Western Gas Light Company has recently erected extensive works near Kensal Green. The gas is here made from Cannel coal, on a principle patented by Mr. Palmer. The retort-house is a remarkable building. It is a polygon of twelve sides, 166 feet in diameter, and contains 360 retorts. The processes, after the making of the gas in the retorts, differ in many respects from those usually adopted; principally in the mode of purifying the gas. The largest gas-holder or gasometer is of great magnitude; it is 135 feet in diameter by 25 feet deep, and will contain more than 350,000 cubic feet of gas.

The recent agitation of the gas question in London has led to the formation of a new company, by whom mains have been laid down through the principal streets, and a much lower rate of charge introduced than was before known. The mode of charge per cubic feet, as estimated by one among the many varieties of *meter*, is gradually superseding the old mode of charge per burner.

There have been some singular projects lately brought before public notice, relating to gas-lighting. One is White's *Water and Resin Gas;* which is proposed to be formed by heating small coal and fragments of iron in a retort; dropping water on the burning materials; and mixing the gases thus evolved with carburetted hydrogen formed by decomposing resin or fat. M. Jeannery's *Soap-suds Gas* was devised by him as an economical mode of using the soap-suds or scouring water of a woollen-factory at Mulhausen; the sediment from the suds is strained, mixed into a paste with quicksilver, dried, and distilled in a retort. A *Portable Gas* apparatus has been recently introduced, capable of making gas on a small scale for isolated buildings, workshops, &c. The furnace, retort, and purifying vessel can all be comprised within a space of eight or nine square feet. The fuel used is any kind of fat or grease; and on this account it is conceived that such an apparatus might be valuable for emigrants and other residents in sheep or ox-farming countries. Another novelty is Holliday's *Self-generating Gas-lamp*, which, according to the comprehensive eulogy of the inventor, is 'smokeless, portable, safe, durable, clean, of intense light, simple, requiring no attention when once lighted; no fixings, pipes, or meters, consequent on the old gas plan; nor liable to derangement; and is applicable to every purpose.' It comprises a cotton-wick through which naphtha flows; and this naphtha becomes converted into gas or vapour before it reaches the burner: it is a sort of medium between a spirit-lamp and a gas-lamp. An invention, which is now attracting much attention in America, is Payne's *Water-Gas;* this is a plan by which water is decomposed through the agency of an electro-magnet; and the hydrogen is carbonised by being passed through spirits of turpentine, whereby it is converted into carburetted hydrogen—all this is scientifically possible; but whether it is commercially advantageous remains to be seen.

Gas works have recently been constructed in Mexico; and as there were difficulties in procuring the usual sheet-iron gasometers, Mr. Hancock has ingeniously contrived a gasometer made of canvas saturated with india-rubber. These gasometers are cylindrical bags, 12 feet diameter by 15 feet high, formed by two thicknesses of strong canvas cemented together by indai-rubber solution. Iron rings are placed at intervals to keep the bags in shape; and the whole can be flattened to the form of a circular disc a few inches in depth for convenience of transport. The cost of each of these gasometers was about 55*l.*

In Mr. Rutter's recent Treatise on Gas-Lighting, it is stated that there are 560 proprietary gas-works in England and Wales, and 170 in Scotland and Ireland; that these represent a capital of ten and a half millions sterling; that they all, taking one with another, pay a dividend of about five per cent. (a remarkable approximation to that which railway companies show a tendency to converge to); that the quantity of gas produced is about 9000 millions of cubic feet annually; that the coal consumed to produce this gas is about 1,125,000 tons; that the cost of mould candles to produce a light equal to all this gas would be eleven millions sterling; that the cost of sperm oil for the same purpose would be thirteen millions sterling; that the price at which the gas is sold is about 1,600,000*l.*; and that the number of persons constantly engaged in various ways in the manufacture and its subsidiaries is about 20,000.

There is a constant supply of new patents relating to the manufacture of gas, to the forms of burners for consuming it, and to the construction of meters for measuring its quantity.

GASTRIC JUICE. This term is applied to the fluid, secreted from the interior of the stomach, which is the principal agent in digestion. The gastric juice is a transparent slightly viscid liquid, which, when obtained from the stomach of an animal while fasting, possesses neither acid nor alkaline reaction, but has a saline taste. During the process of digestion, on the contrary, it is distinctly acid. Gastric juice possesses strong antiseptic properties, suspending putrefaction, and restoring the freshness of the tainted meat: it also coagulates milk, which property is independent of the presence of any acid. But the most remarkable quality of the secretion of the stomach is its solvent effect, which will even act on nutritive substances out of the body.

GAUGING is the method of determining by actual measurement the number of gallons contained in any vessel intended to hold goods.

The books which relate to this subject give rules and formulæ, according to the shape of the vessel to be gauged.

GAUZE, is a light transparent cloth made of fine silken threads. The texture is different from that of plain weaving, in which the warp, or longitudinal threads, are always parallel to each other. The essential character of gauze-weaving is, that between each cast of the shuttle a crossing of the warp thread shall ensue, and thus the weft (which forms the cross-threads interlaced by the warp) is not brought into absolute contact with the the cross-thread immediately preceding. The intervals left between the interlacings cause that degree of transparency which, without such arrangement, could only result from a looseness of texture, incompatible with beauty and utility.

GEARING, or GEERING, in machinery, is a term somewhat indefinitely applied to a train of toothed wheels, or other similar contrivance, for transmitting motion. Couplings [COUPLING] may in some cases be considered a kind of gearing; and the expression 'to throw machinery *into* or *out of gear*' is commonly applied to the act of engaging or disengaging such connections.

GELATINE is the jelly of animals separate from the other constituents of the body. It is procured by the action of boiling water from bones, tendons, ligaments, membranes, and skin. *Glue-size* and *isinglass* are all varieties of gelatine. In France the gelatine of bones is extracted and employed as a part of the diet in hospitals, with excellent effect.

The substance sold in the shops as *animal gelatine* is obtained from bones, skins, or inferior isinglass. Gelatine has even been obtained from *fossil* bones: those of the mastadon. *French gelatine* is done up in small thin cakes and coloured with beet-juice, spinack-juice, or some other vegetable juice. Very pleasing specimens of gold-printing are now effected on thin and carefully-prepared sheets of coloured gelatine.

GEMS; JEWELS. Besides mere purposes of ornament, the hard and beautiful stones or crystals which constitute gems are applied to many useful purposes.

The application of Gems in watches is noticed elsewhere [JEWELLING OF WATCHES.] A well-known application of the *diamond* is in cutting glass [DIAMOND]. Gems are occasionally employed for the nibs of pens; thus, pens made of gold, with small *rubies* at the nibs, have been known to bear constant use for many years without any appreciable wearing. Many years ago Messrs. Hawkins and Mordan patented a new pen, of which the barrel was made of horn or tortoiseshell, and the nib of a small fragment of diamond or ruby, imbedded into the horn by pressure. From the high refractive power of the diamond, it is employed to form minute and exquisitely accurate lenses for the best kinds of microscope; Mr. Pritchard succeeded in forming such lenses, after the professed diamond makers had pronounced it to be impossible; and Sir David Brewster has had similar lenses made of rubies and garnets. In respect to the general operations of the lapidary or jewel-cutter, they could hardly be conducted without the aid of diamond-dust; for the general mode of cutting and shaping precious stones is to hold them against a very small metallic disc or wheel, which is rotating with great velocity, and to moisten the edge of this disc with oil and diamond dust; the exceedingly hard particles of diamond enable the disc to cut the stone or jewel.

The manufacture of *factitious* or *artificial* gems is a very curious department of art. Any one who glances round a shop containing cheap jewellery, will at once see that no inconsiderable portion of the glittering store is of this nature. Where pence instead of shillings are charged—or in some cases pence instead of pounds—it is easy to see that such must be the case. The brilliant transparency of the diamond, the purple of the ruby, the blue of the sapphire, the green of the emerald, the orange tint of the hyacinth, the transparent blood-red of the garnet, the variegated tints of agate and porphyry, the delicate subdued whiteness of the pearl — all are imitated. Most of these imitative gems are made of glass, called *paste* in this country and *strass* in France; it is of this substance that most artificial diamonds are formed; and by mixing various metallic oxides with the strass, the colours of other gems are imitated. The strass is not common glass, but is carefully made from a mixture of rock-crystal, potash, borax, and oxide of lead. The oxides of iron, antimony, arsenic, manganese, copper, chromium, cobalt, &c., are employed to give to the strass the requisite colour for other gems.

Many artificial gems are *doublets*, and deceive the eye by a curious contrivance. Two little fragments of glass, previously shaped, are cemented together with Venice turpentine and mastich, coloured with carmine, lake, Prussian blue, verdigris, or some other pigment; a humble sort of imitative gem is thus produced. A still humbler method, and the cheapest of all, consists in simply placing a bit of coloured metal foil behind the fragment of transparent glass.

The manufacture of artificial *pearls* is more remarkable perhaps than that of any other gem. They are made of glass beads, coated on the inside with a peculiar substance. A fine and narrow glass tube is held in a lamp at one end, while the workman blows through it from the other; the heated end is blown out into a globnlar form: and the workman breaks off the bead thus made and proceeds to form another. So rapidly is this done, that a workman can make 5000 or 6000 in a day. The pearl-liquor, or *Essence d'Orient*, is made by steeping in water the scales of the bleak or blay fish; and a single drop is dexterously blown into every bead by means of a little tube; the bead is shaken, to equalize the contact of the liquid with the interior surface. Each bead is then filled with wax, to strengthen it, and a hole is made through the wax to receive a string.—Artificial pearls are chiefly made in Paris.

GENE'VA, the smallest of the Swiss cantons, except Zug, is rendered productive by the industry of the inhabitants: about one-third of it is sown with corn, another third is pasture-land, a much smaller proportion is planted with vines, which yield an indifferent sort of wine ; the rest consists of woods, orchards, and gardens. The number of cattle is small. Manufactures and commercial speculations form the principal sources of wealth of the Genevese. Watches and jewellery are now the principal manufactures ; they are exported to France, Italy, the Levant, and other countries.

In the chief town, also called Geneva, the staple manufactures of the town are watches, musical boxes, and jewellery: of watches about 20,000 are made annually. All these manufactures will be illustrated by specimens at the approaching Exhibition.

GENEVA. This spirituous liquor is frequently confounded with *gin*. It is procured by the fermentation of the berries of the *Juniperus communis*. From the quantity of sugar which they contain they can easily be caused to ferment and yield a spirit. Geneva is a very powerfully stimulating liquor, containing a large proportion of alcohol : 337,042 gallons of proof Geneva were imported in 1850.

The more common English liquor, *gin*, for which *geneva* is a polite but incorrect name, is malt-spirit flavoured by a variety of herbs, fruits, seeds, sugar, &c.

GENOA. In the province of Genoa, in the Sardinian dominions, the industry of the inhabitants has turned to advantage every spot capable of cultivation ; but the produce is not equal to the consumption. The chief products are wine, chesnuts, oil, silk, cotton, hemp, citrons, oranges, lemons, figs, pomegranates, almonds, and other excellent fruits. Marble, alabaster, slate, limestone, asbestos, and coal are found : and a good deal of salt is made along the coast. The principal occupations, besides those indicated above, are trading by sea, fishing, and manufactures of jewellery, velvet, embroidered cambrics and muslins, cloth, furniture, both plain and ornamental, &c.

The town of *Chiavari* is famous for the manufacture of light willow chairs. *Borzonasca*, a large village inland among the Apennines, is important for its cloth manufactures. *Lavagna* has extensive slate quarries. *Rapallo*, a flourishing town, has manufactures of lace and oil. But the chief place in the province is *Genoa*, the famous old Italian city. At Genoa there is regular communication by steamers with Marseille, Barcelona, Leghorn, Civita Vecchia, &c.; and Genoese vessels trade to the Levant, the Black Sea, the Baltic, to America, and even to the coasts of the Pacific. The yearly importations amount to nearly three millions sterling, the exports to somewhat above two millions. The principal articles of export are silk, rice, hemp, oil, and paper. There are at Genoa manufactories of silk stuffs and velvet, woollens, surgical and optical instruments, jewellery and fancy articles, musical instruments, canvas, cordage, paper, and cotton.

GENTIAN. This useful plant is one among many species of *Gentiana*, common in the mountainous and sub-alpine districts of Switzerland, Germany, &c. Though the whole plant is bitter, yet, as this property is most concentrated in the root, that part only is used in medicine. This should be taken up in autumn, and is best when the plant is only one year old. It is generally cylindrical, often an inch thick at the summit, but below rather branched, of a dark or brown colour externally; internally fleshy and yellow. In commerce it is met with in pieces, cut longitudinally, from half a foot to a foot in length. The greater portion is procured from Germany; the specimens from Switzerland are generally thicker and darker coloured. When fresh it has some smell, which is almost entirely lost by drying. The taste is at first somewhat sweet, then purely and strongly bitter. Yellow Gentian-Root is often confounded with the roots of other species of this genns. Gentian-Root is a pure and excellent bitter tonic: it yields its properties to water, particularly when warm, to alcohol, and to wine.

GEOLOGICAL STRATA. Geology as a science is beyond the scope of the present work; but the connection between geology and manufactures is illustrated in such articles as ALUM; COAL; COPPER; GRANITE; IRON; MINING; SLATE; &c.

GEORGIA. The chief vegetable productions of this little-known province of the Russian dominions are grapes, cotton, madder, rice and saffron. There is every reason to believe that great mineral wealth is concealed in the mountains, but hitherto nothing of any importance has been discovered. The present commerce of these countries by the Caspian Sea is carried on from the ports of Derbend, Baku, Shamakhi, and Lencoran, to Persia, and to Astrakan. The overland trade is with Russia and Persia, as well as with Asiatic Turkey. The commerce by the Black Sea is carried on from the mouth of the Rion with Odessa and other Russian ports, as well as with Constantinople; and there is a small traffic with the highlanders of the Caucasus.

GEORGIA is also the name of one of the

United States. The cotton grown in a number of islands off the coast, known by the name of Sea-Island Cotton, fetches a higher price in the market than any other. In the southern districts of Georgia the temperature is suitable to the sugar-cane, orange, olive, fig, pomegranate, &c. The chief products are cotton and rice, of which large quantities are exported, but tobacco, as well as Indian corn, wheat, and other kinds of grain are also grown. The hilly region resembles, in climate as well as in products, the countries of Middle Europe, and much of it is covered with pines, and some of it with oak, hickory, cedar, and other trees. Iron and copper occur in several places in the hilly country, and the ore is said to be rich. Gold is found in the northern part of the state in considerable quantity. A few other industrial statistics of Georgia will be found under UNITED STATES.

GERMANY. This large and Important country, including the states which form the ZOLLVEREIN or German Customs Union, will occupy an important position at the Exhibition of the Industry of all Nations. In addition to the brief details given under the heads of the component countries, [BADEN; PRUSSIA; SAXONY, &c.], we will give the following abstract, relating chiefly to the arrangements for the Exhibition.

To carry out the intentions of the English commissioners it became necessary to establish special commissions in Berlin and the leading points of the Prussian monarchy—in Munich, Stutgardt, Dresden, Brunswick, Wiesbaden, and Frankfort, in order to digest and arrange the applications for space in the Crystal Palace. The results of the collective labours of these several commissions have been transmitted to Berlin, to be from thence forwarded to London. By these it appears that there have been 1,572 applications from the artistic and industrial producers within the Customs Union. Of this number 455 belong to the eastern, and 430 to the western provinces of the Prussian monarchy; 197 to the southern states, Bavaria, Wurtemberg, and Baden; 339 to the central German States, Saxony, Brunswick, the Anhalt, and Thuringian territories; and 151 to the states of western Germany, viz., the two Hesses, Frankfort, Luxemburg, Nassau, Birkenfield, and the principality of Lippe.

In a long and valuable report which the Prussian commission has issued a review is taken of the industrial resources of Germany, and of the power which she possesses to occupy a distinguished place in any Exhibition of produce and manufactures. Germany is the great store-house for zinc; in 1849 she produced 452,546 cwts. In the Rhenish provinces more than 1,800,000 cwts. of iron were made in that year. Anhalt, Westphalia, and the Rhenish provinces can produce specimens of lead and antimony; Prussia and Saxony can contribute copper; cobalt and smalt are found and abundantly used in Bavaria; coal is found in various parts of the Zollverein; salt is abundant; aluminous clays, pottery clays, building stones—in short almost every kind of mineral produce useful in the arts is to be met with in one or other of the German states; and the Prussian Commissioners have striven so far as lay within their authority, to have all these varieties represented at the Great Exhibition. The same may be said of vegetable and animal produce used in the arts. In the section of manufactures Germany is in a condition to produce a most varied assemblage, if her manufacturers put forth their best powers; while in machinery and in the fine arts, there is no reason why she should not equally maintain a high reputation.

As an example of the admirable way in which a systematic arrangement enables the Zollverein to contribute from each state what it can best contribute, we may take the department of *Drugs, Perfumery, Dyeing and Tanning materials* and *Printing materials.* Here we find that balsams and mountain herbs will be exhibited from Hirschberg. Perfumes by Farina (the elder and younger of Cologne), by other houses in that city, and in Dusseldorf. Specimens of woad—an article which was once of great commercial importance—will be sent from Erfurt, where the last remnant of its cultivation has been still preserved. Madder and madder dyes will be sent from Mulhausen; indigo carmine from Cologne; printing ink from Markttift (in Lower Franconia), and from Mayence; ink for copperplate printing from Frankfort-on-the-Maine; extract of gall-nuts from Ratisbon; alkaloid and Peruvian bark from Rhenish Hessen; printing colours from Leipsic; aquarell, Indian ink, and paints from Saalfeld, in Meiningen.

In respect to textile materials, fleeces will be sent from Limmenau, Dombran, Zwerbrodt, Hennersdorf, and Oberberg, all in Silesia; from several places in the Grand Dukedom Posen, Prussia proper, Brandenberg, and Saxony. Raw silk will be exhibited from Berlin and the Grand Dukedom Posen. Bristles of peculiarly good quality will be sent from Alach, in the neighbourhood of Erfurt. And so likewise in respect to tanned leather. Hides will be sent from Neckarsteinach (exhibiting a novel and peculiar process of tanning); from St. With, Muhlheim, Trier, Bingen, and Mayence. The eastern provinces, Berlin, Magdeburg, Stettin, Weissenfels, Mühlhausen, and Gera, will send samples. Lacquered leather, skins, &c., will be sent from Palgorsheim in Bavaria, Bingen, Offenbach, Frankfurt, Worms, and Mekenheim. Sheep skins and morocco leather will be sent from Wäldin, on the Lahr, in Baden; parchment and drumskins from Erfurt; instrument leather from Altenburg; saddlery, harness, Russian and strop-leather will be forwarded from Trier, Barmen, and the Marches. String-gut will be sent from Tilsit and Brüel; animal glue from Cologne, Mühlhausen, and Stralsund; grainy and fine-ground animal charcoal from Tilsit; carmine, and other animal dye-stuffs, from Elberfeld, Berlin, Liegnitz, and Schweinfurt.

Nearly all the other departments are equally rich in examples.

The shipping trade between Great Britain on the one hand, and the entire of Germany on the other (including both Austria and Prussia) exhibited the following results in 1850.—The vessels which entered British ports were 3,147, of 464,770 tons; while those which left British ports were 2914, of 405,218 tons.

GERMINATION is the first growth of a seed, the act by which it exchanges the condition of an embryo for that of a young plant. Attempts have been made to expedite the process of germination by steeping seeds in a weak solution of chlorine, but no practical advantage has been derived from the experiment. A more effectual plan has been found for hard-shelled seeds, such as those of the Acacia, namely, boiling the seeds for a period between one and five minutes.

GERS. In this department of France, wheat, maize, peas, beans, oats, and rye are grown in quantity more than sufficient for the consumption. Marble, building-stone, plaster-of-Paris, marl, potters' clay, and a fusible spar used in glass and china works are found. Some mineral springs, but no metals, are found in the department. Of manufacturing industry there is little. Coarse woollens, bricks, glass, pottery, and other articles of common necessity are made for home use. The quantity of leather tanned is in excess of the consumption, and some of it is exported. The other exports are brandy, wine, corn, flour, wool, poultry, and cattle. The quantity of wine produced in this department yearly is about 25 millions of gallons, about one-fourth of which is used for home consumption, and the greater part of the remainder is distilled into brandy, known by the name of Armagnac, from the former name of the district. In quantity of alcohol, the Armagnac brandies bear to the Cognac the ratio of about 8 to 9. Until lately, all brandies paid in France the same duty, whence came the general preference for Cognac, as it contained a greater quantity of alcohol. But for mildness and delicacy of flavour, and for a peculiarly agreeable aroma, both of which qualities improve with age, the Armagnac is a very superior spirit; and it has this advantage over Cognac, that it comes from the still at a strength ready for consumption, whereas Cognac requires reduction of strength, which process, it need not be said, endangers, and may mar, the peculiar excellencies of that spirit. The best qualities of Armagnac are distilled from two varieties of white grape, called *piquepoul* and *clairet*, in the cantons of Montréal, Eauze, Cazaubon, Manciet, and Nogaro.

GHEE, is a species of butter used by the natives of India. The milk, when first taken from the animal, is boiled in earthen pots for an hour or two; it is then allowed to cool, and a little curdled milk, called Tyre, is added to promote its coagulation. By the next morning the whole mass has been converted into tyre, or coagulated acid milk. This milk, well churned and boiled with water, produces the ghee, which is rather distasteful to Europeans.

GHENT, the capital of East Flanders, in Belgium, was formerly one of the most famous manufacturing and commercial cities in Europe. By the prosperity consequent on its manufacturing industry, the city increased so rapidly, that towards the end of the thirteenth century it exceeded Paris in extent and population. At the beginning of the fifteenth century, the number of its citizens employed in the manufacture of woollens is said to have amounted to 40,000. Ghent afterwards sank in commercial importance; but it has nevertheless continued to be a place of considerable note.

About 19,000 persons are employed in spinning, weaving, bleaching, and printing cotton. Sugar refining is carried on to a large extent in several establishments. Among the various other manufactures are those of lace, silk-weaving, salt-refining, paper making, woollen cloths, tanning, bleaching, soap-boiling, and pin-making.

GIBBONS, GRINLING. At a time when the beautiful art of carving is undergoing such a judicious revival, and is about being applied so largely to decorative purposes, it is right to pay a tribute of admiration to Grinling Gibbons, whose taste produced such exquisite specimens of the art nearly two centuries ago. Having been recommended by Evelyn to Charles II., he was employed by that monarch on the ornamental carving of the chapel at Windsor; he produced such emblematical objects as doves, pelicans, palm-branches, &c. For the choir of St. Paul's he carved much of the foliage and festoons belonging to the stall work, and those in lime-tree which decorate the side aisles of the choir. Much of his choicest work is at Chatsworth: mere ornament, indeed, such as foliage, flowers, feathers, &c.; but finished with such exceeding delicacy and truth, that the workmanship not only confers value on the material, but also on the subject. Occasionally he exerted his skill on subjects altogether trivial in themselves, and merely curiosities in art; such as feathers and pens, that might be mistaken for real ones. He presented to the Duke of Devonshire, on completing his labours at Chatsworth, a point-lace cravat, wrought up in wood. At Southwick, in Hants, he carved the embellishments of an entire gallery; and also those of a room at Petworth, which has generally been deemed one of his chief performances. Gibbons died in 1721.

GIBRALTAR. This celebrated rock-fortress is so much more important in a military than an industrial point of view, that we need say little of it in this place. The natural productions are wild rabbits, woodcocks, teal, and partridges. The trade of Gibraltar is not large. The British produce exported thither in 1849 amounted to 533,481*l*. The principal imports thence to Great Britain in the same year consisted of bark for tanning, gum Arabic, raw silk, and brandy. Mail steamers call at Gibraltar three times a month, from Southampton; these steamers keep up a communication between Gibraltar and Vigo, Oporto, Cadiz, Malta, Alexandria, and Constantinople. In fact, Gibraltar is a kind of half-way station on the overland route.

GILDING. In the gilding of articles of metal, pure gold is first combined or amalgamated with quicksilver, by boiling the gold in five or six times its weight of quicksilver. The boiling mixture is poured into cold water, by which it loses a great deal of its fluidity; and it is then squeezed through chamois leather. The amalgam has now the consistence of a stiff clay, has a greasy and gritty feel, and is in the most convenient state for being weighed out into portions requisite for each respective quantity of work. The main object of bringing the amalgam to this consistence and these proportions is to have it in a form convenient for division and apportionment, as well as for the sake of having a uniform standard by which to ascertain the quantity and value of the gold employed.

On the application, however, of this amalgam to the surfaces of metal, it is found that, as there is no chemical affinity between the substances thus brought into contact, the direct union of them is impossible. Nor can it be effected by allowing them to remain in contact for any length of time. The intervention of a solution of nitrate of mercury is therefore used. The solution is, by the operatives, termed 'quick-water.' When a piece of copper or brass is immersed in or brought in contact with this solution, its surface is immediately converted into an amalgam. To this amalgamated surface mercury and gold amalgam closely adheres, by means of the molecular attraction of the particles of the fluid metals for each other.

The manner in which this agent is applied in practice varies according to the description of articles to be gilt. If they are small, strong, and to be gilt all over, as copper buttons, buckles, and rings, a quantity of them, three or four pounds in weight, is put into a deep glazed earthen pan, or 'jowl;' to these are added about three or four tea-spoonfuls of the 'quick-water,' together with the requisite portion of amalgam. The whole is then thoroughly stirred with a brush or stick, till the amalgam entirely covers the surface of every article. When they are completely covered, they are by some gilders rinsed in cold water and dried by shaking in a bag of warm sawdust; while by others this part of the process is postponed to a later period of the operation, and they are put in their wet state, with the generated nitrate of copper still hanging about them, into the cage.

The 'gilding-cage' is made in a cylindrical form, and is generally about 18 inches in length by 9 or 10 in diameter. It is formed of coarse iron-wire gauze, supported by an external framework of iron, and furnished with a solid iron door at one extremity. It is provided with an axle, which extends to a length of about three feet from the end at which the door is placed, and is then terminated by a winch, and to a distance of five or six inches in the opposite direction. The articles under process of gilding are placed in this cage, and the door of it securely fastened; it is then suspended by its axle on two supports in an iron cylinder. The cylinder being previously heated by a coal fire beneath it, to such a degree as to be red-hot over a large proportion of its inferior surface, the cage is introduced, and the doors of the cylinder closed. The heated air contained within the cylinder soon raises the temperature of the substances immersed in it, and, as the cage is kept continually revolving, they have all an equable share of heat, and allow of a nearly equal evaporation of the mercury from all their surfaces. The hinder part of the cylinder is connected with a chamber and flue so constructed as to carry off the deleterious fumes of the mercury.

After the cage, with its contents, has been in the cylinder for a length of time, varying, according to the temperature at which it has been kept, from five minutes to a quarter of an hour, the mercury will be found to have entirely evaporated from the gilt surfaces. Another application of 'quick-water,' and another heating in the cage, are sometimes necessary to bring the surface to a proper state. The gilt articles are then 'heightened,' which is done by continuing to revolve them at the same high temperature within the cylinder, occasionally taking out the cage and shaking them together, that they may all have an equal share of the heat. The end intended to be effected is a partial oxidation of the surface of the gold. This partial oxidation occasions a slight difference of colour, which is perceptible by an experienced eye, and confers on the gold a degree of that orange colour which is so generally admired in golden and gilt articles.

Buttons and articles of a similar description are often gilt only on their tops, or on some other portion of their surfaces, while the remainder is left uncovered with gold, and of the native colour of the metal of which they are manufactured. This is accomplished by brushing them over the part to be gilt with a hard brush wetted with 'quick-water,' or by rubbing it with a piece of chamois leather similarly moistened. They are afterwards briskly rubbed with a dry brush. They are then put into the 'gilding-cap,' which is a white felt hat of a peculiar sort and shape. The amalgam is put into the gilding-cap along with them. The whole is then well shaken together for a few minutes, when the amalgam will be perceived clinging to the amalgamated parts of the goods, but leaving the remainder in their original state. They are then put into the cage, the mercury is evaporated, and they are afterwards heightened in the manner already described.

For larger goods, and where considerable portions of hidden surface are not required to be gilt, there are two modes of preventing the amalgam from adhering to those parts. One is to lacquer those parts, and, after the spirit of wine is thoroughly evaporated, to immerse them in the quick-water, and afterwards apply the amalgam. The other mode of applying the gold is to distribute the quick-water over the parts requiring it by a small brush or camel's hair pencil, and these then have the amalgam applied as before. If, as is sometimes the case, the goods are to be entirely covered, they are immersed at once in the quick-water. If the articles are of a kind which would be injured by revolving in the cage, the heating is effected by other means. Gilt articles are afterwards coloured to a deeper orange tint by the application of several chemical mixtures aided by heat.

Most gilt articles are burnished by a stone burnisher, formed of a polished piece of black hæmatite. This is fixed into a proper handle. Small articles, as buttons, &c., are placed in a lathe, and the stone applied to them as they revolve; and those that do not admit of this are burnished by hand on a table or bench.

Steel and iron are gilt by being immersed in a mixture of the nitro-muriate of gold with sulphuric ether or alcohol. By combining these liquids together, an alcoholic solution of gold is formed, from which the metal is precipitated by the iron or steel.

Ivory may be gilt by immersing it first in a solution of sulphate of iron, and afterwards in one of nitro-muriate of gold.

The edges of the leaves of books are gilt by applying to them, when squeezed in a press, a composition of four parts Armenian bole and one part sugar-candy, ground together with the white of eggs. Gold leaf is then laid on, and is afterwards burnished by rubbing with a polished piece of agate.

The gilding of porcelain is accomplished by the application of gold-leaf during the process of its manufacture, which is fixed by that intense heat which confers on this substance its enamel or glaze, and is afterwards burnished by a stone as above described.

Carved wood or wood-mouldings are gilt by laying on a foundation of whiting and size, and a further series of layers of gold-size, to which leaf-gold is made to adhere by wetting the surface underneath it: this is 'burnish-gilding.' In 'oil-gilding,' the gold is made to adhere by using oil-gold-size, instead of burnish-gold-size wetted with water. The former kind of gilding admits of being burnished with a smooth piece of agate, but not the latter.

Glass may be gilt by applying leaf-gold to the glass when wetted with a solution of isinglass.

For the process of Electro-Plating, which is now much employed as a substitute for metal-gilding, see Electro-Metallurgy.

GIN, or GYN, a machine employed instead of a crane, chiefly by artillerymen, for the purpose of raising guns, howitzers, &c. on their carriages. It consists of three round poles, placed up in a pyramidal form, within which a windlass and tackle afford the means of raising weights. A similar contrivance is often used in the coarser kinds of Engineering.

Gin is also the name of a machine employed in the United States for cleaning cotton; in which a number of revolving spikes disentangle the cotton fibres.

GINGER. This useful condiment is the rootstock of a plant which grows extensively in the East and West Indies, and other hot countries; it is one among many species of the genus *Zingibera.* The ginger-plant is propagated either by seeds or by cuttings of the root. When the cuttings are planted out in spring, which is the mode generally pursued in its cultivation, in the course of three or four months the rootstocks have a mild aromatic flavour; and it is in this state they are used for the preparation of what is called *preserved ginger.* At the end of the same year, or the beginning of the next, they are considered fit to yield the ginger of commerce. The rootstocks are then prepared in two ways: either by scalding them in boiling water, and drying them with artificial heat; or by peeling, and drying them in sunshine. The former method produces the *black ginger* of commerce, and the latter the *white ginger.*

About 14,000 cwts. of Ginger were imported in 1848.

GINSENG, is a root found in China, to which extraordinary properties have been ascribed. It is not only considered a universal remedy for all maladies, but is spoken of in the highest terms as a specific in particular circumstances. European botanists have, however, some doubts concerning the identification of the plant.

GIRONDE, the largest department of France, is rendered remarkable, in an agricultural point of view, by the district called the *Landes.* These landes are sandy heaths, of which only a small part has been brought into cultivation, and which occupy nearly half of the department, extending from the sea to the valley of the Garonne. The sands of the downs along the sea-shore, driven inland by the winds, gradually overspread a considerable tract of country, encroaching yearly from 70 to 80 feet along the whole extent of the coast. The increasing devastation has however been checked by planting broom and other shrubs, by means of which the sand has in most parts become fixed.

The department produces wheat, rye, maize, and millet. The rye and millet are raised in such parts of the Landes as have by dint of manure been brought into cultivation. Excellent fruits and a large quantity of hemp are grown. But the staple produce of the department is wine, of which 40 to 50 millions of gallons are produced annually. The finest clarets are from this part of France, as the growths of Lafitte, Latour, Château-Margaux, (these are in the Médoc district, on the left of the Garonne and Gironde, between Bordeaux and the sea) Haut-Brion, Sauterne, Barsac, and the Vins de Grave. The extensive woods which skirt the sea-coast, or pervade the Landes, consist chiefly of the pine (*Pinus maritima*), from which turpentine, pitch, and charcoal are procured, as well as timber for building and masts for vessels. The cork-tree is abundant. The inhabitants of the Landes make charcoal, or tend the numerous flocks, which obtain scanty food amid these sandy wilds. The chief manufactures of the department are calico, muslin, soap, chemical products, pottery, paper, vinegar, brandy, sugar, beer, leather, glass, &c. Ship-building is extensively carried on in Bordeaux. There are several tobacco factories, dyehouses, rope-walks; and a great deal of salt is made along the coast. The department contains upwards of 1,600 wind-mills and water-mills, about 50 iron-foundries, and 350 to 400 factories of different kinds.

The most important commercial town is Bordeaux. Next to this is *Blaye,* which has linen and woollen factories, glass-works, potteries, ship-building yards, and a considerable commerce in wines, brandies, spirits, oil, soap, fruits, ship-timber, staves, &c. Vessels put into the port of Blaye to complete their cargoes, and to supply themselves with provisions. *St. Vivien* has a great trade in salt, of which 6,000,000 bushels are annually produced from the neighbouring salt-works. At *Libourne* the manufactures are of cotton yarn, iron, leather, ropes, and nails; ship-building is also carried on. The trade is in wine and brandy, oak staves, iron, coal, and salt. *Castillon* has cotton factories, tan yards, rope-yards, and cooperages, and nails are manufactured to a considerable extent.

GLAMORGANSHIRE. This is the most commercial and manufacturing county in Wales. It has all the elements of increasing greatness. Its canals, its railways, its mines, its manufactures, its shipping, are all important. The chief rivers, such as the Taff, the Daw, the Ogmore, the Avon, the Neath, the Tawe, the Loughor, and the Cynon, are all made the media of bringing mining produce to the sea, or have been so until canals and railways were made. The Cardiff Canal extends from Merthyr Tydvil to a point a mile and a half below Cardiff; about 25 miles. The Aberdare Canal runs from the Cardiff Canal to near Aberdare;

about 6½ miles. The Neath Canal makes a short cut between two points on the Neath River; about 14 miles long. The Swansea Canal extends from Swansea Harbour into Brecknockshire; about 17 miles. The Penclawd Canal has a short course of 4 miles into the æstuary of the Burry. There are many railways for conveying minerals, among which are the Duffryn, Llynvi, and Porth Cawl; the Bridgend; the Aberdulais; the Oystermouth; and the Aberavon railways. The Tâf Vale Railway is both for passengers and goods; and so is the South Wales Railway, which now traverses the county from east to west.

The coal-measures occupy all the northern part of the county. The miner finds coal without any considerable descent; for the whole county is intersected with deep valleys in a north and south direction; and the miner, taking advantage of this, drives levels into the adjacent hills and obtains ironstone and coal. There are however many mines in valleys and low places. The coal which occurs in the county is of very varied quality and applicable to many different purposes. Ironstone is found in the valley of the Neath, but most abundantly near Aberdare and Merthyr, which last may be considered as the capital of the iron district of South Wales. There are some lead mines in the district occupied by the carboniferous limestone, near Cowbridge and Llantrisaint. Limestone is quarried in various places.

A few details illustrative of the produce and industry of this busy county will be met with under CARDIFF, MERTHYR, and SWANSEA. All the chief towns will contribute towards the Industrial Exhibition.

GLASGOW. This city and its river are among the wonders of our empire. Until 1775 the Clyde was only navigable by vessels of very small burthen; but since that time large sums have been expended in its improvement, the banks have been widened, the bed deepened, and the numerous sand banks and other obstructions to the navigation have been removed. There are now quays on both banks nearly a mile in length. Vessels drawing 14 feet of water can come up close to the lowest bridge. The revenue derived from the harbour in 1847 was 54,000*l*. Port Glasgow, situated 14 miles down the Clyde, belongs to Glasgow, and is governed wholly by the Glasgow magistrates.

Prior to the union in 1707, the commerce of Glasgow was limited to France and Holland, and consisted principally in the curing and exportation of salmon; but after that Glasgow entered so extensively into the trade with Virginia and Maryland, that before the commencement of the American War in 1776, which suspended the tobacco trade, the annual imports exceeded 50,000 hogsheads. At the present time the trade with the United States and the West Indies, and the timber trade with North America, are carried on upon a very large scale. There are about 80,000 tons of iron, and 130,000 tons of coal exported annually from the Clyde. The ships which are owned by Glasgow houses amount to about 600, with a tonnage of 150,000 tons.

Glasgow is also quite as much a manufacturing as a commercial town. With the exception of some large establishments near Aberdeen and Stirling, almost the entire cotton manufacture of Scotland is confined to Glasgow and the country surrounding it to the extent of 25 miles. The manufacture of linens, cambrics, &c., was first introduced into Glasgow about 1725, the power-loom in 1793, and at the present time the numerous establishments for weaving and spinning are on the most splendid scale. The School of Design at Glasgow is rendering valuable service in respect to the artistic department of textile manufacture. But, although the cotton manufactures have hitherto constituted the staple trade of Glasgow, those of iron become annually of greater extent; and from the peculiarly advantageous position of the town, in a mineralogical point of view, Glasgow is becoming more and more the centre of an iron district, especially since the introduction of the hot-blast in the iron manufacture. Shipping and steam engines are among the important manufactures of Glasgow.

Glasgow is the centre of a very extensive system of railways, which radiate from it in every direction.

The population of Glasgow has increased at a very rapid rate. It was only 14,000 in 1651; in 1811 it had increased to 112,330; in 1821 to 150,818; in 1831 to 207,393; in 1841 to 274,533; and it is supposed that the present population is more than 370,000.

In a series of papers recently given in 'Chambers' Edinburgh Journal,' and founded on personal researches, are some valuable statistics of the industry of Glasgow in 1850. We will note down a few of the more prominent features.

Glasgow itself was estimated in 1849 to contain 367,000 inhabitants; but it is the centre and metropolis of a district which now contains not less than 600,000. It is the metropolis for Paisley and its shawls; for the shipping of Greenock and Port Glasgow; for Kilmarnock and its carpets; for Pollockshaws, Barrhead, and Johnston, and their cotton spinning and weaving mills; for the vale of Leven and its bleach works; for the cotton manufacturing district of Lanark, Blantyre, and Campsie; and for the great iron mining and smelting district of Airdrie and Coatbridge.

The harbour of Glasgow is now fitted to accommodate vessels of 1,000 tons burden, and exhibits not less than 10,000 feet of quays. The largest merchant ships, from all parts of the world, can come almost into the very heart of Glasgow; and the finest mail steamships receive their engines from the quays within the limits of the town.

The following is given, by the authority alluded to above, as the result of a very careful enquiry into the textile factories, and those immediately dependent on textile manufactures, in Glasgow in 1850; giving the number of firms, and the number of operatives employed:—

	Firms.	Operatives.
Cotton and thread spinners	76	25,000
Power loom weavers ..	24	3,640
Hand loom weavers ..	..	3,200
Calico manufacturers ..	240	4,000
Gingham ,, ...	37	1,840
Muslin ,, ...	40	920
Silk ,, ...	22	720
Lace ,, ...	16	140
Carpet ,, ...	5	260
Shawl ,, ...	10	64
Woollen and worsted ,, ..	14	1,570
Rope and sail makers ..	45	840
Calico printers & bleachers	64	1,860
Dyers	50	1,400
Calenders and packers ..	48	500
Designers and block cutters	35	520
Cylinder engravers ..	6	750
Miscellaneous	150	700
	882	47,924

These numbers, even supposing them to be strictly correct, could only apply to one particular week; but they afford a useful approximation. Besides the operatives employed by these firms, there are many thousand clerks, packers, and porters. These numbers refer to Glasgow alone; the textile factories in Paisley and the other towns of the Glasgow district form a wholly distinct series.

Vast as these textile manufactures are, they only employ two-thirds of the regular operatives of the Glasgow district, the other third being employed chiefly in the mineral and chemical manufactures. On the east and south of Glasgow the district is bristled with iron furnaces. There are in this district about 100 firms engaged in the smelting and casting operations, by whom 600,000 tons of iron are now annually manufactured. At the Govan and Calder works alone (Messrs. Dixon's) are no less than 13 blast furnaces; at Gartsherrie (Messrs. Baird's) 16; at Dundyvan (Messrs. Wilson's) 10; at Tollcross (Messrs. Dunlop's) 9; at the Monkland works 6.

The customs' receipts at Glasgow in 1850 were 645,669*l.*; and those of Greenock (which in many respects may be deemed a second port for Glasgow commerce) 383,487*l.*; making a total of upwards of a million sterling for the Clyde ports.

The chemical works are another mighty element of Glasgow industry. At the St. Rollox works of Messrs. Tennant chemical manufactures are conducted on a scale which no other establishment in the world, we believe, equals; and there are many others of considerable magnitude.

Glasgow is well fitted to take a commanding position in any Exhibition of the World's Industry.

GLASS MANUFACTURE. This transparent and beautiful substance, though exceedingly brittle while cold, is rendered so flexible and tenacious by a high degree of heat that it may with the utmost facility be moulded into any form. It is so ductile while heated, that it may be spun into filaments of the greatest conceivable fineness, and these when cold are pliant and elastic in a high degree.

The time at which glass was invented is very uncertain. The ancient Egyptians were certainly acquainted with the art of glass making. The manufacture was long carried on at Alexandria, from which city the Romans were supplied with that material; but before the time of Pliny the manufacture had been introduced into Italy, France, and Spain. Glass utensils have been found among the ruins of Herculaneum. The application of glass to the glazing of windows is of comparatively modern introduction. The earliest manufacture of flint glass in England was begun in 1557, and that of plate glass in 1673. The principal seat of the manufacture in England is at Newcastle-upon-Tyne and the neighbouring town of Shields; next in importance is Stourbridge; then the works in and near Liverpool, including the Plate-glass Company's establishment at Ravenhead; next follow Bristol, Warrington, Birmingham, Leeds, and London. There are several manufactories in Scotland and Ireland.

There are five distinct kinds of glass, which differ from each other in regard to some of the ingredients of which they are made, and in the processes of manufacture. These kinds are *flint glass*, or *crystal; crown glass*, or

German sheet glass; broad glass, or *common window glass; bottle glass;* and *plate glass.*

The principal ingredients used for the production of each of these kinds of glass are silex, or flint, or sea sand, and an alkali. The differences in the various kinds result from the description of alkali employed, and from the addition of certain accessory materials, usually metallic oxides. The alkali employed for making fine flint glass is purified pearlash. Barilla, kelp, and wood ashes, combined with many impurities, are used for making inferior kinds of glass: the impurities even assist towards fusing the silex. Coarse alkaline substances all contain iron in some degree, and it is to the presence of this metal that the green colour of common glass is owing.

Flint Glass, known in other countries under the name of crystal, is the most generally useful, the most brilliant, and the heaviest description of glass. The following is one among many ratios of ingredients:—

120 parts fine clean white sand,
40 „ well purified pearlash,
35 „ litharge, or minium,
13 „ nitre; and a small quantity of the black oxide of manganese. The litharge is employed to assist the sand to melt; nitre is used to dissipate carbon, and manganese to dissipate colour. The ingredients are intimately mixed together before they are put into the crucibles or pots, which are previously placed in the furnace. A very strong and long continued heat is necessary, not only for the perfect fusion and amalgamation of the materials, but also for the discharge of the impurities which they contain. The glass is cooled down to a pasty mass, and then wrought. There is perhaps no process of manufacture which excites so much the surprise and admiration of a stranger as that of fashioning flint glass into all the various objects of convenience and ornament for which it is employed. To see a substance, proverbially brittle, blown by the human breath, pulled, twisted, cut, and then joined again with the greatest facility, never fails to strike with astonishment those who are unaccustomed to the sight. The tools with which all these operations are performed are of the most inartificial description, and do not appear to have received any notable improvement from the earliest records of the manufacture.

Crown Glass.—This is the best description of window glass; and one recipe for it is:—

120 parts of white sand,
60 „ purified pearlash,
30 „ saltpetre,
2 „ borax,
1 „ arsenic,

with the addition of a minute quantity of manganese. Crown glass is made by blowing, in the form of circular plates of 50 to 60 inches diameter. A quantity of glass in the pasty state is collected upon the end of a hollow iron tube; and this glass is then converted, by blowing through the tube, into a hollow globe of the requisite thickness. This globe is transferred to the end of the rod, and after several re-heatings it is twirled round by the workman somewhat in the manner that a mop is twirled to drive off the moisture; with this twirling the softened material is continually driven off from the centre by the centrifugal force, until at length the whole substance is converted into a flat disc of circular form, and, except at the centre, where it is attached to the rod, of a uniform thickness.

Broad Glass is an inferior kind of window-glass, made with a cheaper kind of alkali. It is blown to a cylindrical form, cut open, and spread into a flat plate.

Bottle Glass is still inferior in quality to broad glass, the alkali employed being the cheapest that can be procured, with the addition of a portion of lime to assist fusion. Bottle glass is fashioned by blowing into hollow moulds.

Plate Glass is both blown and cast. The following proportions and ingredients are given by Parkes:—

Lynn sand, well washed and dried	720 parts.
Alkaline salt, containing 40 per cent. of soda	450 „
Lime, slaked and sifted .	80 „
Nitre	25 „
Broken plate glass . .	425 „
	1700 parts.

It requires 40 hours' exposure to the full heat of the furnace to reduce the materials to the proper state of fusion and vitrification. When this is accomplished, the glass is transferred from the melting pot to a large vessel called a *cuvette*, and from this to a large casting table, where it is distributed by means of a roller over the whole surface of the table, bars of metal being placed at each side along its entire length, and across the bottom, in order to prevent the glass from running upon the floor. The casting of large plates of glass is one of the most beautiful processes in the arts: the large mass of melted glass, rendered in a high degree luminous by heat, exhibits changing colours in the sheet after the roller has been passed over it.

When annealed, which all glass requires to be before using [ANNEALING], the plates of glass are ground with powdered flints, and then with emery powder, and are afterwards polished with oxide of iron laid upon woollen pads. Plate glass is silvered for looking glasses with an amalgam of mercury and tin-foil.

There has perhaps never been known a more signal effect produced on a manufacture by fiscal arrangements, than that which has resulted from the removal of the glass duty in 1846. What is the amount of this effect, it would be difficult to say, as there is no account now kept by the excise of the quantity of glass manufactured. Until 1846 the excise regulations were most vexatious to the glass manufacturer. The annealing ovens were under lock and key, and no glass could be put in or taken out of them without the presence and sanction of the excise officers. The efforts of the manufacturers to improve their wares were paralysed; for they could not even institute experiments without paying duty for the glass wasted in so doing. The sum realised to the revenue in 1845 amounted to 115,000*l*. The export has very largely increased since the remission of the excise duty; in 1850 it amounted to 336,614 cwts. of flint, window, and bottle glass, besides plate glass, which is estimated by measure and not by weight: the value of all the four kinds was 308,346*l*.

It may be safely asserted, that without the remission of the glass duty in 1846, the Palace of Industry in Hyde Park could not have been constructed on Mr. Paxton's plan; whatever the building might else have been, it would not have been a 'crystal' palace. Until the duty was removed, the successful experiments in making large sheets on the *broad glass* method would hardly have been made; and it is only on this method, and at the cheap prices which now prevail, that the acres of glass could have been provided for this beautiful structure. The vast establishment of Messrs. Chance at Birmingham is now one of the most interesting centres of industry in the country: the many hundreds of men employed; the surprising skill with which the workmen (Englishmen and Frenchmen working in harmony) make the cylinders which afterwards become sheets of broad glass; and the rapidity with which the immense supply for the Hyde Park building has been furnished — all have tended to render these works lately well worthy of study.

Nor are there wanting examples of the beneficial results of the fiscal change in other directions. *Dairy* glass is now an important article; and we find that in London and other large towns establishments have been opened for the sale of glass — coarse but strong — fashioned into an amazing variety of utensils and implements. Rough plate for skylights and conservatories, and rough plate for floors (as much as an inch and a half in thickness); glass tiles and slates; perforated glass for ventilation; glass milk pans, cream pots, lactometers, preserve jars, pastry slabs, rolling pins, glass syringes, leech glasses, and pill-making slabs; bee glasses, propagating glasses, wasp traps, cucumber glasses, hyacinth cups, flower dishes, crocus glasses, peach and grape protecting glasses, and fern shades; glass cornice poles; glass churns, glass syphons — these are some among the many articles now made of this beautiful and useful substance.

An important modern application of glass is as a material for pipes, in cases where iron, stone, and wood would be less efficient. Several hundred feet of glass pipes have been recently laid down on the estate of the Earl of Zetland.

A very remarkable and brilliant effect is now produced in cut glass by coating parts of the interior with silver, on a plan recently patented. A brief notice of this, and of the ordinary mode of silvering looking glasses, will be found under SILVERING.

The glass manufacturers of the Tyne district are expected to make a worthy display of their art at the approaching Exhibition. They will send specimens of plate glass in all the stages of progress, some of them alnost unparalleled in size; and the other kinds of glass will be fittingly illustrated. From St. Helen's we are promised other specimens; and there can be little doubt that this department of our national manufacture will be well represented. Our manufacturers, in return, will be eager to see what Bohemia and Bavaria and France can produce, in this beautiful branch of industry.

GLASS PAINTING, or STAINING, is practised as follows: — The design having been first drawn on paper, the glass is laid thereon, and the outline traced with a coloured fusible glass. The parts intended to be yellow, orange, or red, are then coated, either on one or both sides, according to the tint required, with a mixture composed of silver, antimony, and oxide of iron. The glass is then exposed to a red heat, in which process the tracing colour is fused, and adheres permanently to the glass. The mixture of silver and antimony stains the glass, but does not melt, so that the oxide of iron, which is in the state of dry powder, may be brushed off, leaving the glass coloured, but as transparent as before. The other colours, composed, as for enamel [ENAMEL], of a very fusible glass coloured with metallic oxides, are then added, and the glass is again fired. In subjects which are too large to be executed in one piece, the joinings are carefully arranged to run in the outline; and for draperies, &c., the artist avails himself of glass already coloured in the manufacture (pot metal), and which requires shadowing, diapering, &c.

In *painting* glass, the colours applied remain on the surface of the glass, and interfere with its transparency. In *staining* glass, the colour sinks into the glass a very small distance, but leaves it as transparent as before. The only colours which modern artists are able to produce by staining are yellow, orange, and red. There are two modifications of painting or staining on glass, called melting and embossing, produced by special chemical means.

The glass stainers of St. Helen's, Newcastle, and other towns, are preparing large and fine specimens of their art for the Great Exhibition.

GLAUBER SALT occurs as a mineral body. It is found as an efflorescence, and also crystallised; whitish, translucent, and having a cool bitter taste. It is a hydrated sulphate of soda.

GLAZE; GLAZING. One of the modes in which the word *glazing* is employed is to designate the fixing of panes of glass into windows. As a manipulative art, glazing is very simple; the putty with which the glass is fixed is a mixture of whiting and linseed oil; and the glass itself is cut by a diamond—though (see COKE) it seems as if a much less costly material may be made available for this purpose. The largest and most interesting specimen of glazing ever yet executed is perhaps the Glass Palace in Hyde Park: the contrivances for enabling the workmen to pursue their avocations in the most difficult positions have been truly admirable for their simplicity and efficiency.

In the earthenware and china-ware manufacture *glaze* is the name of the vitrified gloss or varnish applied to the ware. The nature of this kind of glazing is noticed under POTTERY and PORCELAIN.

GLIADINE, is a peculiar azotised vegetable matter which exists in small quantity with the gluten of wheat, and to which its adhesive properties are owing. It may be separated by boiling alcohol, together with a thick fluid oil which is separable by ether. Gliadine is adhesive, and is insoluble in water. When dried, it is hard and translucent like horn; it dissolves in acetic acid and solution of potash.

GLOBE-MAKING. This is in many respects a remarkable branch of art. It is said that there are only four globe-makers in England and one in Scotland; and that the annual sale of globes is only about a thousand pair. The price of a pair of globes varies from six shillings to fifty pounds. But from the smallest 2-inch, to the largest 36-inch globe, a systematic process is carried on at every step of its formation. The following account of the manufacture is condensed from Dickens' 'Household Words.'

Globes are made of paper and plaster, shaped upon a model or mould. This mould is turned out of a piece of wood, and has for an axis a piece of iron wire at each pole. On this mould a boy will in a very short time form a pasteboard globe. He first covers it entirely with strips of strong paper, thoroughly wet, which are in a tub of water at his side. The slight inequalities produced by the over-lapping of the strips are immaterial. The saturated paper is not suffered to dry; but is imediately covered over with a layer of pasted paper, also cut in long narrow slips. A third layer of similarly pasted paper—brown paper and white being used alternately—is applied; and then a fourth, a fifth, and a sixth. Here the pasting process ends for globes of moderate size. For the large ones it is carried farther. This wet pasteboard ball has now to be dried,—placed upon its axis in a rack. The extrication of the wooden mould from its prison then takes place. The wooden ball, with its solid paper covering, is placed on its axis. A sharp cutting instrument, fixed on a bench, is brought into contact with the surface of the sphere, which is made to revolve; and the pasteboard ball is quickly cut in half. Within every globe there is a piece of wood—we may liken it to a round ruler—of the exact length of the inner surface of the sphere from pole to pole. A thick wire runs through this wood, and originally projected some two or three inches at each end. This stick is placed upright in a vice. The semi-globe is nailed to one end of the stick, upon which it rests, when the wire is passed through its centre. It is now reversed, and the edges of the card rapidly covered with glue. The edges of the other semi-globe are instantly brought into contact, the other end of the wire passing through its centre in the same way, and a similar nailing to the stick taking place. We have now a paper globe, with its own axis.

The paper globe is next placed on its axis in a frame, of which one side is a semi-circular piece of metal. The workman applies to the surface of the globe a coating of whiting, glue, and oil; and this is repeated five or six times, with intervening periods of drying. The globe is therefore by this time a paper sphere enveloped in another sphere of plaster. If it does not revolve quite equably on its axis a few shot are introduced into the too-buoyant portions.

What may be called the artistical portion of globe-making here commences, in which the intelligent labour of females is available. The workwoman takes the polished globe in her lap, for the purpose of marking it with lines of direction for covering it with engraved strips; which lines are those of latitudes and longitudes. These lines are struck with great rapidity, and with mathematical truth, by an instrument called a 'beam compass.' The sphere is now ready for receiving the map, which is engraved in fourteen distinct pieces. The arctic and antarctic poles form two circular pieces, from which the lines of longitude radiate. These having been fitted and pasted, one of the remaining twelve pieces, containing 30 degrees of longitude and 133 degrees of latitude, is also pasted on the sphere, in the precise space where the lines of longitude have been previously marked; its lines of latitude corresponding in a similar manner. The paper upon which these portions of the earth's surface are engraved is thin and extremely tough. It is rubbed down with the greatest care, through all the stages of this pasting process. We have at length a globe covered with a plain map, so perfectly joined that every line and every letter fit together as if they had been engraved in one piece,—which, of course, would be absolutely impossible for the purpose of covering a ball.

The artist who thus covers the globe, called a paster, is also a colourer. By long experience the artist knows how the various boundaries are to be defined, with pink continents, and blue islands, and the green oceans, connecting the most distant regions. The globe has now to be varnished with a preparation technically known as 'white hard,' to which some softening matter is added to prevent the varnish cracking. Four coats of varnish complete the work.

The globe has to be mounted. The brass meridian ring has been previously accurately graduated; this operation is comparatively rapid; but for the largest globes it involves considerable expense. After great trouble Messrs. Malby have succeeded in producing cast-iron rings, with the degrees and figures perfectly distinct; and these applied to 36-inch globes, instead of the engraved meridians, make a difference of ten guineas in their price. For furniture they are not so beautiful: for use they are quite as valuable. The axis of the globe revolves on the meridian ring, and of course it is absolutely necessary that the poles should be exactly parallel; this is effected by a little machine which drills each extremity at one and the same instant; and the operation is termed poleing the meridian. The mounting of the globe,—the completion of a pair of globes,—is now handed over to the cabinet-maker.

Globes have occasionally been constructed of very large size. Such a one was designed in 1823 by an ingenious mechanician, M. Delangard. The spectator reached a circular gallery in the centre of the globe by a winding stair. The sea was represented by transparencies coloured and varnished; the land being opaque and tinted, as in ordinary globes. Another was constructed in 1844 by M. Charles Guérin, who constructed another in the Champs-Elysées. It was placed within an ornamental house of wood; the globe was more than 30 feet in diameter, was viewed by the spectators from a central gallery, reached by a double-winding stair; an iron framework representing the lines of latitude and longitude, gave the outline of the globe, and supported the varnished calico which stretched over the entire surface, and upon which the map was painted. This exhibition was called the Géorama.

But Mr. Wyld, the eminent map publisher, is about to eclipse all previous attempts in this direction. He has paid 3000*l*. for the lease, for a definite period, of the central area in Leicester Square; and on this area he will construct a building for exhibiting an immense globe, 60 feet in diameter. There will be two galleries within it for spectators, at different elevations. The countries, oceans, &c. will not be merely coloured: they will exhibit many of the features of physical geography. The mountains will be in relief. The globe will be formed of ribs of zinc, in the direction of the meridians, and will be covered with some convenient woven material, on which the lines and colours will be depicted.

GLOUCESTERSHIRE. The commerce of this county is greatly aided by canals. The Thames and Severn Canal connects those two great navigable rivers; it commences at Lechlade, and joins the Stroudwater Canal at Wallbridge, near Stroud; its length is about 30 miles; it has a tunnel at Sapperton 2⅜ miles long. The Stroudwater Canal commences at the Severn, near Framiload, and terminates in the Thames and Severn Canal at Wallbridge; its length is 8 miles. The Hereford and Gloucester Canal is open from Gloucester to Ledbury, 18 miles. The Gloucester and Berkeley Canal, by which the navigation up to Gloucester is shortened 11½ miles, extends from Gloucester to the Severn near Berkeley, 16¼ miles. Portions of the Midland Railway and of the Great Western Railway pass through this county.

The south-west corner of the county is occupied by the coal field of the Forest of Dean. Iron appears to have been wrought here during the Roman occupation; and we find it recorded in the reign of Edward I. that there were then 72 furnaces for smelting iron in the Forest. The iron ore here is not very rich in metal, and it is now therefore comparatively little worked. Two hundred pits have been opened for the coal in different parts of the Forest, but the coal is not considered so good as that of Staffordshire. Lead ore is found in many parts of the county, but not in sufficient quantities to defray the expense of working. Pyrites, or sulphuret of iron, has been found in great abundance. Lapis calaminaris, petrosilex, barytes, quartz crystals, gypsum, limestone and freestone are met with in the county.

The manufactures are numerous and important. The cloth manufacture is extensively carried on at Wotton-under-Edge, Stroud, Minchinhampton, Bisley, Uley, Norsley, Cam, Painswick, Rodborough, and King's Stanley. At Frampton, Cotterell, Winterbourn, Bitton, and Westerleigh, there are considerable hat and felt manufactories, and some persons are also engaged in stocking-making. The last-mentioned manufacture is extensively pursued at Tewkesbury, where frame making likewise gives employment to some of the inhabitants; some of them are also engaged in lace-making. In Gloucester and in the suburbs of Bristol there are pin manufactories. At Newland and English Bicknor tin plates are made. Edge-tools are made at Cooley; and glass bottles in the suburbs of Bristol. At Moreton and a few other places cheese cloths and other articles of linen are made. The large commercial city of Bristol has also several manufactories, and works in brass, iron, floor-cloths, lace, hats, soap, vinegar, &c.

Flax was formerly cultivated to some extent in the Vale of Gloucester, but the belief that it was a very scourging crop, and returned nothing to the land, has led to the prohibition of it in leases. Teasels are raised for the use of the manufacturers of woollen cloth, but not to such an extent as they were once. Gloucestershire is essentially a dairy country, and has been always renowned for its butter and cheese. There are fine orchards in different parts of the Vale and Forest districts, and some very good cider and perry are made in the county. *Gloucester*, the chief town, (if we except Bristol, half of which is in this county) is a flourishing commercial place, which has water communication with most parts of the kingdom. In the year 1850 there were 491 vessels arrived at the port of Gloucester, with cargoes from foreign countries; and the customs revenues at the port amounted to 94,082*l*. *Cheltenham* is more notable for its fashion than for its manufactures. At *Lechlade* commences the Thames and Severn Canal, and the Thames first becomes navigable for barges of 70 or 80 tons' burden; in consequence of these favourable circumstances, the place has much traffic in the produce of the country and in London goods. At *Marshfield* a considerable quantity of malt is made for the supply of the Bath and Bristol brewers. The borough of *Stroud* comprehends an important part of the west of England clothing district. The peculiar features of this district are, the situation of the mills on streams in deep ravines, the scattered and irregular manner in which the houses are built on the hill sides, and the contrast between the high land, in many cases with few inhabitants, and the valleys, studded with houses and thickly peopled. This district comprehends the market-towns of Stroud, Minchinhampton, Painswick, and several other places. The site of Stroud was early chosen by clothiers and dyers, and the town has been improving of late years. At *Tewkesbury* the chief manufacture is of cotton and lambs'-wool hosiery.

There were in the county of Gloucester, in 1850, one cotton factory, 49 woollen spinning factories, 11 woollen weaving factories, 20 factories for mixed woollen goods, 3 flax factories, and 7 silk factories—the whole employing 8618 persons.

GLOVE-MAKING. The great seats of the leather glove manufacture in England at present are—Worcester, Woodstock, Yeovil, Leominster, Ludlow, and London. The number made every year in the town and immediate neighbourhood of Worcester has been estimated to exceed 6,000,000 pairs. It is almost entirely a hand manufacture. Worsted gloves are made chiefly in and near Leicester, cotton gloves in Nottingham, and silk gloves in Derby. The manufacture of these three kinds is closely connected with that of stockings, and will be found briefly noticed under Hosiery Manufacture.

In the year 1850 there were 3,261,061 pairs of leather gloves imported, chiefly from France. Very few English-made gloves are exported.

GLUCI'NIUM is the metallic base of an earth or oxide (*Glucina*) discovered by Vauquelin in 1798. It is a fine powder of a deep gray colour, very difficult of fusion. When burnished, it acquires the metallic lustre. It suffers no change by exposure to air or water, at common temperatures; but when heated to redness it burns, combines with oxygen, and is converted into glucina. *Glucina*, the only known oxide of the metal, is a light white powder, inodorous, tasteless, infusible, insoluble in water. *Chloride of Glucinium* is colourless, sweet, very fusible and volatile, and sublimes readily in white brilliant needles; it deliquesces in the air. Glucinium combines also with bromine, iodine, and sulphur. The salts which glucina forms with acids are not important. They are all colourless, except the chromate, which is yellow; the taste is sweet, and hence the name of the earth, and slightly astringent. This rare metal has not yet been of much practical value in the arts.

GLUE. This useful substance is prepared from the clippings of hides, hoofs, &c., by washing in lime-water, boiling in water, skimming, straining, evaporating, cooling, and drying. When properly prepared, glue is of a deep brown colour, translucent, and free from spots and clouds. When required for use, it is broken into pieces, and steeped for about 24 hours in cold water, by which it swells and softens; after this it is heated in a glue-pot, which is a water-bath made for the purpose.

Another variety of glue, which is much softer and called *size*, is obtained from parchment cuttings and several animal membranes.

Jeffery's *Marine Glue*, introduced within the last few years, and so remarkably adhesive for many purposes, is not strictly glue: it is a cement.

GLYCERIN is a nearly colourless viscid liquid, obtained from olive oil; it cannot be made to crystallise. Its taste is extremely sweet. It mixes with water in all proportions, and is not fermentable.

GOAT-SKINS. Goat-skins, both with respect to the *felt* which forms the foundation and the *hair* which forms the surface, are useful materials of manufactures. There were 241,333 goat-skins imported in 1848: while there were foreign manufactures of goat's hair imported to the value of 57,994*l.* in 1848, and 93,306*l.* in 1849.

GOLD. This costly and beautiful metal has been known from the remotest antiquity, and has been universally employed as a medium of exchange. Although the quantity of gold which is found, when compared with that of other metals, is small, yet it occurs in greater or less abundance in almost every part of the globe. It occurs in the native state, and combined with silver, and frequently mixed with metallic sulphurets and arseniurets. The greatest quantity of gold, next to that recently discovered in California, is the produce of South America; the richest mines of Europe are those in Hungary, and of Asia, in Siberia; it has been found also in the sands of the Rhône, the Rhine, and the Danube; small quantities are occasionally found in the stream tin-works of Cornwall, in Wicklow in Ireland, and in the Lead Hills in Scotland. In 1826 one piece of native gold was found in Siberia weighing 26 lbs.

Native gold occurs crystallised, capillary, and massive; the primary form is a cube. Gold not unfrequently occurs alloyed with silver, and this compound, where the quantity of silver is considerable, is known by the name of *electrum.* Gold is separated from the various substances with which it is mixed by the process of *amalgamation;* this consists in combining it with mercury, and heating the amalgam formed, so as to distil the mercury, which is thus repeatedly used for the same purpose.

Gold is of a fine yellow colour, and is susceptible of a high degree of polish. It is nearly as soft as lead. For its malleability, see GOLD-BEATING. It is also exceedingly ductile; a single grain may be drawn out into 500 feet of wire. Gold suffers no change by exposure to air or moisture, even when heated. It melts at about 2016° of Fahr., according to Daniell's pyrometer; when in fusion, it appears of a brilliant green colour.

Most metals are susceptible of combining with gold to form *alloys*, of which the following are the chief. *Arsenic* and gold form a brittle gray substance. *Tellurium* and gold, but mixed also with a considerable portion of lead, occur in combination, constituting three varieties known as *graphic tellurium*, *yellow tellurium*, and *black tellurium*. *Antimony* and gold form a pale yellow finely grained substance. *Manganese* and gold form a pale brittle alloy. *Zinc* and gold yield a pale green alloy, very brittle. *Tin* and gold form a pale yellow alloy, slightly flexible. *Iron* and gold form an alloy of a pale yellowish-gray colour; it is very ductile, and may be rolled from the thickness of three-quarters of an inch to that of a guinea. *Nickel* and gold form a brittle yellow alloy; as do *Cobalt* and gold. *Copper* and gold combine in all proportions, with little alteration of the colour of the gold; the density is diminished, but the hardness is increased. *Bismuth* and gold form a brittle yellow alloy. *Silver* and gold combine well; the resulting alloys are very ductile. Silver and copper are both used as alloys in gold coin. *Lead* and gold yield a very brittle alloy. *Mercury* and gold form an *amalgam* much used in the arts [AMALGAM; GILDING]. *Platinum* and gold form an alloy in which the colour of the gold is destroyed.

The *Salts* of Gold, formed by the combination of the metal with acids, are not much employed in the arts, and are mostly of an unstable character. A compound of gold with peroxide of tin forms the beautiful *purple powder of Cassius.*

GOLD-BEATING; GOLD-BEATERS' SKIN. The peculiar substance called *Gold Beaters' Skin* is prepared from the outer or peritoneal membrane of the large intestine of the ox, by successive processes of soaking, scraping, washing, alkalising, &c. The manufacture, called in France (where it is chiefly carried on) *boyauderie*, is an exceedingly dirty and offensive one; but the resulting product is a remarkably fine and beautiful kind of membrane.

Gold beating is a process whereby gold is brought to the state of very fine leaves, for use in various kinds of gilding. The remarkable ductility of gold—a quality possessed by it to a greater degree than by any other known substance—is here taken advantage of to the fullest extent, as a means of limiting the quantity of this costly material required on a given surface.

It is by a combined process of rolling and hammering that the attenuation of the gold is produced. An ingot of gold is milled or rolled, to a thickness of about $\frac{1}{800}$ of an inch; and this riband is then hammered. The hammering does not take place on the gold itself; but thin membranes are interposed between the hammer and the gold. These membranes are of three kinds: an outside covering of common parchment: a set of leaves made of very fine and smooth calf-skin vellum; and another set made of gold-beaters' skin. The riband of gold is cut up into small pieces, each measuring exactly an inch square; and 150 of these are beaten or hammered at once, interleaved between the membranes, until they are expanded to nearly four inches square. They are removed, cut into quarters, replaced between new membranes of gold-beaters'-skin, and beaten again; they again expand to nearly four inches square and are again removed, cut into quarters, and replaced between the skins. A third beating expands them nearly as before. The thickness of the film of gold, by this time, varies from $\frac{1}{200,000}$ to $\frac{1}{300,000}$ of an inch, according to the purpose to which it is to be applied. The attenuation may be rendered more intelligible by stating that 100 square feet of the leaf gold weighs no more than an ounce—a result nearly as surprising as anything presented in the mechanical arts. A certain greasiness which comes upon the interleaved membranes is removed by beating them between pieces of white paper. The beating of the gold is effected by hammers weighing from 10 to 16 lbs., on a smooth block of marble: 150 small squares of gold form the group or bundle for the first beating, 600 for the second, and 800 for the third.

Two other metals, silver and copper, have sufficient malleability to be brought into the state of thin leaves by hammering; and both are used to a limited extent in this state in the arts. But these metals would fracture long before such a degree of thinness could be obtained as in the case of gold; consequently leaf-silver and leaf-copper are thicker than leaf gold.

GOLD-WEIGHING MACHINE. In 1843 Mr. Oldham described before the Institution of Civil Engineers the beautiful Gold-weighing Balance, invented by Mr. Cotton, at that time Governor of the Bank of England. In the transactions between the Mint and the Bank on the one hand, and between the Bank and the public on the other, scrupulous accuracy is requisite in weighing the sovereigns and half-sovereigns. When there is a coinage of new gold, the gold is conveyed from the Mint to the Bank in parcels called 'journeys,' each journey weighing 15 lbs., and containing 701 sovereigns. A group of 200 sovereigns is accurately weighed, and other groups are then balanced against them, so that the pieces are not counted. The officers of the Mint are allowed an overplus called the 'remedy,' amounting to twelve grains in every lb. weight, but they generally work to within one-half of this amount: that is, in two bundles of 50 new sovereigns each, the total weight will not differ so much as six grains.

But it is in the circulation of the gold coins between the bank and the public that the varieties of weighing arise. It is computed that, at a rough average, 30,000 sovereigns pass over the bank counter every day; and it is necessary—either as a regular system, or at stated periods—to ascertain how much the coins have lost in weight by the friction of usage. With the old bullion-scales, 4000 sovereigns could be weighed in six hours, and a deficiency amounting only to $\frac{1}{000}$ of a grain could be detected; but the agitation of the air by the sudden opening of a door, the breathing of persons near the apparatus, and many other minute circumstances, were sufficient to disturb this delicate instrument; while the eyes of the teller or weigher became wearied and dimmed, by constantly watching the indicator of the balance, after weighing three or four thousand sovereigns. Mr. Cotton therefore, endeavoured to plan an instrument which while it should be still more accurate than the bullion-balance, might at the same time be easier and more expeditious in use; and with the aid of Mr. Napier, the Engineer of Lambeth, he completely succeeded.

KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 24.

The exterior of Mr. Cotton's apparatus presents a plain brass case, with a small hopper tube on the top plate. About four inches from the hopper there is an opening in the top plate, through which is seen a platform in the shape of a quadrant, suspended above one end of a balanced beam. On one side of the case is a till, to receive the sovereigns as they are weighed; it is partitioned so that one division is left for standard coin, and the other for such as are light; and each division has a sliding door, for removing the coins. The hopper being filled with gold coins, a system of clock-work within the machine places a sovereign on the little platform; if the sovereign is of standard weight, a small tongue comes rapidly forward and pushes it into that side of the till allotted to such coin; if light, another tongue pushes the sovereign into the other side of the till. These tongues act at right angles to each other. While one sovereign is being thus weighed, a succeeding one is on its way from the hopper to the platform; and the moment the preceding sovereign is disposed of, another supplies its place. All that the attendant has to do, when the machine is wound up for action, is to keep the hopper supplied with sovereigns, and to remove the weighed sovereigns from the till from time to time. The machine can weigh 10,000 sovereigns in six hours. It can separate into two groups sovereigns which differ in weight by a fraction of a grain so inconceivably small as to be scarcely credible to those who are not acquainted with the high excellence of this delicate branch of art.

During the investigation of the Royal Mint Commission, in 1848, it appeared by the evidence of Mr. Miller, weighing clerk in the Bank of England, that Mr. Cotton was led to the invention of his machine by an injustice which the bank unconsciously inflicted on the public. Sovereigns which were issued from one counter at the bank as being full weight, were refused at another counter as being light; and when this matter was investigated it was found that numerous causes rendered the attainment of uniformity in the action of the bank scales quite hopeless, however small the actual amount of error might be in each individual case. Between 1844 and 1848 there were 48,000,000 gold coins weighed by Mr. Cotton's machines at the Bank of England; and the bankers, who pay and receive more coin at the bank than private persons, place undoubting reliance on the accuracy of the machines. Every sovereign now paid over the counter of the bank, has been passed through the machine before being so paid. The bank, according to the evidence of Mr. Miller, has six of these machines in action, five for sovereigns and one for half-sovereigns; each of which will weigh 33 coins per minute! The machines require cleaning once a week—an easy hour's work to each machine. The machines cost about 200*l.* each, and have never yet needed repair. The bank saves about 1000*l.* per annum in wages to weighers, and the public is shielded from unintentional wrong on the part of the bank, by the use of these truly wonderful little machines.

GOLD-WORKING. We are in the habit of associating our ideas of mines of gold with a few favoured spots; but in truth this precious metal is very widely diffused throughout the world. Spain has gold among the sands of the Tagus, but in too small quantity to be worth collecting. France, Piedmont, and Tuscany, also present a few traces. In the territory of Salzburg gold occurs in sufficient quantity to attract attention. Ireland has a little gold among the Wicklow mountains. But it is in Hungary and Transylvania that the greatest European deposit is met with; at Konigsberg, Borson, Schemnitz, Felsobanya, Telkebanya, Kapink, Vorospatak, Offenbanya, Zalatua, and Nagy-ag, in those countries, gold mines are worked, and gold obtained to the extent of one to two thousand lbs. annually. Asia presents numerous gold mines at Breezof and other places on the Ural, and especially in Siberia; in Tibet, Lydia, Japan, and Ceylon. The Eastern Archipelago presents traces of gold in Formosa, Java, Sumatra, Borneo, and the Philippines. Africa presents its store of gold dust, in greater or less quantity, in Kordofan, Sofala, and the wide region which bounds the Sahara desert on the south. America is, however, the richest part of the globe for gold. In Brazil, Chili, Peru, Ecuador, New Grenada, Mexico, North Carolina, and—last, though not least—California, this precious metal is found. Perhaps we may name California, Siberia, and Brazil, as at present the three richest gold-producing countries. From all the countries and districts named, the gold brought to market is mostly derived from alluvial sand, and is extracted by washing.

Under CALIFORNIA and RUSSIA will be found a little notice of the quantities of gold procured from those countries; but we may here say in addition, in respect to California, that it has lately been ascertained that during the year 1850, gold was shipped as freight from St. Francisco, to the value of nearly 30 million dollars; besides an estimated amount, for gold brought away by returning adventurers, and gold retained in California as a circulating medium, of 18 millions more making 48 million dollars' worth as the produce of one year.

The gold obtained from the sand of river valleys is separated from the sandy particles by repeated processes of washing; but the smaller grains of gold, which cannot easily be so separated, are subjected to the process of amalgamation by means of quicksilver. Sometimes the gold is found mixed with sulphurets of copper, silver, arsenic, or other metals; and to separate these sulphurets requires the combined processes of washing and amalgamation. The recent furor concerning California has led to the invention of a number of new machines to facilitate the separation of the gold from the sands. A *gold winnowing machine*, recently introduced at Paris, is intended for emigrants to California. Leaving out the separate lumps of gold, it is said that the auriferous sands yield about one ounce of gold in 500 lbs. of sand; so that this weight of sand must be washed, before the gold can be procured. The new winnowing machine is intended by its inventors to separate much more gold from the sand than by the ordinary washing, and to do it much more quickly. The machine acts by keeping up a constant agitation among the particles, with a provision to allow the escape of the earthy matter. The sand is put into a kind of hopper, whence it descends into a receptacle where a rotating fan or winnow works; the winch which works this fan at the same time pumps up water from a river through a hole; the sand and water flow down a trough into the river, while the gold is left in the machine. It is said that one of these machines is to be sent to the Great Exhibition.

The working of gold into purposes of use and ornament gives rise to many important and interesting branches of manufacture. The coining of gold into money is noticed under MINT; and the making of thin leaves under GOLD BEATING. Gold and silver plate is an important branch of manufacture. By mechanical means (pressure between steel rollers) a thin layer of gold or silver may be made to adhere to a thicker plate of some cheaper metal; but true gold plate has no such inferior layer. The processes of rolling, casting, punching, chasing, hammering, stamping, soldering, riveting, all come into requisition in the manufacture of a piece of gold plate. The approaching Exhibition will contain many magnificent specimens of this art, especially from London and Paris; some of the works from Paris will be of great value. The Goldsmith's Company of London, in order to encourage an art with which they are so intimately connected, have offered rewards to the amount of 1000*l.* for the best specimens prepared for the Exhibition. The prizes are to be one of 200*l.*, three of 100*l.*, three of 50*l.*, three of 30*l.*, six of 25*l.*, three of 20*l.*, two of 15*l.* and two of 10*l.* The articles are to be the modelling and manufacture of British artists; they are to bear the London Hall-mark of 1850-1; and they may be of silver, silver-gilt, or gilt in part. The articles named are groups of figures, table candelabra, shields, salvers, sideboard and altar dishes, dessert services, sideboard ewers, ornamental cups, entrée dishes, candlesticks and light-branches, tea and coffee services, communion services, salt cellars, claret jugs, bread or cake baskets, tea or coffee salvers, tea kettles, inkstands, spoons, and forks.

A considerable quantity of gold is used in the manufacture of watch-cases; but much more is consumed in the numerous trifles which come under the general name of jewellery. Pencil cases, pen-holders, thimbles, bodkins, toothpicks, tweezers, broaches, finger-rings, watch-rings, ear-rings, chains, bracelets, buckles, clasps, &c.—these lead to a large consumption of gold in London and Birmingham, and to the employment of a considerable number of persons. Some of these small trinkets are made of solid gold, some with a thin film of gold on a substratum of silver or copper. Most of these articles are made by persons who receive the material from manufacturers or wholesale dealers, and who employ a few apprentices and assistants to make up the trinkets. Lathes, vices, rollers, hammers, punches, files, draw-plates, wire-drawing apparatus—all these, on generally a small scale, are employed in working up the gold to the required form.

GO'NDOLA is the name given to the pleasure-boats at Venice, which are very numerous, and serve, on its canals, for persons of all classes to proceed from one district to another. The gondola is shallow, long, and narrow, looking, as Byron describes it, like a coffin in a canoe, owing to the black curtains, &c., of the cabin in the centre. The gondolieri once formed an important corporation, several thousands in number, and distinguished for their wit as well as for their skill and honesty. The number of gondolas has greatly decreased in consequence of the decline of the prosperity of Venice.

GONG, is a Chinese musical instrument of percussion, made of a mixed metal of copper and tin, in form much like the cover of a large culinary chaldron, being circular, varying from about fifteen to twenty inches in diameter, and having a rim of from two to three inches in depth. It is struck by a kind of drum-stick, the head of which is of hard leather. It is a very sonorous and powerful instrument.

GONIO'METER is an instrument employed to determine the angle at which the planes of crystals are inclined to each other. The common goniometer consists of two arms of metal, like the letter X, turning on a joint at the intersection. Two contiguous planes of the crystal are placed between the shorter arms, and a graduated arc between the longer arms serves to measure the inclination of the planes. As this instrument is incapable of affording results sufficiently accurate to determine the species to which a crystal belongs, we proceed to describe the more perfect instrument invented by Dr. Wollaston, and called the *reflective goniometer*. This instrument consists of a graduated circle mounted upon a horizontal axis, to one extremity of which is attached a moveable pin, having a slit for the purpose of receiving a small brass plate. To this plate the crystal is attached by means of a piece of wax, so that it may project beyond the edge of the plate. The pin (which is provided with a vertical and horizontal movement) is then raised or lowered until the reflection of any convenient object above appears to coincide with some other object beneath. The instrument being thus adjusted, the graduated circle is turned until a similar reflection is obtained from the contiguous side of the crystal. The arc which the circle will then have described will be equal to the supplement of the inclination of the crystalline planes; but, the margin of the circle being graduated in an inverted order, the true inclination is given without further computation, and may be read off with considerable accuracy. In turning the crystal, the direction of the edge common to its two planes should not be altered, and the rays in both instances should be reflected from that portion of the planes which is nearest to their common edge, otherwise the observation will be affected by parallax. By this instrument the inclination of planes, whose area is less than the 100,000th part of a square inch, may be determined, by means of a vernier, within a minute of a degree.

GOOSE-FEATHERS. The product which chiefly renders the goose valuable in the Arts, is noticed under FEATHERS.

GOOSEBERRY. In the manufacturing districts of Lancashire, and the adjoining counties, the cultivation of the gooseberry has been brought to surprising perfection, at least as regards the size of the fruit; and this chiefly by the manufacturing classes, in consequence of prizes being awarded to successful competitors at the gooseberry-show meetings. Judging from the quality of the varieties grown for competition in this way, it appears that weight is the only qualification required.

GÖTHEBORG, or GOTHENBURG, a town in Sweden, is in a very thriving state. Its commerce is extensive and very active, especially with England. About 600 vessels are engaged in its trade with foreign countries, and nearly as many in that with other Swedish harbours. Its exports consist chiefly of iron and steel, timber, tar, and pitch. Many vessels are built here. The manufactures, though numerous, are on a small scale.

GOTHIC ARCHITECTURE. We can only touch on this large subject in the present work so far as regards brief descriptions, under their several headings, of the mechanical structure involved in the chief parts of a gothic building.

GÖTTINGEN, a principality of the kingdom of Hanover, has large forests and good pastures. The mineral products are iron, salt, basalt, freestone, millstones, potter's and porcelain clays, coals, and alum. The manufactures consist of linen yarn and linens, iron and copper ware, deals, mirrors, glass, pottery, woollens, leather, paper, &c. The chief town also called Göttingen, is more famous for its University than for its industry and commerce. The expenditure of those connected with the university forms the principal means of subsistence to the inhabitants; but they have however considerable manufactures of woollens, tobacco, leather, soap and candles, musical and scientific instruments, stockings, &c.

GOURD, a kind of fruit obtained from various plants of the natural order *Cucurbitaceæ*. In countries having hot and dry summers the different kinds of this fruit are held in high estimation, and are a valuable article of consumption, acquiring a very large size, abounding in nutritious matter, and being moreover very wholesome. The largest is the kind called Potiron Jaune by the French, which sometimes weighs above 2 cwts.

GRADUATING INSTRUMENTS. The name of graduation is given to the marking of degrees and fractions of a degree, on mathematical and astronomical instruments. This graduation, or, as the workmen more generally style it, *dividing*, is performed in two ways, by making a *copy* of a system of divisions already existing, or by *original* dividing. The straight scales and rules which are in common use in cases of drawing instruments, are divided thus:—The original pattern, and the scale on which the copy is to be laid, are placed side by side; a straight edge, with a shoulder at right angles, like a carpenter's square, is made to slide along the original, stopping at each division, when a corresponding stroke is cut by the dividing knife on the copy. With care and practice, this method admits of considerable accuracy. By making the straight edge turn on the centre of a divided circle, the divisions of that circle may be copied upon any concentric circle. Common protractors are thus divided, and scales upon circular limbs. The original circle, which may have several orders of divisions for different purposes, is called a *dividing plate.*

Theodolites and ordinary circular instruments were thus divided, previous to the invention by Ramsden of his *dividing engine.* The general principle of this engine may perhaps be understood by the following description:—A horizontal circle of four feet diameter turns upon a vertical axis; the outer edge is ratched, or notched, by an endless screw, one revolution of which carries the circle round 10′, or one-sixth of a degree; the pressure of the foot upon a treadle turns the screw forward, and there is a series of very ingenious contrivances which enable the divider to turn the screw through any portion of its revolution at each descent of the treadle, and which restores the position of the parts, when the foot is taken off, without allowing any return motion to the screw. The circle to be divided is fixed upon the dividing engine, and made concentric with it, and a division cut after each pressure of the foot. The Board of Longitude gave Ramsden a reward of 300*l.* for the invention of this machine, and 315*l.* for the machine itself, leaving it, during pleasure, in his possession, on condition that he would divide sextants at six shillings and octants at three, for other mathematical instrument makers. Machines of a similar kind, with some alterations and improvements have since been constructed by John Troughton, Edward Troughton, and others, and these are still employed in all instruments which are not large enough, or not sufficiently valuable, to require original dividing.

Dividing engines have been constructed somewhat differently by Reichenbach and others in Germany, and by Gambey in Paris. Much of the German division is excellent, and probably superior to any English engine-dividing. It is understood to be performed by copying. A large circle having been divided originally with great care, the copy is placed upon it, and concentric with it. A microscope is fixed independently over the divided circle, the divisions are brought in succession under the wires of the micrometer, and a line is cut in the copy after each bisection. This process is much more tedious than the English engine dividing, but it admits of the greatest accuracy when the workman is careful and expert.

Original dividing, by which the dividing engines themselves are graduated, and which is employed for the highest class of astronomical instruments, is a process requiring all the resources of delicate mechanical and mathematical art.

GRAIN. In the common weights and measures of this country, a *grain* is the smallest weight now in use. It is of about the weight of a seed of wheat corn, and must therefore be considered rather as a theoretical aliquot part of a larger weight than as itself a proper standard of weight. By a statute of 1266, it was enacted that 32 grains of wheat, taken out of the middle of the ear, and well dried, should weigh a pennyweight, of which 20 should make an ounce, of which 12 should make a pound. Consequently the pound (troy) of this period consisted of 7680 grains, whereas that afterwards in use had only 5760. The reason was, that it became usual to divide the same pennyweight into 24 instead of 32 grains. The grain lost much of its importance by the introduction of the averdupois pound, of which it is not a constituent aliquot part. The ancient averdupois pound is variously stated at from 7009 grains to less than 7000, at which latter number it is now fixed by law.

The weight of one grain is obtained, for practical purposes, without difficulty, by weighing a thin plate of metal of uniform thickness, and cutting out by measurement such a proportion of the whole plate as should give one grain. But a much better plan is to draw a given weight of ductile metal into very thin wire, and to cut from the wire that length which is the same proportion of the whole length as a grain is of the whole weight. In this way pieces of wire are obtained for chemical purposes which weigh only the thousandth part of a grain; and even less weights might be obtained, if it were necessary.

Another popular use of the word *grain* is as a synonyme of *corn;* for a few statistical details concerning which we may refer to Corn Trade.—Adding here, however, a later item, concerning the Corn Trade of 1850. In that year the grain or corn imported into Great Britain amounted to 7,969,435 quarters; while the various kinds of flour and meal imported were 3,873,908 cwts. Nearly half of the grain imported was wheat; and nearly all the meal was wheat-meal or flour.

GRAINS OF PARADISE are hot, acrid, aromatic seeds, obtained from the coast of

Guinea, and used for medicinal and other purposes as stomachic and cordial stimulants. They are produced by the *Amomum Grana-Paradisi* of Linnæus, and *Amomum grandiflorum* of Smith.

GRANADA. This beautiful Spanish province is covered with a luxuriant vegetation. The sumach and the cork trees, the oak bearing the edible fruit, and many other valuable trees and shrubs, form the extensive thickets of the Sierras. The soil is very productive and the agriculture good. Metals are abundant in the mountains. Near Cangajar alone there are 117 lead mines. Copper ore lies on the surface in many places; antimony and quicksilver are found near Malaga, and molybdenum at Ronda. Coal is found on the margins of the Beiro and of the Alfacar, near the capital. Exquisite marbles, jaspers, and alabaster, are abundant.

The famous city of Granada, the capital of the province, has fallen from its ancient grandeur. It still has, however, a royal manufactory for saltpetre and gunpowder, and several manufactories of silk stuffs, such as velvet, taffetas, satin, handkerchiefs, and ribands. The sewing silk of Granada is preferred to all others.

There is yet another Granada — the New Granada of South America, one of the lately formed republics of that continent. The productions of New Granada include cacao, cotton, coffee, tobacco, indigo, rice, and sugar. The forests furnish Nicaragua and Brasiletto wood, fustic, and logwood. To these may be added the Cinchona, or Peruvian bark. The numerous herds which pasture on the Llanos furnish hides and tasajo, or dried meat; horses, mules, and horned cattle are exported to the West Indies. The mineral riches are considerable, and mostly occur on the western declivity of the three chains of the Andes. They consist of gold, silver, platinum, mercury, copper, lead, iron, and rock-salt. The produce of gold seems to be on the increase, but has not yet attained the quantity which was got before the war of independence. Iron and coal are found in the mountains bordering on the table land of Bogotà: some attempts have been made to work the iron-mines, and the coal is used in the smithies and for the steamboats. Rock salt and salt springs occur. The manufacturing industry is not important. It is limited to woollen and cotton stuffs of a coarse texture, only adapted for the use of the lower classes, and mostly made by the consumers. British produce and manufactures were exported to New Granada in 1848 to the value of 247,916*l.*: the chief port of debarkation being Cartagena.

GRANULATION. This term is applied to a process by which metal is reduced to the state of small fragments. While the metal, such as silver or copper, is in a melted state, it is forced into an iron vessel filled with holes; it passes through these holes, into a pool of water, or upon a bundle of twigs soaked in water, and becomes thus solidified into small globular fragments like shot: indeed the making of shot is thus conducted. [SHOT MANUFACTURE]. Silver alloys are granulated previous to refining; and copper is brought to the state called bean shot, by granulation.

GRANITE. This is one of the most abundant rocks seen at or near the surface of the earth. It underlies the stratified rocks, and appears at some remote geological æra to have been in a fluid state from the effect of intense heat.

Granite is one of the most beautiful of rocks, and viewed mineralogically its composition is remarkable. Mica, felspar, and quartz, in distinct crystals, or else filling interstices between crystals, constitute the typical varieties; but other minerals, such as hornblende, actinolite, chlorite, talc, compact felspar, steatite, garnet, zircon, &c., enter into and sometimes considerably modify the aspect of granite, especially in colour, which varies much. Except in a few cases, granite, as its name implies, shows the grains of its component parts; the size of these varies extremely. Granite is indeed rather a name for a mode of aggregation than for a definite chemical or even mineralogical structure; and the varieties are thus too numerous to be distinctly named.

Granite is largely employed in building, especially in the more important engineering works. New London Bridge affords a beautiful instance of its use. It is also much employed in paving the London streets. When polished it presents a fine appearance; but the polishing is a work of great labour, on account of the hardness of the stone. Aberdeenshire, Devon, and Cornwall, furnish our chief supplies of granite.

A very large block of granite, upwards of 20 feet long, and of the finest quality and colour, has lately been raised by the Cheesewring Granite Company, at their quarries, on the Cheesewring-hill, near Liskeard, which is intended to be sent to the Great Exhibition of 1851. The mass of stone, of which this formed a portion of the quarry, contained by measurement the extraordinary quantity of above 4,000 cubic feet, or about 300 tons in weight.

A fine specimen of Irish granite is also to be exhibited, obtained from the Ballyholland quarries near Newry.

GRAPE-SHOT is an assemblage, in the form of a column, of nine balls resting on a circular plate, through which passes a pin serving as an axis. The ball are contained in a strong canvass bag, aud are bound together on the exterior of the latter by a cord disposed about the column in the manner of a net.

GRAPES; GRAPE-VINE. The delicious and well-known fruit of the vine is used as an article of diet in several ways. Its agreeable sweet acid flavour when ripe has always rendered it a very desirable food when fresh. The ancients also, there can be little doubt, were in the habit of drinking the expressed juice of the grape before fermentation. Grapes are also dried and used under the name of *Raisins.* The drying is generally effected by cutting half through the fruit-stalk whilst they are suspended on the tree. Grapes thus dried are called Muscatel Raisins, and are principally brought from Spain and the Levant. The most extensive use of the grape is for the purpose of making wine. [WINE.]

Although our climate does not permit of the grape attaining its greatest perfection in the open air, yet in the forcing system of cultivating grapes by heat, Great Britain probably produces the most delicious grapes in the world. But even in the open air in the southern counties of England, if proper care is taken, very good fruit may be obtained.

Grapes may be kept by packing them in jars, each branch separately wrapped in paper. The bunches and layers of fruit are to be separated by well-dried bran; bran is also laid above and below the grapes; and there are finally laid over the top a piece of paper, a stretched piece of bladder, and a well fitting cover to the jar.

Sugar is obtained from grapes, by saturating the juice with chalk, decanting the clear liquid, evaporating to a syrup, clarifying with white of egg, and then evaporating. It is less sweetening than al-sugar.

Grapes to the value of 30,000*l.* to 40,000*l.* are annually imported.

GRASS LAND includes water-meadows, upland pastures, and artificial meadows. The first are briefly treated of under IRRIGATION. *Upland pastures* are portions of land on which the natural grasses grow spontaneously, varying in quantity and quality with the soil and situation. When a pasture is naturally rich, the only care required is to stock it judiciously, to move the cattle frequently from one spot to another, and to eradicate certain plants which are useless or noxious. The urine of the cattle is the manure which chiefly keeps up the fertility of grass land. A poor arid soil is not fitted for grass, nor one which is too wet from the abundance of springs and the want o outlet for the water. These defects can only be remedied by expensive improvements.

When an arable field is sown with the seeds of grasses and other plants which give herbage for cattle, it is called an *artificial meadow.* The introduction of the artificial meadows in districts where the soil seemed not well adapted for pasture has greatly increased the number of cattle and sheep reared and fattened, and has caused greater attention to be paid to the means of improving the breeds of both. In the neighbourhood of large towns there are many meadows, which, without being irrigated, are mown every year, and only fed between hay harvest and the next spring. The management of this grass land is well understood in Middlesex. An acre of good grazing land, worth 40*s.* rent, is supposed to produce 200 lbs. of meat in the year.

GRASSES. There is a great difference between the value of grasses for pasture; certain kinds suit the meadows, others marshes, others upland fields, and others bleak and sterile hills, where they furnish valuable food for sheep: these kinds will not grow indiscriminately, or are not equally suitable for different soils and situations, and it is therefore essential for the husbandman that he should be capable of discriminating between them. Some indicate the quantity of soil. The same remarks are applicable to the grasses used for various purposes in the manufacturing arts. The principal grasses useful to man are described in this work under their usual commercial names.

GRAVEL. This name is usually given to the small fragments of rocks which have been drifted by any force of water over the surface of the earth. Whether the gravel observed at any spot was transported along the natural drainage hollows of the surface; and whether the waters descending these valleys performed the effects while flowing at higher levels, under the influence of dams, lakes, or other peculiarities; become interesting questions in connection with the past history of the earth's surface. But in relation to the industrial arts, gravel is not much used except as a material for roads, paths, terraces, &c.

GRAVITY, CENTRE OF. If a lever were balanced by means of two solid spheres of uniform density hung at the ends, the equilibrium would still remain if all the matter of either of the spheres could be concentrated at its centre; the centre of the sphere is then its *centre of gravity.* When a body is suspended by a string, and allowed to find its position of rest, the centre of gravity is in the line of continuation of the string.

In every kind of machinery this important law, by which the centre of gravity always tends to assume the lowest place, is kept constantly in view in arranging the weight of different parts of a machine or engine.

GRAVITY, SPECIFIC. [SPECIFIC GRAVITY.]

GREAT BRITAIN. The industrial statistics of Great Britain are briefly glanced at under the headings—ENGLAND, SCOTLAND, WALES, the names of counties, and the names of the chief towns and rivers; as well as under such headings as CUSTOMS DUTIES, EXCISE DUTIES, FACTORIES, IMPORTS AND EXPORTS, SHIPPING, &c. Beyond the features which illustrate produce, industry, and commerce, we have nothing to do with geography in this work. A few data under our present heading will suffice.

Great Britain has about 84,000 square miles of surface, and about 4000 miles of coast-line. There are seven rivers 100 miles or more in length, viz., Thames 200, Severn 190, Tay 150, Trent 144, Ouse 120, Wye 120, and Tweed 100; these seven rivers, with their tributaries, drain about 24,000 square miles of surface. There were in 1827 (since which year new inclosures and cultivation have gradually increased) about 14 million acres of farms and gardens, 21 million acres of meadows, pastures, and marshes, 10 million acres of improveable wastes, and 13 million acres of unimproveable wastes. It is a useful fact to bear in mind, (with sufficient accuracy for general comparison) that Ireland and Scotland have about equal areas, and that Ireland and Scotland united have an area about equal to that of England and Wales united. In respect to population these ratios altogether fail, for England is more populous than the other three combined.

GREECE. This once celebrated country has little to interest us in respect to its present industry and commerce. In the plains of the Morea the peasantry are not proprietors, all the land belonging either to the state or to the wealthy families of the primates or archontes. In the mountains there is a great number of small proprietors, generally thrifty and industrious husbandmen. The resources of the continental part of the kingdom are derived chiefly from agriculture. There are about 120,000 families of cultivators of the soil, of which 20,000 are proprietors. The vineyards are almost all private property. There are also about 215,000 olive trees, chiefly in Attica, Megaris, and the eparchy of Salona, a great part of which is national property. Greece produces about two-thirds of the corn required for its consumption. Wheat, barley, and Indian corn are the species cultivated; oats and rye are not in use. Tobacco thrives, especially near Argos and Calamata, and cotton grows also in considerable quantity. The wine made is enough for the home consumption; it is generally good-bodied, but for want of proper management in making it, and of cellars, it does not keep beyond a year or two. Currants are cultivated in various districts, especially in the eparchies of Patras and Vostitza, and are of excellent quality. The olives are of good quality, but the art of pressing and refining the oil is very imperfectly understood, and the oil is inferior to that of Provence. Silk is made in Messenia and Laconica, and also at Tinos, and in other islands, but is inferior to the Italian silk. The almond, the fig, the chestnut, the orange, and the lemon thrive well. Horned cattle are not numerous, nor sufficient for the labours of the field, for which they are almost exclusively used, and oxen are imported for that purpose from Thessaly and Asia Minor. There, are, however, numerous flocks of sheep and goats, which migrate to the mountains in the spring, and return to the plains after the harvest. The produce of wool is considerable, but of a coarse kind, and is used chiefly for home manufacture. Pigs are scarce, except in Arcadia. The only milk used is that of ewes and goats, and the butter and cheese made of it is very inferior. The fine forests with which the mountains were once clothed have been sadly wasted, and for the most part entirely destroyed.

The commerce and navigation of Greece are centered in the ports of Nauplia, Mesolonghi, Patras, Galaxidi, and the islands of Hydra, Spezia, and, above all, Syra. The number of Greek merchant vessels is somewhat over 1000, exclusive of small craft, or coasting boats. The extensive line of coast and the numerous islands supply a multitude of good sailors. The principal traffic of the Greek vessels is the carrying trade between the ports of the Mediterranean and the Black Sea. The Exports from Great Britain to Greece in 1848 amounted in value to 284,834*l*. Among the imports from Greece in the same year were 225,175 cwts. of currants, being more than half of our consumption.

GREEN. In dyeing green, the usual custom is to impart a blue dye first, and then change this to a proper tint by a yellow dye. The same principle is followed in many kinds of painting; a lively green being produced by a mixture of blue and yellow pigments; and a dingy green by a mixture of blue with orange or with yellowish brown. There are, however, many green pigments produced without this admixture. *Green bice* is a carbonate of copper. *Brunswick green* is a carbonate of copper, mixed with chalk, white lead, alumina, or magnesia. *Friesland green* is an oxychloride of copper. *Scheele's green* is an arsenite of copper. *Prussian green* is a modification of Prussian blue. *Sap green* is prepared from the juice of buckthorn berries. *Iris green* is prepared from the juice of the petals of the blue flag plant. *Verditer* is a mixture of oxide of copper with whiting.

GREENHOUSE. Structures of this kind were formerly erected with slated roofs, like dwelling-houses, and with large upright windows in front, divided and supported by pillars; examples of which may yet be seen in several of the royal gardens about London, and also in different parts of the country. It was soon found that handsome specimens of plants could not be grown in houses of this description, and the only purpose to which they are now applied is the growing of orange or lemon trees, and protecting other plants in winter. The best kinds of greenhouses are those with span-roofs, which are often built in the following manner: a neat wall, about three feet high, is built round the front and ends; the back wall being about two-thirds of the height of the roof. Along the top of the front wall a row of glass sashes, eighteen inches in height, is placed upon the brickwork, which will raise the front to 4½ feet. The span-roof will then be supported upon this in front, and its back sashes will rest upon the back wall. A greenhouse should always, if possible, front the south.

To what extent the increased use of glass, noticed under CONSERVATORY, will be available for greenhouses, it rests with gardeners to decide.

GREENOCK. This busy Clyde port has a harbour which, at the beginning of the last century, was only fit for the reception of fishing boats; but ten acres were afterwards enclosed between two circular quays; and subsequent improvements have rendered the outer harbour available for ships of large burden. This has been the means of raising the place to an important position as a sea-port. The number of vessels belonging to the port is about 450. Ship building is extensively carried on in and near the town; and great commercial activity is observable. The large Customs' returns at Greenock are noticed under GLASGOW. Greenock is, in many particulars, a port for Glasgow.

GRENADE, frequently called hand-grenade, is a shell or hollow ball of iron, 2½ inches in diameter, which, being charged with powder and provided with a fuze, is thrown as a missile during sieges. As soon as the composition in the fuze is consumed, the fire communicates with the powder, and the ball is burst in fragments.

GRENOBLE. In this ancient town, formerly the capital of Dauphine, in the south of France, the chief manufactures are kid gloves, of which about two million francs' worth are exported to England and America annually; liqueurs, chamois and other leather. The dressing of hemp gives employment to about 1000 workmen. The trade of the place is much promoted by the navigation of the Isère; other articles of trade are wrought iron, marble, and timber.

GRIMSBY. This Lincolnshire port has hitherto been a place of little importance; but the extensive works now progressing under Mr. Rendel, will render it a commercial emporium of considerable rank. There is already a dock at Grimsby, but it is wholly above the level of high water mark, and is supplied with water by land streams. Between that level and low water mark is an unsightly mass of muddy shore; and it is this useless expanse which Mr. Rendel is bringing into requisition by forming magnificent docks. About 130 acres are to be enclosed, of which part will form a dock, and the rest will afford sites for wharfs and warehouses. The water area of the dock will be 27 acres; there will be 5000 feet of dock wharfage, and 6000 feet of river wall. There will be a basin of 11 acres, to connect the dock with the Humber; and two piers of 600 feet long each will bound the basin on the east and west. Such is the full scope of the plan proposed by Mr. Rendel, part of which is now being carried out by the Sheffield and Lincolnshire Railway Company, to whom the works belong.

GRINDSTONES. The stones used for sharpening cutting instruments vary greatly in texture, from the roughest grindstones to the smoothest hones. The sizes are equally varied; some of the stones used by the saw-grinders of Sheffield are as much as seven feet in diameter. The grindstones for table-knives are from three to four feet in diameter, and six inches thick; they are formed of a species of sandstone. In one of the large grinding establishments in that town, where cutlery from pen-knives to saws are ground, the grindstones are of all sizes, from four inches to seven feet in diameter. There are many quarries in England from which stone fitted for such purposes may be obtained. Some grinding wheels have a surface of crocus or of emery applied to them, to aid in particular kinds of grinding.

The grinding and sharpening stones prepared by Mr. Meinig, present a remarkable variety. He has natural grindstones, from quarries belonging to himself, of ninety-seven different diameters, from 1½ to 24 inches; and of thirteen degrees of thickness, from an eighth of an inch to 3 inches. The same sandstone is cut into other shapes, for various abrading processes. German hones are prepared for sharpening fine tools; whereas a kind called green-water hones are used for giving an edge to razors and lancets. Turkey oil-stone presents five different degrees of hardness and texture to suit different modes of application. Petrified wood is employed as a material for whetstones or hones; it can be cut into the form of wheels, up to three or four inches in diameter.

GRIT. Hard sandstones are called grits in the north of England, and indeed many soft sandstones are so termed. In particular districts some distinctive terms are applied, as millstone grit, red grit, white grit, grindstone grit, &c. Almost universally in the north of England the term Freestone belongs to such gritstones as will work easily and to a good face.

GRITS or GROATS. This useful material for gruel is made of oat seeds deprived of their husks. When bruised, ready for use, they are denominated Embden grits, or prepared or patent groats or grits. A greater or smaller quantity of these are to be used to a pint of water, according to the object in view. When employed for an article of nourishment, the gruel may be made thick; when required as a demulcent or diluent, to promote perspiration at the commencement of a cold, it should be thin. This is regarded as a light and digestible article for invalids. The husks are frequently steeped in water for a few days, and then drained off. The liquid when boiled stiffens into a dish called sowens in Scotland. This is slightly acid, and forms with milk a favourite food of the peasantry for supper.

GRODNO, a government of Russia in Europe, produces quantities of barley, rye, oats, hops, hemp, and flax. The crown holds a great number of the forests, which abound chiefly in pine. Horned cattle and sheep are numerous. Much wax and honey are made. The minerals consist of iron, limestone, clay, chalk, and saltpetre. The manufactures of the province are woollen cloths, hats, leather, paper, and spirits. There is a good export trade in grain, wool, cattle, and timber, with Memel, Riga, and Königsberg.

GROINS are the lines formed by the intersection of arched vaultings. Such intersections are called 'groinings,' and the vaultings 'groined arches.' Groins, which arose in the first instance out of the simple intersection of arches, were in later times the foundation of an extensive system of decoration. This system is exemplified in the elaborately groined ceilings of many of our ecclesiastical buildings. Groined arches are constructed of stone, brick, and wood and plaster. When constructed with stone or brick, a centering of wood is used to turn the arch and form its groins. Great nicety is required in the execution of the groined work, and the best workmen among bricklayers and masons are always selected.

GUAIACUM. This is the name of a genus of small crooked trees inhabiting several of the West India Islands, in low places near the sea. The most remarkable species yields the hard, compact, black-green wood called *Lignum Vitæ*, which is so heavy that it sinks in water, and from which pestles, ship-blocks, rollers, castors, &c., are turned. The same species also produces the gum-resin known in medicine under the name of *Gum Guaiacum.* For medicinal purposes, the wood should be procured from the central part of the trunk, as being the richest in the active principle. This wood is very dense, heavier than water, of an obscure greenish fawn colour; but the recent fracture is yellowish, exhibiting an unequal cleavage, with a fatty shining appearance, if the specimen be good. The wood of the circumference is lighter, both in colour and weight, pale fawn, and opake. Genuine guaiac-wood or lignum vitæ is destitute of smell, but if rubbed, and still more if set on fire, it evolves an agreeable aromatic odour. If long chewed, the taste is peculiar, guttural and bitterish. The wood is less used than the resin. Guaiac-resin exudes spontaneously, or in consequence of incisions, and hardens on the bark. Resin obtained in this way is generally in spherical or long tear-shaped pieces.

Guaiac possesses the property of stimulating the system generally. It is not prized now so highly as on its introduction into European practice in the sixteenth century, when it bore a most extravagant price, four ducats being often given for a pound of the wood. It is however a useful medicine, and the wood is applied to many purposes in the arts.

GUANO. This valuable manure is the excrement of sea-fowl, and appears to have been used as a manure long before Peru was visited by the Spaniards. A recent German traveller, Meyer, says, 'Along almost the whole coast of Peru this excrementitious matter covers the small islands and cliffs near the coast, and on some spots lies in such enormous beds as could only be produced by the accumulation of thousands of years.' About the commencement of 1843 guano was discovered on the island of Ichaboe, about two miles and a half from the main land of Africa, in 26° 13' S. lat., and 14° 15' E. long. The place soon attracted notice, and by the end of 1844 the whole of the guano had been carried away. As many as 350 ships have been anchored off the island at the same time. The guano was from 35 to 38 feet in depth, and the deposit extended to a length of about 1100 feet, with an average width of 400 feet. Towards the close of 1844 another guano island (Malagas) was discovered at the entrance of Saldanha Bay. The guano covers an extent of about eight miles, and the thickness is from about four yards to eight yards. It has been supposed that the excrement of the sea-fowl which swarm on some parts of the coast of Great Britain might be used as a fertiliser with the same results as Peruvian or African guano; but the quantity which could be collected is comparatively small, as the animal accumulation is in most cases washed away by the rains, and the valuable properties of that which remains are dissipated by the changeable nature of our climate.

The value of guano is to be estimated according to the proportions which it contains of—1, ammonia; 2, phosphates; 3, organic matter. African guano has the largest proportion of soluble matter, and that from Peru is remarkable for the quantity of uric acid that it contains, an element which dissolves very slowly. It is said that 4 cwts. of guano, which is the usual quantity applied to one acre, are equal in effect to fifteen tons of farm-yard dung. It is usually mixed with pulverised earth to prevent it from coming in contact with the seeds. For small allotments or gardens it is often most convenient to use guano in a liquid state, in which case 4 lbs. of guano may be mixed with twelve gallons of water, and used after it has stood twelve hours, and the proportion per acre may be from a half to one cwt. of guano to 160 gallons of water.

The quantity of guano imported in the last four years has been very considerable:—

1847	82,134 tons.
1848	71,414 „
1849	83,438 „
1850	116,926 „

GUERNSEY. In this member of the Channel Islands group, the pursuits of agriculture are carefully attended to; as much as 54 Winchester bushels of wheat have been raised per acre. The ashes of sea-weed are the manure chiefly used for corn crops. Red-wheat is the chief of these crops. Neither sheep nor horses are carefully reared; but the breeding of cattle, especially of cows, is an object of great attention. The dairy is on all farms of any size the principal object of attention, and the chief source of the farmer's profit. The butter that is made is in high repute. English fruits, and fruits of more southern climates, are much cultivated. The shores are abundantly supplied with fish. The manufacturing industry of Guernsey is but small; and the same may be said of the little islands near it —*Alderney*, *Serk*, *Herm*, and *Jethou*. There is steam communication to Guernsey from Southampton, Plymouth, Torquay, St. Malo, and Granville.

GUINEA. Many parts of the region of West Africa, known by the name of Guinea, are rich in produce which gives rise to much commerce. Thus, in the country called the *Grain Coast*, the valleys produce rich crops of rice, which is exported to a large amount. Cattle, sheep, pigs, goats, poultry, rice, pepper, camwood, and ivory are abundant. The *Ivory Coast* and the *Slave Coast* are the names of other portions of Guinea, the produce of which is exported to various countries. *Sierra Leone* will call for a word of notice elsewhere, in respect to its produce and commerce. [SIERRA LEONE.]

GUITAR. This musical instrument, in various shapes, may be traced to the remotest periods of antiquity. It was often called *Cittern* and *Gittern* by the old English poets. The English and French guitar of the last century was wide and thin in body, short in the neck, and strung with wire. The modern guitar, which is of the Spanish kind, and differing little from the lute, consists of a body from seventeen to eighteen inches in length, four in depth, and of a neck of about sixteen inches, the latter carrying a finger-board divided by seventeen frets. It has six strings, three being of silk covered with silvered wire, and three of catgut. The compass of this elegant instrument is from E below the base staff to A above the treble staff, including all the intermediate tones and semitones. The best and cheapest guitars are made in Germany.

GUM. This vegetable juice is of more universal occurrence than any other secretion by plants. It is the material generally prepared by them for their own nourishment, and is at first in a state of solution; but when it escapes to the exterior of the bark it frequently becomes thickened, and even solid and pulverisable. The purest gum (arabic) consists of a principle termed *arabin*, and is soluble in water, forming with it a mucilage. Other gums contain *bassorine*, either alone or with arabin and other matters. The term gum is sometimes erroneously applied to gum-resins, such as assafœtida, &c.

Most of the commercial gums are obtained by incisions made in the bark of several species of acacia growing in Arabia, India, Upper Egypt, Senegal, &c. The specimens differ considerably in colour, even when obtained from the same species. Genuine gum-arabic occurs in pieces from the size of a pea to that of a walnut, or larger, which are irregular in shape, or roundish or angular; either white, yellowish, or dark wine-yellow; scarcely any odour; taste mawkish, glutinous. Gum, when in powder, is often adulterated with starch, the presence of which is detected by tincture of iodine; or, when cold water is used for the solution of the gum, the starch will remain undissolved. The mucilage made with cold water is not only purer, but keeps better, and for all purposes for which it can be used is preferable to that made with warm water, which is the common method.

Gum is highly nutritive, six ounces in twenty-four hours being deemed sufficient to sustain the life of an adult; yet it is not very easily digested when taken alone. Gum will often pass through the stomach nearly unchanged, if not associated with some bitter or astringent principle. This property however renders it demulcent in affections both of the throat and also of the intestines, by sheathing the membrane from air or the irritation of acrid secretions. Hence allowing a portion to dissolve is also used to suspend many insoluble matters in water. Its agglutinating properties render it valuable in many of the arts.

Of four kinds of gum which are enumerated in the Board of Trade tables, the quantities imported in 1848 were—

	Cwts.
Gum-arabic	24,022
Gum-Senegal	7,404
Gum-copal	2,958
Gum-tragacanth.. ..	234

GUM-RESINS are secretions of plants, which are produced in the greatest quantity, and most perfectly elaborated, in warm countries. They are obtained chiefly from trees and shrubs of particular tribes of plants. They either exude spontaneously, or are procured by incisions of the stem and branches. When they first escape to the surface they are fluid, and of a light colour, but gradually harden, and become of a deeper hue, either by the evaporation of some of their volatile oil, or by the absorption of oxygen from the air, and the conversion of the oil into a resin. Some remain in a semi-liquid viscid state, such as *sagapenum* and *galbanum*, which are only pulverisable in winter. Most gum-resins possess a strong odour, which in many instances is disagreeable, such as that of assafœtida, with a warm acrid taste, and by application to the skin for any considerable time they cause redness and inflammation.

Gum-resins, which are largely employed in medicine, should be kept in cool well-closed places, to prevent the evaporation of their volatile principles.

GUN-COTTON was first discovered by M. Schönbein of Basel, and made known in the year 1846. It is prepared with cotton wool, and explodes at 400° Fahr. Gunpowder explodes at 600°. In consequence of this, gun-cotton may be fired on gunpowder without igniting it. This peculiarity results from the minute division of the cotton fibres; for mealed powder, or gunpowder dust, will explode at a much lower temperature than grained powder.

Gun cotton may be prepared in various ways. Mr. Taylor made it by saturating cotton wool in a mixture consisting of equal quantities of nitric and sulphuric acids. This must be done as rapidly as possible by pressing the cotton in the mixture with a glass rod. When this is done, it is taken out, and as much as possible of the mixture is squeezed out of it. The cotton is then washed in successive portions of water until it loses all taste of acid. It is then pressed in a linen cloth and dried. Sawdust, wood-shavings, and any body consisting principally of carbon, may be rendered explosive by preparation in a similar way.

The manufacture and use of these preparations are however dangerous, and they have in consequence been prohibited generally in France. Gun cotton is more powerful than gunpowder, *i.e.*, with equal quantities by weight a much greater effect is produced by the cotton; in consequence of which there is every probability that it will supersede powder for the purposes of blasting, for which it possesses the important advantage that it does not generate smoke. It remains however to be proved whether it will answer for military purposes. The experiments of the French government are against it, in consequence of the production of an inconvenient quantity of moisture by its explosion. M. Schönbein has secured the patent for his preparation in England, and it is manufactured on his account by agents appointed by him. So extremely explosive is this material, that many serious accidents have happened in connection with its manufacture.

GUN MAKING. The manufacture of muskets and fowling-pieces is carried on to a very large extent at Birmingham. More than five million pieces of fire-arms were made in that town between 1804 and 1818. Yet there are no gun-factories properly so called. The same gun travels about from factory to factory, from shop to shop, before it is finished.

The most essential part of a gun is the *barrel*. The interior of the barrel is usually a smooth cylinder, but the exterior is made slightly conical by thickening the metal at the *breech* or hinder end. The commoner barrels are formed of tenacious soft iron, which is rolled into the form of flat bars, called *skelps*, each of which is sufficient to form a single barrel. The length of a skelp is usually about three feet, and the breadth about four inches at one end, and two and a half at the other. In welding these skelps into barrels, the thicker end is heated to redness, and hammered upon a hollow cavity in an anvil until the edges are turned up. A mandril being then inserted in the concavity between them, the edges are turned over and welded together. The skelp is thus gradually converted into a tube or barrel, after many beatings and hammerings. This laborious process of welding is now to a great extent superseded by improved methods. In one of these methods, the barrels, instead of being formed of skelps forged to the length of the barrel, are made from slabs of refined bar-iron, ten or twelve inches long, and weighing from 10 to 11 lbs. Each slab, by being heated and passed between rollers of a peculiar shape, is bent round into a tubular form; and repeated drawings between other rollers weld the two edges firmly together, and at the same time elongate the tube to the proper dimensions, a mandril being placed inside to preserve the bore of the barrel. The above processes are for *plain* barrels. *Twisted* barrels are made of long and very narrow strips of iron; one of which, being moderately heated to increase its pliancy, is wrapped spirally round a cylindrical mandril, in such a way as to form a tube, which may be slipped off the mandril at pleasure. As the rods are not usually made of sufficient length for one to form a barrel, several are usually joined end to end, those which form the breech being thicker than those at the muzzle end. By heating and hammering, these pieces are welded into a continuous and very strong and tough tube. Partially worn or 'scrap' iron is preferred for these purposes. The twisted barrels, technically termed *wire-twist*, are formed of narrow rods of compound metal, composed of alternate bars of iron and steel forged into one body, and then rolled out to the requisite tenuity. *Damascus* barrels are composed of similar metal, but the rods are twisted upon their own axes until their component fibres have from twelve to fourteen turns in an inch, and the rods are thereby doubled in thickness and proportionately reduced in length. Two such rods are welded together side by side, their respective twists being reversed. The varieties in the modes of making twisted barrels are very numerous.

After welding, the barrels are carefully examined, and, if needful, straightened by a few blows of the hammer. They are then bored in a machine with an angular plug of tempered steel, which is caused to revolve rapidly within the barrel, a stream of cold water being directed upon the outside to check the heat generated by the excessive friction of the tool. The outside is brought to a smooth surface either by grinding on a large grindstone or turning in a lathe. The breech end of the barrel is tapped with a screw-thread, to receive the breech-plug, which closes it at that end.

The barrels are then ready for *proving*, which consists in firing them in a building in which their explosion can do no harm, with a charge four or five times as great as they will have to bear when in use. A great number of barrels are fired at once, by laying them upon a strong framework of wood, with their touch-holes downwards, and connected with a train of powder which is conducted outside the building, within which is laid a heap of sand to receive the bullets. They are then carefully examined, and such as show any defect are returned to be reforged, after which they must be proved again, while such as have stood the test satisfactorily are stamped with a distinguishing mark.

Sporting guns are often made with two barrels fixed side by side upon one stock. Such barrels are made separately, and have their adjacent sides filed flat, in order that they may lie close together. They are secured together by ribs running between them from end to end.

The wooden *stock* upon which the barrel is mounted is most commonly made of walnut-tree. When the shaping of the stock is completed, it is shod with brass, the trigger-guard and other metallic fittings and ornaments are let into the wood, and every part is fitted with suitable screws and fastenings, after which the whole is taken to pieces; the woodwork is finished by staining and polishing, the brass-work is filed and polished, and the barrels are sent to be finished, which is done in various ways. Most barrels are now *bronzed*, by the application of some chemical liquid aided by heat. Until a comparatively recent period all military guns, and most of those used for sporting purposes, were made with flint locks, in which the ignition of the priming-powder was effected by the sudden stroke of a wedge-shaped flint against a piece of steel, by which a stream of sparks was directed into the pan containing the priming. But *percussion caps*, containing an explosive powder, are now generally used. The fulminating substance is usually placed in a small copper capsule resembling a thimble in shape, which fits on to the nipple of the touch-hole, and if not blown to pieces by the explosion, is removed previous to reloading. The hammer is provided with a shield to prevent any fragments of the copper cap from flying against the face of the shooter.

In the manufacture of common infantry guns, Birmingham is beginning to feel the competition of Liége, in Belgium; but in the better kinds of fowling-pieces she has no competitor but London.

Of the hand guns used in past ages, the variety was greater than many readers would suppose. The following are the names of most of them:—*Arquebus*, *haquebut*, *demi-haque*, *musquet*, *wheel-lock*, *currier*, *snaphaunce*, *caliver*, *carabine*, *esclopetta*, *fusil*, *musketoon*, *petronel*, *blunderbus*, *dragon*, *hand-mortar*, *dag*, *pistol*, *trickerlock*, *firelock*, *&c.* Of those whose names are best known at the present day, the *musquet* was a Spanish invention, originally very clumsy; the *carabine* is a short gun, about forty inches long; the *fusil*, a French invention, was as long as the musquet, but much lighter; the *blunderbus* is shorter than the carabine, and has a wide barrel; the *pistol* was invented at Pistoia in Tuscany, in the time of Henry VIII.

At Vincennes in France, specimens of all the fire-arms in Europe have been lately tried by the government authorities, with a view to determine the relative efficiency of different forms and different manufactures.

GUNPOWDER. The date of invention of this explosive composition is involved in obscurity. It has been said that it was used in China as early as the year A. D. 85, and that the knowledge of it was conveyed to us from the Arabs on the return of the Crusaders to Europe; that the Arabs made use of it at the siege of Mecca in 690; and that they derived it from the Indians. Roger Bacon has been supposed to allude, in an enigmatic way, to the composition of explosive force of gunpowder; and about 1336 Berthold Schwartz, a monk, is said to have also discovered the mode of manufacturing it.

Whatever may have been the history of its origin, gunpowder at the present day consists of a very intimate mixture of nitre, or nitrate of potash, charcoal, and sulphur. The proportions vary; but they generally consist of about 6 parts of nitre to 1 of charcoal and 1 of sulphur. According to a comparative table which has been published, gunpowder for sporting contains the largest ratio of nitre, gunpowder for blasting the largest ratio of sulphur, and the Austrian gunpowder the largest ratio of charcoal; but the range of difference is only small—chiefly observable in the sulphur. The ingredients must be of the greatest attainable purity; and the nitre is fused before use. The charcoal, either of alder, willow, or dog-wood, is prepared in iron retorts; and the sulphur is the volcanic kind imported from Sicily, and is refined by melting or subliming.

When the ingredients are prepared, they are separately ground to a fine powder, and mixed in the proper proportions. The composition is sent to the gunpowder mill, which consists of two stones vertically placed, and running on a bed-stone. On this bed-stone the composition is spread, wetted, and ground, and is then taken off and taken to the corning-house to be corned or grained; here it is first pressed into a hard and firm body, broken into small lumps, and the powder grained by these lumps being put into sieves in each of which is a flat circular piece of lignum vitæ. The sieves are made of parchment skins, having round holes punched through them; several of these sieves are fixed in a frame, which by machinery has such a motion given to it as to make the runner in each sieve go round with velocity sufficient to break the lumps of powder, and force them through the sieves, forming grains of several sizes. The grains are separated from the dust by proper sieves and reels; they are then hardened, and the rougher edges taken off by being run a sufficient length of time in a close reel, which has a proper circular motion given to it.

The gunpowder, thus corned, dusted, and reeled, is sent to the stove and dried, care being taken not to raise the heat so as to dissipate the sulphur. The heat is regulated by a thermometer.

The theory of the action of gunpowder is this: that particle on which a spark falls is immediately heated to the temperature of ignition; the nitre is decomposed, and its oxygen combines with the charcoal and sulphur, which are also heated; this combination extricates as much heat as is sufficient to inflame successively, though rapidly, the remaining mass. The cause of the expansive force of gunpowder is the production of carbonic acid, carbonic oxide, and nitrogen; and, these being liberated at a very high temperature, the effect is greatly increased. The firing may be effected by the electric spark, and also under some circumstances by percussion.

In ascertaining the goodness of gunpowder, which is done by determining its strength, an *éprouvette* is employed to measure its projectile force. This is a small strong barrel, in which a given quantity of the powder is fired, and the comparative expansive force is measured by the action exerted on a spring or weight.

The principal gunpowder works near London are at Waltham Abbey, Dartford, and Hounslow. The magazines require very cautious management, to obviate danger of explosion.

GUNTER'S SCALE. [SLIDING RULE.]

GUTTA PERCHA. This lately-discovered and very useful substance exudes from a tree grown in Singapore, Borneo, and other of the eastern islands. The first specimen seen in England was sent to the Society of Arts, London, in 1843, by Dr. Montgomerie. The first articles made of this substance in England were a lathe-band, a short piece of pipe, and a bottle case, which were presented to the Society of Arts in 1844.

There seem to be three varieties of this substance, named Gutta Girek, Gutta Tuban, and Gutta Percha. The word gutta means a gum which exudes from a tree; while percha (pronounced pertsha) is the Malayan name for the tree which principally yields this gum. The trees are forest trees, and the natives appear to tap the bark when and how they think they may obtain the largest supplies. The gum is brought to England in shapeless lumps, and is then wrought into the secondary forms of rods, tubes, blocks, sheets, strings, &c., preparatory to being manufactured for various useful purposes.

The articles now made of gutta percha are numerous and varied. The toughness of the material (differing somewhat from the elasticity of caoutchouc), and the facility with which it may be softened by heat, render it peculiarly apt to receive, and maintain permanently, any form that may be imparted to it. Pressure in moulds, while the gutta percha is in a warm and plastic state, is one of the most convenient modes of giving it a determinate form. Whether wet or dry, its uses are confined to cold purposes, as it is very readily affected and thrown out of shape by heat. For many purposes, naphtha and other inflammable liquids act as cements and even solvents for the gutta percha. In its usual condition it is a brown substance, and not much unlike very tough leather, but having a peculiar odour; its surface is, however, capable of being prepared so as to receive paint, gilding, japanning, bronzing, and other ornamental modifications. The crude substance, as brought to England, is reduced to a pulp by macerating machines, purified by water, combined with many different substances according to the purpose to which it is to be applied, and pressed into sheets or other forms by rollers; and familiar mechanical processes are then sufficient to work up this prepared material to the required forms.

It was reasonable to expect that, after gutta percha came into general use, it would be employed in some of the processes of bookbinding. Accordingly, in 1845, Mr. Nickels patented a method of using gutta percha for cementing together the leaves of books, exactly in the same way as in caoutchouc binding. The cement is a solution made by dissolving gutta percha in rectified naphtha, rectified oil of turpentine, or some other essential oil. The solution also is used for pasting down the end-papers, attaching vellum or leather to the boards, sizing the exterior for marbling and gilding, and for mixing with the colour for colouring and marbling edges, &c. Sheets of gutta percha are used as a substitute for vellum, leather, cloth, or paper, in covering books; or a covering is made by coating a piece of cloth with gutta percha solution. The same material is used as a substitute for pasteboard for binding: the flexible boards being made of a composition, in which gutta percha is mixed with paper, pulp, leather dust, wool, or cotton. When for any of the above purposes a little more elasticity is required than belongs to gutta percha, a little caoutchouc is combined with it.

Lieut. Rouse, Superintendent of the Greenwich Hospital Schools, has lately caused 800 pairs of boys' shoes to be soled with gutta percha; he states that they are more economical than leather, and that the waterproof quality is fully determined. Gutta percha water-pipes are being gradually substituted for lead. At the Bristol Vitriol Works gutta percha pump-buckets are used. It is employed as a lining for muriatic acid casks at the Patent Candle Works. From its power of resisting the most potent chemicals, it is of the greatest service to the chemical manufacturer, as he is enabled to use it in many operations instead of glass or metal. The most concentrated alkalies do not affect it, nor any of the acids used in pharmacy or the arts, with the exception of the strongest sulphuric and nitric acids. Messrs. Muspratts have had carboys made and wine pipes lined with it, for the conveyance of muriatic acid by railway, instead of glass; and so successful has been the experiment, reducing the carriage, and obviating all danger of breakage, that they are now using nothing else. For the conveyance and stowage of water—entirely preventing the injurious effects arising from drinking water contaminated with lead—it is peculiarly well adapted, as it is not in the least acted upon by the carbonic acid and fixed air which in some waters so readily attack lead. Its applicability to many other chemical purposes, such as funnels, syphons, &c., and for strapping for diseased joints, stopping for decayed teeth, balsam for cuts, catheters, bougies, and stethescopes, is very important. In electrical processes the insulating power of gutta percha is most valuable. Gutta percha was first employed as a cover to the wires in damp tunnels, and its perfect success there suggested the idea of laying down within its protecting folds telegraphic lines between England and the Continent.

The best illustration of the uses of this remarkable substance is perhaps furnished by a list of the articles now made by the Gutta Percha Company in the City Road:—*Domestic, &c.*—Soles for boots and shoes; lining for cisterns; picture frames; looking-glass frames; ornamental mouldings; bowls; drinking cups; jars; soap dishes; ornamental inkstands; vases; noiseless curtain rings; card, fruit, pin, and pen trays; tooth brush trays; shaving brush trays; window blind cord; clothes line; nursing aprons; coloured material for amateur modelling; ornamental flower stands and pots; sheet for damp walls and floors; drain and soil pipes; gutta percha domestic telegraphs; watering tubes for gardens; lining for bonnets; jar covers; sponge bags; watch stands; shells; foot baths; balsam for cuts, chilblains, &c.; lighter stands; water and gas pipes. *Surgical*—Splints; thin sheet for bandages; stethescopes; ear trumpets; liquid gutta percha for wounds; bed straps. *Chemical*—Carboys; vessels for acids, &c.; syphons; tubing for conveying oils, acids, alkalies, &c.; flasks; bottles; lining for tanks; funnels. *Manufacturing*—Buckets; mill bands; pump buckets, valves, clacks, &c.; felt edging for paper makers; bosses for woollen manufacturers; flax holders; shuttle beds for looms; washers; bowls for goldsmiths; bobbins; covers for rollers; round bands and cord; breasts for water wheels; oil cans. *For offices, &c.*—Wafer holders; inkstands; ink cups; pen trays; cash bowls; washing basins; tubes for conveying messages; canvas for covering books, &c.; architects' and surveyors' plan cases. *Agricultural*—Tubing for conveying liquid manure; lining for manure tanks; driving bands for thrashing machines, &c.; traces; whips; buckets, bowls, &c. *Electrical, &c.*—Covering for electric telegraph wire; insulating stools; battery cells; handles for discharging rods, &c.; electrotype moulds. *Ornamental*—Medallions; brackets; cornices; console tables; mouldings in imitation of carved wood. *Uses on Shipboard*—Sou'-wester hats; pilots' hats; life buoys; buckets; pump buckets; speaking trumpets and tubes; drinking cups; powder flasks; fishing net floats; sheathing for ships; waterproof canvas; airtight life boat cells; tubes for pumping water from the hold to the deck; round and twisted cords; lining for boxes; tiller ropes. *Miscellaneous*—Suction pipes for fire engines; fire buckets; stable buckets; lining for coffins; sounding boards for pulpits; tap ferules; communion trays; tubing for ventilation; hearing apparatus in churches and chapels for deaf persons; cricket balls; bouncing balls; golf balls; fencing sticks; portmanteaus; police staves; life preservers; embossed book backs; embossed globes and maps for the blind; railway conversation tubes; miners' caps; beds for paper cutting machine knives; fringe for mourning coaches; fine and coarse thread; alarum tubes for mines, &c.; official seals, &c.; envelope boxes; bible backs; prayer book backs; powder flasks; box lids.

The great seal of Ireland, attached to patents and similar documents, has hitherto been made of a soft, easily-melted wax; but it is now stamped in gutta percha.

An ingenious method has been devised by Dr. Branson of Sheffield, of producing engraved plates of ferns, sea-weeds, &c., by means of gutta percha. The ferns are pressed upon a carefully prepared sheet of this material, while warm; and the delicate markings are left in *intaglio* or cavity on the gutta percha surface. A cast in brass may be taken from this intaglio; and impressions may be printed from the brass.

The advance in the trade in gutta percha has been astonishingly rapid, as will be shown by the amount exported from Singapore to Great Britain:—

1844	230 lbs.
1845	22,000 lbs.
1846	710,000 lbs.
1847	1,200,000 lbs.
1848	1,700,000 lbs.

It was computed that 300,000 trees were destroyed to obtain the above quantities.

GUYA'NA, GUAYA'NA, or GUIANA, is the north-eastern portion of South America, extending from the banks of the river Orinoco southward to those of the river Amazon. Few countries on the surface of the globe can be compared with it for luxuriance of vegetation, which shows itself especially in the great number of indigenous plants and the large forest trees which cover perhaps not less than one-half of its surface. Timber, furniture-wood, and dye-wood are afforded in abundance. Indian corn, rice, mandioca, yams, sweet potatoes, arrow root, bananas, pineapples, cocoa-nuts, sugar, coffee, cotton, tobacco, ginger, pepper, clover, nutmegs—all are grown in Guyana. Wheat does not thrive well. Black cattle grow to a greater size than in Europe, but their flesh is not so tender nor of so fine a flavour. The wool of the sheep is converted into hair. Among the ferocious animals are the jaguar and couguar. Other animals are the armadillo, agouti, and bear, sloth, monkeys, lizards, iguana, alligators, bats, and snakes. The birds and insects are very numerous.

In that portion of Guyana which belongs to Great Britain, an interesting commercial feature has displayed itself. In the year 1846, about seventy creole field labourers clubbed their savings together to buy an estate on the west bank of the Demerara River, for which they gave 25,000 dollars: an instance which Governor Light, in a despatch to Earl Grey, adduces to show the rising character of many of the working population. In 1838 there were 308 coffee and sugar estates in cultivation; in 1846 the number had fallen to 251, owing to the disasters attending the sugar trade. In 1846 there were 641 vessels entered the port of Demerara, with a tonnage of 107,820; those at the port of Berbice were 170, with a burthen of 2000 tons. The imports from the United Kingdom in 1849 amounted in value to 326,821*l.* These numbers relate to *British* Guyana. *Dutch* and *French* Guyana have commerce chiefly with the mother countries.

The postal arrangements established by England, France, and Holland, with the three Guyanian colonies, are all managed by the Royal West India Mail Packet Company, and will be shortly improved by the new contract entered into by that company.

GYPSUM, or sulphate of lime, is a mineral which is found in a compact and crystallised state, as alabaster [ALABASTER] and selenite, or in the form of a soft chalky stone, which in a very moderate heat gives out its water of crystallisation, and becomes a very fine white powder extensively used under the name of Plaster of Paris. [MANURE.]

The principal demand for pure white gypsum is by the Staffordshire potters, who form their moulds with it. Fine blocks of gypsum are selected for making alabaster ornaments. The plaster stone of Paris, mixed with water, forms an adhesive cement or mortar much used in building. Coloured stuccoes for walls are made of gypsum, ghee, and some colouring matter.

H

HAARLEM. In the southern suburbs of this fine old Dutch city are the famous nursery flower-gardens, which formerly supplied a great part of Europe with tulips, hyacinths, and other flowers. There are extensive bleaching establishments here, which formerly supplied large quantities of linen to England, whence the article came to get the name of *Holland*, as coming from that country. Silk, cotton, velvet, ribands, linen, and thread are among the principal manufactures.

The lake of Haarlem, which lies south east of the town, is 14 miles long, 10 broad, and 14 feet deep, between water and mud. The mud of the lake is manufactured into valuable bricks called clinkers. The project of draining this lake has been briefly adverted to under DRAINING; and we give here a few additional details concerning the progress of the works. The area of the lake is between 400,000 and 500,000 acres, and it is intended to leave not more than 700 under water. The drainage is now about two-thirds completed. The area of the lake is expected to sell for above 7*l.* per acre, subject to the land-tax of about 7*s.* per acre. The soil is a peaty loam, and the whole is to be kept dry, after the present operations are completed, by a canal through the middle and smaller inlets into the lake.

HADDINGTONSHIRE. Several attempts have been made to introduce manufactures into this Scottish county. Pot-barley mills, flax mills, cotton mills, paper mills, and starch works have been tried at different times, but from various causes they have failed; and the manufactures at present carried on in the county are very unimportant. A good deal of fishing is carried on near the coast. From Haddingtonshire the improved system of agriculture has been diffused over Scotland, and this county continues to hold a high rank in respect of agriculture and produce. The smaller farms are on the most productive soils. Wheat is the principal grain cultivated, though large crops of beans and oats are likewise raised. The turnip crops are very large. Barley is not much cultivated. Since the increase of pasture land the breeding of sheep and cattle has been extended; but breeding in the lowland and midland districts is carried on upon a very limited scale, the more usual practice being to purchase and fatten for the Edinburgh market. In the Lammermuir district, however, the breeding of live stock is the chief business of the farmer. The town of Haddington carries on a considerable trade in wool, in tanning, and in preparing bones and rape cake for manure. It is also one of the largest wheat-markets in Scotland.

HAGUE. This large and beautiful Dutch city, though neither manufacturing nor commercial in its general features, is preparing for the Great Exhibition carved rosewood furniture, silver embroidery, chased silver cups, and other specimens of workmanship.

HAINAULT, is a very fertile, busy, and prosperous province of Belgium. The chief crops are wheat, rye, oats, barley, beans, rape, flax, hops, and potatoes; tobacco and chicory are also grown. Much of the land near the rivers is laid out in meadow; in other parts trefoil, lucern, and sainfoin are cultivated. Horned cattle, horses and sheep of excellent breed are numerous; poultry, game, and bees abound. The province is traversed by several good roads and numerous canals, by which communication was much facilitated, even before the making of railways; and, like every other part of Belgium, it is well supplied with this new and rapid means of transit. The commerce of the province is composed of its varied industrial products—glass, porcelain, pottery, salt, spirits distilled from grain, beer, machinery, woollen stuffs, linen, lace, Brussels carpets (the great manufacture of which is in Tournay), &c. The most considerable articles of export are coal, iron, and lime, which are transported by canals and railroads to France and the neighbouring countries. Slates, marble, and building stone are quarried.

Charleroi is one of the manufacturing towns; glass, salt, sugar, leather, nails, woollen yarn, &c., are among its products. The town stands in a most extensive coal field, which gives employment to 10,000 men, and yields annually 3,000,000 tons of coal. The number of smelting furnaces, iron foundries, and nail factories in the surrounding district is very great. At *Chimay* are numerous breweries, iron works, and coal mines. *Lessines* is a place of much trade; the neighbouring quarries furnish large quantities of paving and building stone. There are salt refineries, distilleries, and chicory-factories; and there is much trade in coal, wood, and oil. There are many other large manufacturing towns in the province, several of which are on the list of those who will contribute to the Industrial Exhibition.

HAIR; HAIR-WORKING. The hairy coverings of animals are composed of long delicate processes of a horny substance, which grow from bulbs situated in or beneath the skin. Human hair is more or less flattened, so that a transverse section presents an elliptical form, or sometimes, from one side being grooved, has the shape of a bean. The hair of the whiskers, beard, and mustachios, and in general all short curly hair is most flattened. In most instances flatness and curliness are directly proportionate, and both attain their maximum in the crisp woolly hairs of the negro, which are sometimes as much as two thirds broader in one direction than in the other. Except at their base the hairs are perfectly solid, and in most animals their substance is similar throughout. The hair of the head is sometimes known to have attained a length of seven or eight feet.

Hairs are very elastic; they admit of being stretched nearly one third of their length, and regain their original length almost completely; in proportion to their size they are very tough and firm. In chemical properties hair resembles horn, nails, &c. It is soluble in water at a very high temperature, as in a Papin's digester, leaving a large quantity of oil mixed with sulphuret of iron, and some sulphuretted hydrogen. It is this oil, with the sulphuret of iron, which gives the colour to the hair, and by whose absorption grayness is produced. The iron is most abundant in the darkest hair, and the sulphur is the ingredient on which the action of the various black dyes for red or gray hair depends.

In the manufacture of hair into various articles of use and ornament, the hair of different animals is employed; but the most singular feature connected with the manufacture is the *hair harvest* in France. Young women in England, who have beautiful tresses, are often urged by poverty to part with them for money to the hair-workers; but in France it is a regular system. There are hair merchants in Paris, who send agents in the spring of each year into the country districts to purchase the tresses of young women, who seek to obtain an annual crop with the same care as a farmer would a field crop. The agents frequent fairs and markets; and have with them a stock of handkerchiefs, muslins, ribbons, &c., which they give in exchange for the hair. So sensitive a barometer is commerce, of slight changes in the value of exchangeable goods, that the agents know the hair of a particular district to be worth a few sous more per pound than that of a district thirty or forty miles away: a fact which naturalists would have been long in finding out. It is estimated that 200,000 lbs. of hair is purchased at each spring harvest. The price paid is about five francs per lb. The agents send the hair to their employers, by whom it is dressed and sorted, and sold to the hair workers in the chief towns at about ten francs per lb. That which is to be made into perukes is purchased by a particular class of persons, by whom it is cleaned, curled, prepared to a certain stage, and sold to the peruke maker at twenty to eighty francs per lb. The peruke maker gives it the form which, as is well known, commands a very high price; a peruke is often sold for double its weight in silver.

In respect both to the hair itself, and to perukes and other articles made of hair, France supplies a considerable quantity to England and the United States. The importations of hair, and of manufactured goods in which hair is the only or chief material, have lately been to the value of about 20,000*l.* annually.

Differences are observed in manufactures from *curly* or from *straight* hair; the former is spun into a kind of elastic cord; while the latter is woven into cloth for sieves, or damask hair chair bottoms. The hair here spoken of is horse hair, obtained chiefly from the tail. It may be dyed of various tints. The mode of weaving horse hair cloth does not differ essentially from other kinds of weaving: there are a few minor adjustments of the loom necessary, to accommodate the rigidity of the material. In many kinds of such cloth the warp is made of black linen thread or yarn. The cloth is hot calendered after weaving to give it a gloss. The manufacture of hair pencils is noticed in a later article. [PENCILS.]

HALEB, or ALEPPO, is one of the busiest cities of Syria, or of the east generally. Before the earthquake of 1822 Haleb was supposed to possess 12,000 artisans, and was celebrated for its gold and silver lace, its manufactures of silk and cotton goods, shawls, &c. It carries on a great caravan trade with Persia, and the eastern parts of Asia. The goods destined for the European market are shipped from the port of Latakia. Consuls from all the commercial states of Europe reside at Haleb. The inhabitants of the district around Haleb only cultivate the land in the mountainous districts, which produce wheat and other sorts of corn, melons, olives, cotton, tobacco, figs, &c.: the level parts of the country are abandoned to the Kurds and Arabs.

HALIFAX takes a high rank among the clothing towns of the West Riding. The chief articles at present manufactured at Halifax are worsted stuffs, including shalloons, tammies, calamancoes, duroys, everlastings, moreens, shags, serges, merinos; also baizes, narrow and broad cloths, and kerseymeres. Bombasins, crapes, and other fabrics, composed of silk and worsted, are also manufactured here, and the cotton trade is carried on to a considerable extent. Halifax has joined with the other West Riding towns to furnish a combined series of specimens for the Great Exhibition: a mode well calculated to illustrate the resources of this highly interesting district.

HAMBURG. This large city, the most important centre of commerce in Germany, is the main channel of communication between North Germany and foreign countries. The number of vessels that enter from the sea is about 4000 annually, with an average tonnage of about 150 tons per vessel. In 1845 the entries from the sea were 3990 ships, as follows:—

435 from Transatlantic ports;
1566 from British ports
1989 from other European ports;

and these numbers will afford a tolerably correct ratio for later years. Of the values of the commodities imported by this mass of shipping we have no specific returns; but, taking imports and exports together, the sea-borne trade of that year was about 22½ millions sterling.

The imports are composed chiefly of sugar, coffee, raw and manufactured cotton, cotton yarn, tobacco, hides, dye-stuffs, wine, brandy, tea, rum, spices, &c. The exports comprise grain of all sorts, wool, seeds, bark, spelter, butter, salt provisions, rags, wooden clocks, linens, all kinds of German manufactures, Rhenish wines, &c. Hamburg possesses about 600 ships, including a few steamers. It has regular steam communication with London, Amsterdam, &c.; steamers daily ascend the Elbe to Magdeburg.

A very large model of St. Stephen's Church, the chief church in Hamburg, is to be deposited at the Great Exhibition; the former church was destroyed at the great Hamburg fire in 1842; and the present structure has been built from the designs of an English architect. Some beautiful specimens of ivory carving are said to have been prepared at Hamburg.

HAMPSHIRE. The New Forest in this county has varied in area from time to time: at present it includes 64,000 acres, and is the property of the crown, subject to rights of common and other ancient claims. Much of the oak and beech timber for the navy is grown here. Alice Holt Forest also contains much valuable timber. The northern part of the county is naturally very unproductive, and till within a few years was almost entirely covered with a brown heath, on which some hardy forest sheep and a few miserable cattle were reared, and contrived to pick up a scanty living; but a good deal of heath has recently been brought into cultivation. South of this district the chalk prevails, better adapted for pasture than for corn culture. In the valleys and along the lower slopes of the chalk-hills the soil is of a tough tenacious nature, very difficult to cultivate; but it can be made to yield good crops of beans, wheat, and oats. Hampshire, although it cannot be compared with some eastern and northern counties for agricultural improvements, is not far behind them; and there are some farms as well managed as any in England. The farm-buildings and the agricultural implements are gradually improving. The native hogs, which live on the acorns and beech-mast of the New Forest, although the flavour of their flesh may be good, are coarse, raw-boned, flat-sided animals, and are now seldom met with. The improved breeds produced by crosses of the Berkshire, the Suffolk, Essex, and Chinese pigs, are those from which the Hampshire bacon is usually prepared. The excellence of this bacon is mainly due to the care with which the curing is effected.

Hampshire cannot be deemed a manufacturing county; although there are several bustling towns. Alton is celebrated for its ale breweries, and for the hop-plantations near it. At Andover the chief business consists in malting, and in the manufacture of silk. The malting and corn trades constitute the principal business of Basingstoke. At Fareham considerable trade in corn and coal is carried on. At Fordingbridge there are some manufactures of sail-cloth and bed-ticking. Winchester depends more on its ecclesiastical antiquities than on its trade and commerce. PORTSMOUTH and SOUTHAMPTON call for a word of notice elsewhere.

HAMS. Hams are usually prepared from the legs of pigs; but those of the sheep are also sometimes prepared. They are salted either by immersion in the pickle, or by having salt rubbed over them. A little powdered saltpetre is sometimes rubbed over them before salting; and moist sugar or treacle is frequently employed for flavouring. About three weeks are required for wet-salting, and four for dry-salting; mutton hams do not require so long. When properly salted, the hams are ready for smoking.

There were 11,751 cwts. of hams imported in 1849; and 16,268 cwts. in 1850.

HAND-GLASS is a name given by gardeners to a portable glazed cover which they place over certain plants for one of two purposes; either to screen them from the effects of cold and wet without depriving them of much light, or to maintain around them an atmosphere of uniform humidity. Bell-glasses differ from hand-glasses in no respect with regard to the purpose they are intended to serve, but are blown from a single piece of glass instead of being composed of many pieces fastened together. Glasses of this description are principally used to assist cuttings of plants in the process of striking root, or newly planted individuals in establishing themselves in the soil.

HANOVER. The mountains in the southern part of this kingdom abound in mineral wealth, and are covered with forests of red pine and fir, with some oaks and other timber. Agriculture is the chief source of subsistence to the inhabitants, which is much favoured by the facilities for exportation when the harvest is abundant, as well as by the transit trade, and the consumption of the neighbouring maritime towns. In the marsh-land the breeding of cattle is more followed than agriculture. The county produces flax, tobacco, hops, fruit, pulse, potatoes, &c. Timber is abundant, and considerable quantities are exported.

Manufactures are not carried on to any considerable extent. Thread, linens, woollens, and calicoes are manufactured to a small extent. The commerce is not of large amount. The principal commercial port is Embden; and Münden, at the junction of the Werra and the Fulda, has an active trade with the interior of Germany.

The Hanoverian produce imported into Great Britain in 1849 was valued at 185,287*l.*; and the British produce and manufactures exported to Hanover 150,927*l.*

It has been stated that the manufacturers of Hanover have not received from their sovereign, in respect to contributions towards the Industrial Exhibition, that countenance and assistance which most continental sovereigns have afforded in their respective countries; and that the specimens transmitted to England will be limited by this circumstance.

HANSEATIC LEAGUE. This was a very remarkable commercial association, which took its name from the ancient German word 'Hanse,' signifying an association for mutual support. The cities of Hamburg, Lübeck, and Bremen were, in the middle ages, the depositories of the manufactures of Italy and Germany, with which they supplied the northern countries of Europe in exchange for their raw produce. The wealth which they acquired excited the envy and the rapacity of the princes and nobles; the imposition of new and the augmentation of old tolls were great impediments to trade, which was likewise rendered unsafe by numerous banditti and pirates who infested the roads and the neighbouring seas and rivers. Hamburg and Lübeck concluded an alliance in 1241 by which they engaged to maintain ships and soldiers for the purpose of protecting their commerce. The city of Brunswick joined the alliance in 1247. In course of time most of the trading towns in Europe joined this association, which included London, Rouen, Bordeaux, St. Malo, Bayonne, Marseille, Barcelona, Seville, Cadiz, Lisbon, Antwerp, Danzig, Dort, Amsterdam, Bruges, Rotterdam, Ostend, Dunkirk, Leghorn, Messina, Naples, Bergen, Novgorod, all the towns on the Baltic, the Elbe, and the Weser, Embden, Cologne, and other towns, to the number of eighty-five. Their principal factories were Bruges, London, Novgorod, and Bergen. All the towns sent deputies to a congress which usually met in Lübeck. The Hanse Towns became so powerful, that in 1348 they defeated the kings of Norway and Denmark, deposed Magnus, king of Sweden, and gave his crown to his nephew Albert; they equipped in 1428, 40 ships of war and raised 12,000 troops, exclusive of seamen, in a war with Erick, king of Denmark; and in the same century they compelled Edward IV. to restore all their privileges and property in England, which he had attempted to withhold. That part of the city of London called the Steelyard was their exclusive property, and Bishops-Gate, one of the principal entrances to London, was intrusted to them to guard. But when the roads and seas were no longer insecure, when America was discovered, and India was reached by doubling the Cape of Good Hope, the Hanseatic League gradually declined, and at the last general assembly at Lübeck, in 1630, the deputies from the several cities appeared merely to declare their secession from the League. Hamburg, Lübeck, and Bremen, formed an association in 1641, and remained free republics till December 1810, when they were incorporated with the French empire, but in 1813 they were again separated from France, and with Frankfort-am-Main are now called the Free Hanseatic Cities of the Germanic Confederation.

HARBOURS OF REFUGE. Among the engineering works now in progress, in the southern half of our island, the formation of harbours of refuge is not the least important. Numerous as are our ports, harbours, bays, and æstuaries, fitted to receive and despatch merchant shipping, there is a deficiency of harbours into which fleets could go to find shelter during a storm, and which would serve as general places of rendezvous for shipping.

Dover is in many respects one of the most important harbours on the coast: chiefly from its proximity to the continent. Yet is it only a tidal harbour, and has a shallow entrance even when the tide is in. Many a merchantman would be glad to avoid the perils of the Goodwin Sands by a temporary anchorage in Dover Harbour, if it were better suited as a refuge. In 1844 a Government Commission was appointed to consider this subject, in relation to the forming of harbours of refuge for merchant ships, and stations for war ships. The commissioners recommended extensive works at Dover, Portland, Seaford, and Harwich, with this object in view: to be proceeded with in the order here specified if all could not be advanced simultaneously. The recommendation was adopted, in its main features, by the Government. The harbour of refuge at Dover is being constructed; there is to be a harbour of 520 acres up to high water mark, or 380 acres at low water; there is to be an entrance 700 feet wide on the south side, and another 150 feet wide on the east. The first work will be a pier, running out from the point called Cheeseman's Head into seven fathoms water; it will protect the existing harbour during south-west gales, and will form the first link in the great wall of masonry which will enclose the harbour. The eastern boundary of the harbour will be far beyond the limits of the present inhabited town of Dover; the harbour will be a mile and a quarter from east to west, and three quarters of a mile from north to south. The existing contract for a part of the works was taken in July 1847; the works were commenced in October of the same year; in 1848 the masonry was carried out 270 feet from the shore; in 1849 this length was increased to 460 feet; in 1850 the works were proceeding steadily, until a terrific storm on the night of the 7th of October, produced very disastrous results on the masonry and scaffolding. Much of the subsequent labour has been in repair of this disaster.

The operations at Portland are briefly noticed in another article. [DORSETSHIRE.] See also the article BREAKWATER.

HARDNESS. In distributing crystals and minerals into classes, an attempt is made to determine their relative hardness. The following are the gradations, from soft to hard:—

Talc, white or greenish; rock salt and uncrystallised gypsum; calcareous spar, cleavable; fluor spar, which cleaves perfectly; apatite, from Salzburg; adularia; rock crystal, transparent; topaz; corundum, from Bengal; diamond.

HARP. This is one of the most ancient as well as most beautiful of all musical instruments. The Welsh triple-stringed harp of the present day extends from G an octave below the first line in the base, to G, or A in altissimo on the *right* side; and from G, the first line in the base, to the same upper notes on the *left* side; the middle row consists of the semitones of the outward rows. Hence, if the outside rows be tuned in the diatonic scale of G, each parallel note being in perfect unison, the notes of the middle row are tuned a semitone higher.

The harp, as a generally useful instrument, may be said to date its existence from the time when pedals were added to it, by the invention of Sebastian Erard. With these it is possible to modulate into all keys, and to execute any music suited to keyed instruments. In the *single action*, the pedals raise the tone of every string half a note; in the *double action*, the instrument is tuned in C flat; and by fixing the pedals in the first groove the instrument is at once transposed into C natural: whereas by fixing them in the second groove it is transposed another semitone higher, into the key of C sharp. The compass of the harp thus improved is from double E below the base to E in altissimo.

HARPSICHORD. This keyed musical instrument, in form the same as the grand pianoforte, but smaller, was strung with steel and brass wires, two to each note; these were struck by *jacks* armed with small pieces of quill, acting as plectrums, and thus made to render a brilliant but somewhat harsh sound, wholly unlike that produced by the hammers of the pianoforte. *Stops*, *swells*, and double rows of keys were occasionally employed to modify the power of the wires. The harpsichord came into use in England in the seventeenth century; but it is now entirely superseded by the PIANOFORTE.

HARROWS. The well-known agricultural implement, the *harrow*, which is drawn over the land when the seed has been sown after the last ploughing, is a frame set full of spikes. The *bush-harrow*, which is drawn over the ground after the seed has been sown by the dibble, is without spikes, but has thorns or rough bushes fitted into it.

At the various agricultural and cattle shows improved forms of harrow are constantly making their appearance. Among those of recent introduction is Uley's drag harrow, or Scarifier and Cultivator; it has two small wheels in front, two larger behind, and five or seven tines or spikes, according to the width. Smith's Iron Harrow comprises three frames linked together at certain spots, and having about sixty tines or spikes arranged in such a way that each tine leaves its scarified mark or line in the ground independent of the others. Crosskill's Norwegian Harrow is used immediately after ploughing, and leaves three or four inches depth of finely pulverised mould, well prepared for sowing; the instrument acting by a rotatory motion given to barrels loaded with spikes, which scratch along the ground as the machine proceeds. Numerous other forms are frequently brought before public notice.

HARTSHORN. The horn of the common stag contains less earthy matter, and more gelatine, than other bones, and is on this account very useful in medicine. It is kept in the form of shavings, of which a sufficient quantity boiled in water yields a jelly suitable to convalescents, which may be flavoured with lemon-juice or wine, &c.

The liquid which is called *Spirits of Hartshorn*, and which is obtained from hartshorn and other kinds of horn, is carbonate of ammonia combined with a peculiar oil.

HARTZ FOREST. The mineral treasures of this district are noticed under GERMANY.

HAT MANUFACTURE. English hats, in the present day, are mostly made of straw, wool and fur, or silk. The first are noticed under STRAW PLAIT. Beaver hats of the finest quality are made with lamb's wool and the fur of English rabbits. To form the body of the hat, the wool and rabbit's fur are separately *bowed* in the manner employed for freeing cotton from its seeds. The two substances are next bowed together until they are intimately mixed; after which the mass is spread evenly, covered with an oil-cloth, and pressed to the state of an imperfectly tangled felt. The next process is to cover the felt with a triangular piece of damp brown paper, and then to fold it in a damp cloth and work it well with the hand, pressing and bending, rolling and unrolling it, until the interlacing or felting is much more perfect, and the mass is compact. The felt thus prepared is next taken to the wide brim of a boiler charged with hot water and beer-grounds and a small quantity of sulphuric acid; it is wetted, rubbed, and rolled, until it no longer contracts. The felt is next stiffened with shell-lac, a solution of which is applied by means of a brush to one or to both sides of the felt; after which it is heated in a stove, and by this means the whole substance becomes duly impregnated with the resin: this renders the hat nearly waterproof. To form the nap of a hat, one-half or three-fourths of an ounce of beaver, and some other less costly fur, are bowed together and imperfectly felted in the manner already described, and shaped the same as the body to which it is to be applied; that body is then softened by immersing it in the boiler, when the nap is applied and worked as in felting, until the required union is effected between the two bodies.

The felt thus covered is brought to the proper shape by working it on a wooden block, and is then dyed black. The hat is softened by steam, the crown is strengthened by placing in it a disc of scale-board, and linen is pasted over this. The nap is raised, and a uniform direction given to its fibres by means of warm irons and hair brushes. The last processes are binding and lining, when the hat is ready to be worn. In the low-priced hats of the present day, commoner wool and fur, and smaller quantities of each, are used.

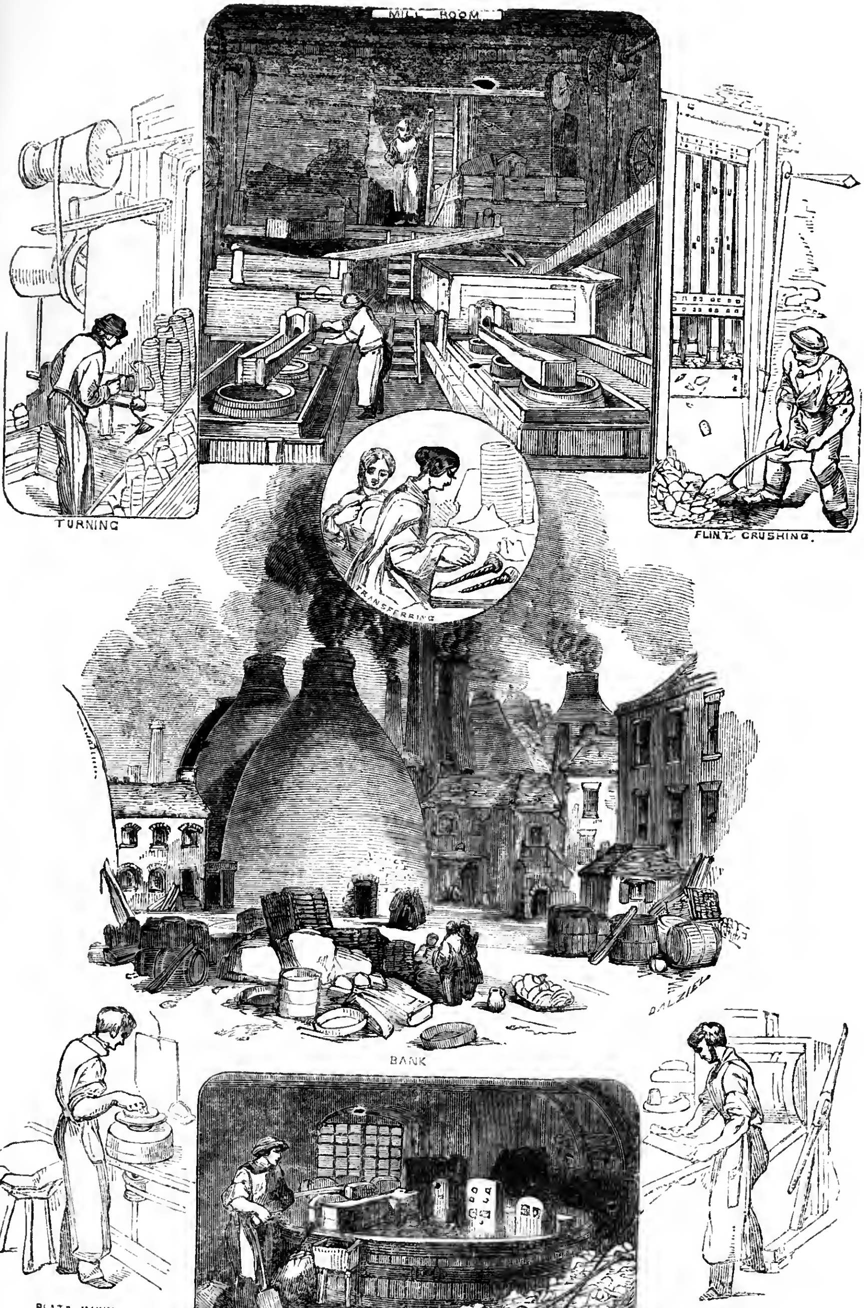
Silk hats consist of a cover or exterior part made of silk plush, which is laid upon a foundation of chip, stiffened linen, or some other light material, previously blocked into shape. The so-called *Velvet* hats and *Satin* hats deserve those titles only so far as the plush resembles those materials. The plush is mostly woven in the north of England. *Paris* hats are for the most part made in England, the silk plush being imported from France, where it is made better than our weavers seem able to equal.

The hats exported in 1848 amounted in number only to 8,768 dozens, and in value to 27,455*l.*: so little demand is there abroad for English hats; the exports are almost entirely to our own colonies. Silk-plush for covering *Paris hats* was imported in 1850 to the extent of 138,909 lbs.

HATCHING APPARATUS. The method, strange to those who do not understand it, of hatching chickens by artificial means, is nothing more than a mode of applying warmth to the eggs. If a hen for any reason does not 'sit' upon her brood, an *artificial* mother is sometimes provided, which will rear several broods at once; it is a board or box lined with soft lambskin, covered with a wicker, and placed near a heated wall in such a way that the young chicks may receive warmth sufficient for their tender condition. These artificial mothers are, however, only a sort of house for chickens newly hatched: they are not hatching-machines. The Egyptians have long been in the habit of applying heat and moisture artificially to the hatching of chickens. Mr. Bucknell some years ago invented a hatching-machine under the somewhat learned name of the *Eccalcobion*; and more recently Mr. Cantelo's *HydroIncubator* has attracted public attention. In this apparatus heat is applied to the upper surface of the eggs as they are ranged in layers. A current of warm water flows over a waterproof cloth, beneath which the eggs are placed. A tank of water is kept continually at a temperature of 109° Fahr., with the surface so arranged that the heated water may flow over the waterproof cloth: a return pipe being so placed as to connect the outer end of the cloth with the bottom of the tank. There is thus a continual flow of water over the cloth, at one uniform temperature. The eggs are placed in drawers having perforated bottoms, with a layer of woollen cloth between; the upper surface of the eggs can just touch the under surface of the warmed waterproof cloth; but the arrangement is such that air can freely circulate between the eggs and the cloth. The water is heated by slowly burning charcoal fires.

Although there is much ingenuity displayed in this apparatus, it seems doubtful whether the method will be a commercially prosperous one.

HAVANNAH. This flourishing commercial town, with the best harbour in the West Indies, or perhaps in the world, has been already mentioned under CUBA. Its magnificent harbour is capable of accommodating 1000 ships of the largest size, vessels of the greatest draught coming close up to the quays. Among the commercial cities of the western hemisphere Havannah ranks inferior only to New York, and for a long period it engrossed the whole foreign trade of Cuba. The principal articles of export are sugar, copper ore, coffee, raw tobacco and cigars of the best quality, molasses, and the precious metals; other exports are mahogany, cedar, rum, cocoa, cotton, wax, hides, fruits and preserves, honey, dye-stuffs, &c. In consequence of the relaxation of the English tariff in 1842, and of the sugar act of 1846, the exports are said to have greatly increased, and this is in part proved by the quantity of sugar exported in 1847, which from Havannah and Matanzas amounted to 1,004,496 boxes. The imports are composed of flour, corn, provisions, cotton goods, wine, linen, hardware and metals, silk, gold and silver from Mexico, spices, leather, butter, lard, cheese, fish, deals, casks, hoops, &c. The trade of Havannah extends to all countries of Europe and America, but chiefly to Spain, the United States, and England. In the nine months from January to September 1850, no fewer than 1262 ships entered the



KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 25.

port of Havannah, with a tonnage of 418,388 tons.

HAVRE. The harbour of this important French seaport consists of three wet docks, and an outer port separated by locks, and capable of containing 450 ships. A fourth dock is in course of formation for steamers. The fine quays which border the docks are always lined with vessels, and present great activity of business. The trade of Havre produces in ordinary years customs duties amounting to about a million sterling, representing a total movement of merchandise to the value of over 20,000,000*l.* Besides vast quantities of foreign and colonial produce for the supply of Paris and the north of France, such as coffee, sugar, spices, the imports consist of raw cotton for the manufacturing districts of Rouen, St. Quentin, &c., of indigo, dyewoods, tobacco, rice, hides, timber, iron, tin, tea, &c. The principal exports are silks, broadcloth, cotton manufactures, lace, gloves, shoes, trinkets, plated and tin wares, perfumery, wine, brandy, glass, furniture, books, &c. Above 450 vessels belong to the port, including 50 of 400 to 500 tons engaged in the whale fishery, and 40 large and small steamers. There is regular communication by powerful steamers with Rouen, London, Southampton, Bayonne, Hamburg, Lisbon, &c., and by packet ships with New York, Bahia, Vera Cruz, New Orleans. Small steamers ply to Honfleur, Caen, Rouen, and Paris. The manufactures comprise vitriol, pottery, lace, paper, oil, carpenters' tools, bricks and tiles, ship cordage, tobacco, furniture, &c. There are also several sugar refineries, and breweries. Outside the town and close to the shore there are five ship-building yards, which have constructed some of the best sailing vessels and swiftest steamers belonging to France.

HAY-MAKING MACHINE. The grasses which form the material of a field of hay are of several kinds. The *sweet-scented vernal grass* gives the delightful odour to newly mown hay; the *cock's foot grass*, a coarser but valuable herbage; the *fox tail grass*, greatly relished by cattle; the *meadow fox tail grass*, liked by sheep; the *meadow fescue*, and many other kinds. All these are alike cut down by the mower's *scythe;* which is a long thin blade of steel, well tempered, and having a rim of iron along the back to within a few inches of the point; the handle is of wood, and is adjusted at a particular angle to the plane of the blade; two short projecting handles are fixed to the principal handle, to facilitate the using.

There is no machine, we believe, to supersede hand labour in cutting hay; and therefore the so-called hay-making machines must be understood as applying to a later process. Under ordinary circumstances, the cut grass is collected into heaps by *rakes*, worked by hand; but on large farms a *horse rake* is sometimes used; there are twenty or more teeth or tines, which are drawn over the field until they have collected as much as the interstices can contain; and then the driver, by lifting up a pair of handles, raises the teeth from the ground, so as to throw out the contents of the rake. The *hay making* or *hay tedding machine*, however, turns the hay over and over in the field; it is chiefly valuable for meadow-hay, which requires more turning and scattering than hay from clover or rye-grass. There is a cylinder, or framework of wheels, with rows of prongs projecting from the surface; the cylinder revolves on the same axis as the driving-wheels, and with the same speed as those wheels. As the cylinder revolves, the hay is caught up by the prongs, and thoroughly *tedded* or spread abroad. Various minor improvements have from time to time been made in the construction of these machines.

HEAT. The fundamental laws of heat, so far as they have yet been discovered, form a very subtle and difficult department of science. Only a few words respecting the action of heat can be admissible in this work.

It is found that *expansion, fusion, evaporation, thermo-electric currents*, and various *physiological* phenomena, are effects of heat or at least accompany its absorption. Besides the solar rays, heat may be produced artificially by any means which propagate agitations internally in bodies; hence friction, hammering, percussion, sudden condensation, chemical combination, and electrical discharges are all proper to produce or rather to develope heat.

The spread of heat throughout a liquid is marked by curious effects. If we place a heated plate on the surface of water in a vessel, but so as not to touch the edges, a thermometer placed in the water will indicate little or no alteration of temperature; and, if the bottom of a vessel of water be heated, the heat will be distributed through the liquid only by currents ascending from the heated part. Liquids indeed conduct heat very slowly; and it is only by the rising of heated particles of water, through their lightness, that a vessel of water is quickly heated.

The agency of heat in promoting chemical action is important and extensive; in some cases no combination can take place without it, and in others it greatly facilitates chemical combinations, while in some instances it decomposes compound bodies, and resolves them either into simpler or elementary forms of matter. In the solution of salt in water, an increase of heat, by increasing the affinity between the solid and the liquid, increases the solvent power. Heat has also great power in modifying as well as in causing chemical action, and different degrees of it produce very opposite effects in some cases. The dilatation of substances by heat is nearly proportional to the increase of temperature, except when they are about to change their physical or chemical states; thus water near the freezing point expands when the temperature is diminished. The following table gives the relative dilatation of different solids from the freezing to the boiling point:—

Glass tube	.00083	Copper	.0017
Crown glass	.00089	Brass	.0018
Platinum	.00093	Silver	.0020
Palladium	.001	Tin	.0022
Cast Iron	.0011	Pewter	.0023
Steel	.0012	Grain tin	.0025
Do. tempered	.0013	Lead	.0028
Gold	.0015	Zinc	.0030

Several instruments have been constructed to measure heat; the most important of which are noticed under PYROMETER and THERMOMETER.

HEDGE. Hedges are made of various kinds of shrubs and trees, trained so as to throw out numerous branches along the stem from the surface of the earth upwards; this is done by judicious pruning when they are young. Holly, which bears prickles on the edges of the leaves, is on this account by far the best shrub to form a hedge; but yew, box, thorn, hornbeam, elder, sweet briar, prickly pear, and privet are all employed for hedges, each having its particular excellencies, and requiring a particular kind of culture. There is a method of repairing hedges which is called *plashing*. It consists in cutting half through some of the stems near the ground, and then bending the upper parts down in a horizontal or oblique position, keeping them so by means of hooked sticks driven into the bank. Thus a live hedge is made, which fills up the gaps in the same manner as a dead hedge would have done, and the bent stems soon throw out shoots.

HELENA, ST. This lonely island, situated in the Atlantic Ocean, 1200 miles west of the coast of Benguela, in South Africa, has one of the healthiest climates under the tropics, and is found beneficial to invalids from India and even from Europe. Viewed from the sea, the island appears barren; but the interior is covered with a rich verdure, and is watered by abundant springs. Horned cattle, sheep, and goats feed on the rich pastures. As an English settlement it is of little importance; it is visited by ships returning from India, who there take in fresh provisions and water.

The British produce and manufactures exported to St. Helena in 1849 amounted in value to 18,315*l*.

HE'LIOSCOPE is the name given to a kind of telescope adapted for making observations upon the sun without the eye being injured by the intense brightness of the solar rays. A coloured glass placed before the lens nearest to the eye, in a telescope, has long been the means used to prevent such injury.

HE'LIOSTAT is an instrument employed in making experiments on light. The instrument consists of a plain metallic mirror, from the back of which projects a rod perpendicularly to its plane. The extremity of the rod is connected with the index of a clock, the plane of whose face is parallel to the equator; and, as the index is turned by the wheel-work, the motion of the rod causes the mirror to turn about a vertical axis, and also about a horizontal axis, so that a pencil of the sun's light reflected from the mirror is always in the same position.

HELLEBORE. *White Hellebore*, a valuable medicine, is prepared by triturating the roots of a plant of the same name, called by botanists the *Veratrum Album*. There are also *black hellebore* and *oriental hellebore*, both used medicinally, but derived from plants of different genera from that which yields the white.

HEMP; HEMP-SEED. The plant which yields this most valuable fibre is the *Cannabis sativa*, nearly allied in many of its botanical features to the nettle. It is said to be a native of Persia, but is now known throughout northern Europe. The hemp plant possesses a remarkably tough kind of woody tissue, capable of being manufactured into canvas and cordage; and its value in this respect has given rise to manufactures and commerce of great magnitude. [ROPE-MAKING; SAIL-MAKING.]

The extraction of the fibre from the plant is so similar to that of flax, that we may refer to FLAX for a brief description. Hemp-seed is made to yield a useful oil by pressure; and the hemp plant is useful in many ways for medicine.

Nearly all our hemp is procured from Russia. During the war, the demand was so large (for ship's cordage), and the supply so precarious, that the price sometimes rose to 118*l*. per ton; in recent years the average price has been about one quarter this amount.

The quantities of hemp, imported in the last four years have been as follow:—

1847	..	811,565 cwts.
1848	..	845,771 „
1849	..	1,061,893 „
1850	..	1,048,635 „

Of these quantities, the supply from Russia has been nearly two thirds.

HENBANE, is one of the species of the plants belonging to the *hyoscyamus* genus. The leaves and seeds contain a powerful principle called *hyoscyamia*, on which the deadly as well as the medical effects of henbane depend.

HERAULT, one of the departments of France, produces corn in quantity more than sufficient for the consumption. There is a considerable breadth of artificial meadows; and large crops of lucern, sainfoin, and clover are grown. For quantity of wine produced, Hérault stands at the head of the wine growing departments of France, the annual produce being nearly 50 million gallons. The red wines of St. Georges, St. Christol, and St. Drézéry, the muscadel wines of Frontignan, Lunel, and Béziers, and the white wines of Marseillan and Pinet, are considered the best. Fruits, especially raisins, olives, almonds, figs, and chestnuts, and all kinds of pulse are grown. The mulberry is cultivated for the production of silk; aromatic and medicinal herbs, and plants used for dye stuffs, are gathered. The principal material of the woods are the chestnut and green and white oak. The industrial products comprise woollen cloths, silks, hosiery, calico, muslin, flannel, blankets, brandy, chemical products, pottery, tiles, honey, perfumes, leather, oil, beer, paper, &c. There are also numerous dye houses, and establishments for the rearing of silkworms. Ship building is carried on at Cette and other towns on the coast. Mines of coal and copper, quarries of marble, building and mill stone, slate, gypsum, and granite are worked. A vast deal of salt is made by evaporation on the lagunes and on the shore of the Mediterranean, this department being one of the chief sources for the supply of that article to France. The exports consists of most of the articles enumerated, but chiefly of wine, dry fruits, and brandy. The imports are wool, cotton bales, staves, colonial produce, raw hides, cork, &c.

HEREFORDSHIRE. The soil of this county is very favourable to the growth of trees, especially the apple tree and oak. In the neighbourhood of towns the land is cultivated chiefly as meadow or pasture. The high lands are generally occupied by oak coppices, which are numerous and extensive; these are felled at periods of from 16 to 20 years, and fetch a price of from 18*l.* to 20*l.* an acre. In the lower lands, crops are raised in the following succession: wheat, turnips, barley, clover, and peas or vetches. Hop yards are common in the middle and eastern portions of the county. Orchards are numerous, and produce large quantities of cyder.

Few of our counties possess so little mineral wealth as Herefordshire; nor are its manufactures or general commerce considerable. There is an iron foundry and a little manufacture of gloves, at Hereford; and miscellaneous manufactures at Bromyard, Ledbury, Kington, Leominster, Ross, and Weobly.

HERRING FISHERIES. A brief notice of the herring fishery, as a department of commerce, is given under FISHERIES.

HERTFORDSHIRE. This county has no minerals of any value. The loams are generally well cultivated, but the heavy clays are capable of much improvement. Wherever the turnip husbandry prevails, the superiority of the crops is striking. Wheat, beans, oats, and fallows are the only varieties. Clover is much less in quantity than might be desired. The old heavy plough with four horses in a line may still be seen. The county is remarkable for its high banks and hedges; in many of the lanes, where two carriages could scarcely pass one another, it is difficult for a man standing on a waggon to see over the hedge; but wherever the old high banks have been levelled, and neat quick hedges have been planted in their stead, the ground which has been gained has soon paid the expense. A species of rough garden husbandry has been introduced on the best soils nearest to London for the growth of early potatoes, cabbages, peas, and other culinary vegetables, which are succeeded in the same year by other crops, the whole being forced by an abundance of manure. The plough is used, but a great portion of the labour is done by the spade and the hoe. There are many orchards chiefly for apples and cherries, which are sold in London.

Very little manufacturing is carried on in the county. The country around Barnet is celebrated for its hay, and a great deal of business is done at the market. At Bishop's Stortford a great deal of corn is accumulated, and the malting trade carried on to a great extent. At Hemel Hempstead the females are much engaged in making straw plat, and there are corn and paper mills in the neighbourhood. At Hertford a good deal of business is done in malting, and there are many corn mills on the Lea, the Mimram, and the Beane. At Hitchin much straw-plat is made;

there are some breweries, and also a silk mill. At Rickmansworth there are several paper and flour mills near the town; and some straw platting and horsehair weaving is carried on. There is considerable trade at Ware; the market is one of the greatest in the county for corn. At Watford there are considerable silk mills, and also a paper mill.

HESSE. The small German principalities under this name do not occupy a very high rank in industry or commerce. In *Hesse Cassel* flax and timber are the staple articles: tobacco, hemp, madder, a few hops, and rape-seed are also among the products. The vine is cultivated only in some parts of Hanau. Garden produce of excellent quality is raised about Cassel and Hanau. Hesse abounds in mineral wealth, producing silver, copper, lead, iron, quicksilver, cobalt, salt (from saline springs and in great quantities), saltpetre, vitriol, and alum. There are also coals, marble, very fine white alabaster, porcelain, potter's clay, and pipe clay, &c. The manufactures are insufficient for home consumption. The principal are linen, mostly coarse, which is exported to the value of 300,000*l.* sterling annually; fine linen is made in Cassel and Herzberg. Cotton spinning is pretty general. Schmalkalden manufactures almost all the steel and iron of the country; Grossalmerode is celebrated for its crucibles, which are exported to all parts of the world.

In *Hesse Darmstadt* the chief productions are corn of all kinds, likewise maize and spelt—wheat and rye, flax, hemp, hops, tobacco, pulse, potatoes, wines, both white and red, garden vegetables and fruit, and timber. Mining is not carried on to any great extent: it is confined to copper, iron, coals, salt, and brown coal. Cobalt, basalt, lime, sandstone, marble, and slate are found in different parts of the grand duchy. The chief manufactures are of woollens, cottons, and linen, leather, and hardware. Wine is produced chiefly in Rhenish Hesse. The most considerable manufacturing and trading town is Offenbach, which has two annual fairs. Mainz is the principal place for the transit trade. The exports consist of the natural productions of the country and of some manufactures.

These two Hessian principalities will contribute to the extent of the resources to the Great Industrial Exhibition. There are two or three other Hesses, very small and unimportant.

HEXACHORD, was a name given by the ancient Greeks to a lyre of six strings; also to a scale of six sounds. The term hexachord was also applied to a system of musical scales now disused.

HIBISCUS. Many plants of this genus yield very useful fibre for rope-making and similar purposes; this fibre is yielded by the bark. The *hibiscus cannabinus* is cultivated everywhere in India in the rainy season for this purpose; and its fibre is often imported into Europe, as a substitute for hemp. In the island of Tahiti rope and string are manufactured from the bark of the *hibiscus tiliaceous*, which is also made into matting of a white colour, and of different degrees of fineness. Almost all the species possess sufficient tenacity of fibre to be used for cordage, whips, &c. They also abound in mucilage, which renders them serviceable as articles of diet; the calyces are often employed in making tarts, and a decoction of them, sweetened and fermented, is used in the West Indies as a cool and refreshing drink. The seeds of the *hibiscus abelmoschus* are said to be added to coffee in Arabia, and are in India employed as a cordial medicine.

HICKORY. This tree is applied to many useful purposes in North America. The wood is coarse grained, very heavy, exceedingly tough and strong, and red at the heart; but it is not very durable. It is employed for the shafts and springs of carriages, for large screws for presses, for bows, chair backs, whip handles, wooden cogged wheels, cask-hoops, and a variety of other purposes. It is one of the most economical kinds of wood fuel. The nuts of a species called the pecan hickory, are eaten in North America; and so, to some extent, are those of most of the species.

HINDOO MANUFACTURES. Under EAST INDIA COMPANY we have glanced at the commercial relations which exist between India and other countries. We have here to speak of the native skill of the Hindoos. It is evident from the most ancient Sanskrit works, as well as from the testimony of the Greeks who visited the country, that the useful and fine arts had attained a considerable degree of perfection among the Hindoos in very early times. The Ramayana (a Sanskrit manuscript of great antiquity) contains numerous proofs of the progress they had made in working metals. The art of smelting iron ore and of manufacturing steel is undoubtedly of great antiquity; and their skill in the manufacture of gold and silver ornaments is evident from the descriptions of the Ramayana. The degree of perfection to which the Hindoos carried the art of weaving in ancient as well as modern times is well known. Their country has always been distinguished for the number and excellence of the substances which it contains for dyeing colours, and the beauty and brilliancy, as well as durability, of their colours were as celebrated among the Greeks and Romans as among ourselves. Silk was probably manufactured in India in very early times. The art of obtaining intoxicating liquors by distillation is mentioned in the Ramayana and the laws of Manu.

In painting the Hindoos have not attained much proficiency: their artists draw with great accuracy, but they have no knowledge of perspective. With regard to music their instruments are numerous; but their compositions are confined to a few simple melodies.

With respect to the present state of the arts among the Hindoos, Bishop Heber remarks, 'Nor is it true that in the mechanic arts they are inferior to the general run of European nations. Where they fall short of us (which is chiefly in agricultural instruments and the mechanics of common life), they are not, so far as I have understood of Italy and the South of France, surpassed in any great degree by the people of those countries. Their goldsmiths and weavers produce as beautiful fabrics as our own; and it is so far from true that they are obstinately wedded to their old patterns, that they show an anxiety to imitate our models, and do imitate them very successfully. The ships built by native artists at Bombay are notoriously as good as any which sail from London or Liverpool. The carriages and gigs which they supply at Calcutta are as handsome, though not so durable, as those of Long Acre. In the little town of Monghyr, three hundred miles from Calcutta, I had pistols, double-barrelled guns, and different pieces of cabinet work brought down to my boat for sale, which in outward form nobody could detect to be of Hindoo origin; and at Delhi, in the shop of a native wealthy jeweller, I found brooches, ear-rings, snuff boxes, &c., of the latest models, and ornamented with French devices and mottoes.'

Architecture.—The architecture of the Hindoos has hitherto been little studied by professional men. On examining the Hindoo works of construction, or edifices erected above ground, we can hardly avoid being struck by the prevalence of pyramidal masses and forms, as exhibited in pagodas or towers. The Egyptian structures of this kind bear a much closer resemblance to natural or rudely constructed prototypes than do those of the Hindoos. The gopuras, or pagoda towers erected over the gateways leading to temples are indeed pyramidal in their general form, but infinitely more complex than, not the pyramidal alone, but anything else we meet with in Egyptian architecture. Neither do they terminate in a point or mere platform, but have generally a great deal of ornament bestowed on their summit, which sometimes assumes, not inelegantly, the form of a crown. Besides this, they differ from the pyramid in being of far loftier proportions. Of a domical termination, if not exactly a dome, we have an example in the great pagoda at Tanjore, which is considered one of the finest specimens of the kind in India.

HINGE. Hinges are constructed in a great variety of forms; but in most of the commoner kinds the action is that of a hollow cylinder working round a fixed central pin. In Collinge's patent hinges, which are peculiarly adapted for hanging large heavy doors and gates, the principal rubbing action is between a hollow cap and an accurately turned sphere, formed, as it were, upon the end of the pin, a cavity being provided for the reception of a supply of oil to lubricate the rubbing surfaces. Mr. Redmund is the inventor of the rising hinges so frequently used for hanging room doors in houses of superior character. In ordinary door hinges the hollow cylinder which works round the axis or central pin is divided transversely into two or more portions; but in the rising hinges, instead of the hollow cylinder being divided transversely at right angles, it is divided by spiral or rather helical lines. The result of this contrivance is, that when the door is opened it is lifted up a little from the floor by the sliding upon one another of the inclined helical surfaces; so that, although the door may shut very close to the floor, it rises, when opened, to a sufficient height above the floor to allow its lower edge to clear the carpet. Other forms of hinges are very numerous.

HISPANIO'LA, known also under the names of SAINT DOMINGO and HAITI, is one of the larger islands of the West Indies, and is the most fertile of the whole. At the end of the last century Hispaniola was noted for its extensive plantations of sugar, coffee, and cotton, but they have now almost entirely disappeared, except those of coffee, which are much reduced. The principal commercial wealth of the island is derived from the forests which cover the greatest part of the mountains. The timber consists chiefly of mahogany trees and different kinds of dye-woods. The capital, Port-au-Prince, has considerable commerce with the United States and with Jamaica.

HOBART TOWN. A few details concerning the commerce and industry of Hobart Town will be found under VAN DIEMEN'S LAND.

HOE; HORSE-HOE. The hoe is an instrument used in gardens and fields for loosening the earth, and destroying the weeds between plants. It has various forms. The most common hoe consists of a blade or flat piece of iron, with an eye in which an handle is inserted at an acute angle with the plane of the blade. This hoe is used by striking the edge of it down into the ground, and the earth is moved by drawing the handle towards the workman. Another hoe has the handle at a very obtuse angle, and is used by pushing it forward and cutting off the weeds an inch or less under the surface of the ground. Hoes are made of different sizes and shapes, according to the work which is to be done. When the earth is to be stirred between plants which are very near each other, the hoe is narrow and pointed, so that the smallest weed may be taken out close to the growing plant. When the distance is considerable, the hoe is wide, and sometimes compounded of several hoes, in order to stir a greater width of earth at once.

One of the greatest improvements in practical agriculture has been the introduction of the hoe into the field for every kind of crop, consequent on the sowing of seeds in parallel rows. Hand-hoeing not having been found sufficiently expeditious on a large scale, a hoe has been invented of a larger form, to be drawn by a horse. The rows have in consequence been widened, and this has introduced the horse-hoeing husbandry, which half a century ago was thought so important a discovery as to receive the name of the New Husbandry, from its great improver, Jethro Tull. The simple horse-hoe is an instrument with a beam like a plough, and two stilts or handles, but much lighter; in this beam is inserted, instead of a coulter, the end of an iron hoe, of the proper breadth to stir the whole surface between the rows. A small wheel is generally added to keep the hoe at a proper depth in the soil. Many varieties of horse-hoes have been invented of more or less complicated forms; but the object of them all is the same, viz., to stir the ground between the rows, and destroy the weeds as fast as they appear. The horse-hoe is now chiefly used in the cultivation of peas, beans, potatoes, cabbage, turnips and carrots.

One recent variety of this instrument is the Uxbridge Expanding Horse-hoe, made of wrought iron. There are two small wheels behind, one in front, two handles, and seven hoes. These hoes are arranged in a peculiar manner. The frame to which the hoes are fixed is expansive, that is, its outside bars are moveable farther or nearer apart; and by adjusting these bars, the cutting edges of the hoes are made to present different angles, according as circumstances may require.

HOFWYL. The name of this estate will always have an industrial interest connected with it, on account of the educational institution of Mons. de Fellenberg. It is situated in a valley about three leagues from Berne, in Switzerland, and consists of a number of distinct buildings surrounded by about 250 acres of land. The founder had for his object the improvement of the condition and character of all classes of society by means of an education adapted to their respective wants. To effect this, he divided the institution into classes, of which the higher, the sons of wealthy parents, paid a large yearly sum; the second class, a smaller sum; and the lowest class were received without payment. All were instructed in agriculture, and the trades connected therewith, all of which were practised on the estate. All the classes also were instructed in the usual branches of school education, and the lower class in the sciences connected with agriculture; but these were carried farther in the second class, and the highest class had a still wider range. The upper class was commenced in 1808, the lowest was added in 1810, and the middle class was not introduced till 1830. Fellenberg was enthusiastic, and succeeded in imparting much knowledge to his pupils, of whom he had usually about 100 who paid stipends, and 100 who were boarded, clothed, and educated for their labour. Fellenberg died in 1844, lamented and respected. The school is still carried on, and has about 40 scholars of the first class, and 70 of the second, many scholars of these classes being English; of the third class the number is still continued at 100. It was Fellenberg's wish to have his institution adopted by the state, but this has not been done.

HOG. The commerce and consumption of these animals, and the useful purposes to which they are applied, are noticed under Pigs.

HOGSHEAD. This ancient measure of liquids, not being mentioned in the Act of 1825, cannot now be considered as having any legal existence, although it is familiarly used. The hogshead of wine was 2 wine barrels, or 63 old wine gallons; the London hogshead of ale was 1½ ale barrels, or 48 ale gallons; the London hogshead of beer was 1½ beer barrels, or 54 beer gallons; and the ale and beer hogsheads for the rest of England was 1½ barrels, or 51 gallons. All Excise measurements being now made in gallons, the term hogs-dead remains in use only as the name of a large cask.

HOLLAND. Although we are in the habit of giving this name to a kingdom, it is in strictness the name of one of the provinces of the Netherlands. Under this restricted meaning, Holland may be described as being flat, and in many parts below the level of the sea, against which it is protected by the sandy downs on the west coast, and by stupendous dykes built along the shores of the Zuider-zee, the Haarlem-meer, and the banks of the principal rivers. The country is traversed by canals in all directions. A railroad passing from Rotterdam through the Hague, Leyden, Haarlem, Amsterdam, Utrecht, and thence to Rotterdam, incloses a very important part of the province. Gardens and orchards are carefully cultivated; some barley, oats, peas, beans, mustard, and other seeds are the chief crops in the northern part of the province; in the southern part more corn is produced. But pasturage prevails much more than arable cultivation: the produce of the dairy farms, butter and cheese, constituting the chief wealth of the landholder. The drained districts called *polders* have been before noticed [FLANDERS]; as well as the great drainage of Haarlem Lake. [DRAINING; HAARLEM.] Flowers are cultivated in the tract between Alkmaar and the Hague, but especially about Haarlem. Hemp, flax, and madder are grown. Wood, both for construction and for fuel, is scarce. The manufactures, which are chiefly carried on in the towns, are important; they are linen, paper, woollen cloths (for which Leyden is famous), silk, leather, tobacco, sugar, &c. The gin distilleries of Schiedam are very extensive, and have been long celebrated. Large quantities of fine lime are made from the shells gathered on the coast of the German Ocean. The fisheries on the coasts are important, and most industriously plied.

Besides the two most notable commercial towns [AMSTERDAM; HAARLEM] there are other busy spots. From *Edam* the export trade in sweet milk cheese is important; the chief industrial products are salt and fish oil. *Helder* is notable for the great *Helder-Dyke*, which protects the extremity of north Holland from the fury of the storms to which it is exposed, and is one of the most astonishing monuments of Dutch industry, perseverance, and skill. It is nearly 6 miles in length, 40 feet broad on the summit, along which there is a good road; it presents to the sea a slant side of 200 feet, inclined at an angle of 40°, the whole constructed of granite blocks brought from Norway. *Naarden* forms the key of all the water communication of Holland, and is important for the defence of Amsterdam, with which it is connected by a fine canal. *Zaanden* has a most singular appearance; it seems to consist of a line of windmills, some of which are of gigantic size, and have houses attached to them, extending along the Zaan, and forming a street nearly 5 miles in length. The number of these mills is variously stated, but it seems to amount to about 700; they are applied to the various purposes of grinding corn, draining the land, sawing timber, making paper, grinding tobacco into snuff, crushing rapeseed to express the oil, grinding colours for painters, grinding stones into sand for the floors of the Dutch housewife, and grinding the volcanic substance called trass into dust in order to form a cement, which hardens under water and is much used in Holland. *Gonda* has tobacco pipe factories that give employment to 6000 men, brickworks (the clay for the supply of which is taken from the bed of the Yssel), rope walks, gin distilleries, and breweries. Gonda numbers also among its industrial products woollen cloth and sailcloth; it is famous as a cheese market. *Schiedam* has glass works, rope walks, white lead works, above 200 distilleries for the manufacture of gin, for which it is universally celebrated. It has a large trade in pigs, 30,000 of which are said to be annually fattened on the grains from the distilleries.

A few of the towns of Holland will be represented at the Great Exhibition.

HOLLY. The common holly or *Ilex aquifolium* is chiefly valued as an ornamental tree, but its fine-grained, heavy, compact timber is used for a great number of useful purposes, especially by the turner and mathematical instrument maker. The berries are poisonous.

HOLYHEAD. [MENAI BRIDGES.]

HONDURAS. British Honduras, in central America, owed its origin to Mahogany cutters. Mahogany trees of great size and beauty grow in this colony; and the first establishment of the English in this quarter was made by mahogany cutters from Jamaica, in the 17th century. Logwood is also largely grown and cut; and the English cutters of these woods had many contests with the Spaniards, before they were permitted to settle finally in their new colony.

Most of the mahogany and logwood trade of Honduras is conducted by five or six firms, established at Belize. The cutters are employed by these firms; and these firms also ship the wood to other countries. The colony took British produce and manufactures in the year 1849, to the amount of about 200,000*l.*

The exports from Honduras are larger than the imports; they consist of mahogany, logwood, rosewood, hides, tortoiseshell, fustic, cochineal, indigo, sarsaparilla, and cocoa-nuts. In 1848 no less than eight million cubic feet of mahogany were exported.

HONEY is a fluid or semi-fluid substance, the materials of which are collected by different kinds of bees, in Europe chiefly by the hive-bee, and solely by the neuter or working bees, from the nectariferous glands in the cup or chalice of flowers. It cannot be said to be a purely vegetable production, for, after being collected by the proboscis of the insect, it is transmitted to that distension of the œsophagus termed the crop, sucking stomach, or honey bag, where it is elaborated, and again disgorged, to be deposited in the cell of the honey-comb. It undergoes less change when the bees are very young, remaining nearly white, and is then denominated virgin honey. At all times it retains qualities derived from the kind of plant whence it has been procured; as is manifest not only by the peculiar odour of the honey, but by the effects which follow the use of honey obtained from certain plants.

Honey is sweet, faintly aromatic, granular, soluble in water, and capable of undergoing the vinous fermentation.

The finest honey in Europe is said to be that of Narbonne, which is supposed to derive its excellence from the rosemary which grows in the neighbourhood. When honey is taken from the honey-comb it is fluid, but gradually thickens by age; and in cold weather a firm and solid mass of honey forms.

Honey is used as a substitute, sometimes for sugar and sometimes for butter. Honey is an ingredient in the useful medicine *Oxymel of Squills*. *Mel boracis* is borate of soda mixed with honey; *mel rosæ* is made of honey and red rose petals; *oxymel simplex* consists of clarified honey boiled in dilute acetic acid. When fermented, honey water obtains the name of *mead*, and is in fact honey wine, which is the name given to it in Germany (*honigwein*). Mead was formerly drunk to a considerable extent in England, and in most parts of northern Europe. Real mead or Metheglin is a fermented wine; but many drinks made from honey are little else than honey water or *hydromel*. Such is the *sbitene* of Russia, which consists of honey mixed with boiling water and boiling milk, and seasoned with pepper.

HONITON LACE. [Lace Manufacture.]

HOPS. This useful plant, the *Humulus lupulus* of Linnæus, is extensively cultivated for the flowers or seed-vessels, which give flavour and permanence to beer by being boiled with the wort in brewing. Hops were introduced into England from Flanders about the year 1524. The most extensive plantations are in Kent, Sussex, and Herefordshire; but they are also cultivated in Worcestershire, Wiltshire, Hampshire, Gloucestershire, Surrey, and several other counties.

The hop is a slender climbing plant, which requires a very rich mellow soil and careful cultivation. The soil of a hop garden must be rich to a considerable depth, or made so artificially. The young plants are raised in beds, and may be raised from seed; but it is more usual to plant the young shoots which rise from the bottom of the stems of old plants. The varieties most esteemed are the Grape Hop, the White Vine, and the Golden Hop. The young plants are placed in groups of three each, about six inches asunder, in the midst of prepared masses of soil about a yard asunder. A watering with liquid manure greatly assists their taking root, and they soon begin to show bines. A stick three or four feet long is then stuck in the middle of the three plants, and the bines are tied to this stick with twine or the shreds of Russia mats, till they lay hold and twine round it. During their growth the ground is well hoed and forked up around the roots, and some of the fine mould is thrown around the stems. In favourable seasons a few hops may be picked from these young plants in the autumn, but in general there is nothing the first year. Early in November the ground is carefully dug with the spade, and the earth, being turned towards the plants, is left so all the winter.

In the second year, early in spring, the hillocks around the plants are opened and the roots examined. The last year's shoots are cut off within an inch of the main stem, and all the suckers quite close to it. A pole about twelve feet long is then firmly stuck into the ground near the plants; to this the bines are led and tied as they shoot, till they have taken hold of it. The ground being well hoed and the earth raised round the plants, the produce this year will average 4 cwt. per acre if the season is favourable. In September the flower containing the seed will be of a fine straw colour, turning to a brown; it is then in perfection. No time should now be lost in picking them. The hops when picked are dried on a hair cloth in a kiln. They are then laid in heaps on the floor, where they undergo a very slight heating. As soon as this is observed, they are bagged. This is done by pressing them into large bags suspended below a hole in the floor; when sewed close and tight, the bag is stored in a dry place till the hops are wanted for sale. The crop of the third year will average 8 cwt. per acre, but will in some cases reach 15.

The occupation of hop-picking is a remarkable one. There is not available labour enough in Kent and the other hop districts to pick all the hops in the requisite time; and hundreds of poor persons arrive from other parts of the country, to sojourn for a few days or weeks in the hop districts, during which time they are employed in picking the hops.

The poles are an expensive article; those of chestnut are the most durable, and also the dearest. They should be put into a shed during winter; or else be placed on end in the form of a cone, leaning against each other.

Besides the use of hops in brewing, they produce a bitter infusion and a tincture which are valuable in medicine for complaints in the stomach.

The number of acres of Hops in England in 1849 was 42,798; the weight of hops charged with duty was 16,650,915 lbs., the duty on which was 145,693*l.* In that year 274,811 lbs. of hops were exported. The excise duty on British hops is 18*s.* 8*d.* per cwt., and 5 per cent. additional; the customs duty on imported foreign hops is 45*s.* per cwt. The produce in 1848 and in 1850 was very much larger than in 1849; in the former year the duty was 394,923*l.*, and in the latter 426,194*l.*

HORN. This musical wind-instrument is of very ancient origin, and of various forms. The *French horn* is a tube of about ten feet, very narrow at top, widening considerably at the bottom, and bent in rings for the convenience of the performer. It is not provided with holes, as the flute, &c.; the production of the various sounds depending upon the lips of the player, the more or less pressure of his breath, and the insertion of the hand in the bell, or wide end, of the instrument. Crooks and shifting pieces are provided to adjust the instrument to different keys or fundamental notes. The *Bugle Horn* is a tube of three feet ten inches in length, doubled up in a small compass. The *Keyed Bugle*, or a Bugle horn with keys, is that now in common use, the scale of which comprehends about two octaves, with the semitones. The *Cornopean* and the *Cornet-à-Pistons* are improved modern forms of this instrument. The *Russian Horn* is an unbent brass tube, conical in shape, of various dimensions: the deepest toned is eight feet long, and nine inches in diameter at the wide end, and the highest is two inches and a half in length by one at the wide end. The former gives A, an octave below the first space in the base; the latter gives E, the third additional line above the treble. Some of these horns have keys, producing one or two semitones, but generally every note has its separate horn; and a band of Russian Horns counts almost as many individuals as diatonic notes in a scale of between four and five octaves. The *English Horn*, or *Corno Inglese*, is a deep-toned oboe, of large dimensions, somewhat bent, the lower end very open, and is to the oboe what the basset horn is to the clarinet, or what the viola is to the violin. The tone of this instrument is extremely pathetic, and by the Italians is thought so much to resemble the human voice, that they sometimes call it the *voce umana*.

HORN MANUFACTURE. The horns of the ox, antelope, goat, and sheep may be described as a number of conical sheaths inserted into one another, the innermost of which lies upon the vascular membrane which covers the bony core. The tip, or that portion of the point of the horn which projects beyond the core, is very dense, and the several layers of which it is composed are scarcely distinguishable; while towards the base the layers may be readily distinguished, owing to their successive terminations forming prominent rings. There are many points of resemblance between the substance of horns, nails, claws, hoofs, scales, hair, feathers, and even skin.

The principal kinds of horn employed in manufacturing operations are those of oxen. The first process is to remove the bony core or pith, which is accomplished by steeping the horns in water for several weeks, by which operation the membrane which lies between the core and the horny sheath is so destroyed or softened by putrefaction that the cores may be easily extracted. These are applied to many useful purposes. The solid tip of the horn is sawn off with a frame-saw, and is employed for making knife-handles, umbrella-handles, the tops of whips, buttons, and various other articles. The remainder of the horn, which is employed for purposes for which thin laminæ are required, may either be left entire or sawn into two or more lengths, according to the use to which it is to be applied. When divided, the lower part, or that next the root of the horn, is frequently employed for making combs; while the portion which has formed the middle of the horn is used for lanterns and for other articles where a thin plate of horn is required. To prepare the horn for use it is softened in boiling water; and, while hot from this operation, it is held in the flame of a fire until it acquires about the temperature of melting lead, and becomes so soft as to be semi-fluid. The slitting is performed while it is in the semi-fluid state, by a strong pointed knife resembling a pruning-knife; and, by the application of two pairs of pincers, one to each edge of the slit, the cylinder or cone of horn is opened until it is nearly flat. Several such pieces are then exposed to pressure between alternate plates of iron until they are flattened. The thin sheets of iron are then scraped, rubbed, and polished.

The various articles made of horn require manufacturing processes differing in different cases. The making of combs is noticed elsewhere. [COMB-CUTTING.] Umbrella handles, snuff-boxes, knife-handles, bell-pulls, drawer-knobs, &c., are made by softening the horn to such a degree that it may be pressed into moulds. Horn is easily dyed of various colours; but in this country it is usually coloured of a rich reddish brown, and spotted to imitate tortoiseshell, by a mixture of pearl-ash, quick-lime and litharge, or red lead, with water and a little pounded dragon's blood.

No part of the refuse of the horn manufacture is without its value. When exposed to a decomposing heat in close vessels, horn produces a large quantity of the gaseous compound which forms the base of prussic acid, on which account hoofs and horn cuttings are in great request among the manufacturers of Prussian blue, and of the beautiful yellow prussiate of potash. The clippings of the comb-maker and of the lantern maker are also used as manure.

HORSE SHOES. This invaluable animal, the horse, subserves many useful purposes to man, after his career as a beast of burden is at an end. The hair of the tail and mane is much employed for weaving into a tough cloth, and for other purposes. [HAIR MANUFACTURE.] The hide is tanned into a valuable kind of leather; the hoof is useful as a horny material; and various parts of the dead animal are employed as materials in different manufactures.

Horse Shoes are implements on which much attention have been bestowed. Nature has given to the foot of the horse a certain degree of expansive or spreading power, which lessens the shock received by placing the foot suddenly to the ground; but the material of the hoof is such that friction will gradually wear it away; and the difficulty arises, how to protect the hoof from wear without destroying or rendering nugatory the elasticity of the hoof. Various contrivances are employed in rude countries to shield the hoof; a covering of strong ox-leather, a wrapper of woven strips of tough fibres, a wisp of straw fastened with a cord—all are used in various countries.

The ordinary English horse shoe is (or ought to be) made of the best iron; and small pieces of steel are occasionally attached to a part which is more than usually worn. The width and thickness vary according to the strength and age of the horse, the purpose for which he is employed, and the particular opinions of the person who has the direction of shoeing the horse. The horse shoe is formed from a bar of iron about an inch and a quarter wide and three quarters of an inch in thickness; and is forged into its proper form by two men. The shoe is fastened on by eight or nine nails, to receive which holes are made in the iron. A sunken groove is also forged, to admit the heads of the nails: this groove is forged by the hammer. It has been proposed to give the necessary grooved surface by drawing the bar of iron between two rollers whose surfaces have pins and ridges inserted, by which the groove and the nail holes are made; it has also been proposed to cast the horse shoes in plaster moulds, and afterwards anneal them. The shoes are fastened to the foot by driving nails into the hoof, but as this has a tendency to break away the substance of the hoof, modes have been devised for fastening with sandals and straps; none of these contrivances, however, have been permanently successful. For heavy draught horses two points or projections stand out from the back of the shoe and are turned downwards; these assist the animal in obtaining a sure footing. Horse shoes vary from twelve ounces to seven pounds weight, according to the service required of them.

Within the cavity of a horse's hoof is a wedge-shaped substance called the *frog*. Farriers used to shoe horses in such a way as to shield this from the ground; but it is now believed that Nature intended this substance to assist the movements of the animal, by its elasticity.

The subject of the proper shoeing of the horse, in relation to the anatomy of the foot, has been treated with much clearness by Mr. Clarendon of Dublin, in his 'Treatise on the Foot of the Horse;' this forms a sequel to another work on the 'Powers of the Horse;' and both are intended to show the means by which the structure of the horse may point out the best modes of practically applying the muscular power. The result of modern enquiries has been to show that the horse shoe ought not to be rigid; that it ought to allow the frog of the foot to come into action. Mr. Bracy Clark has invented a shoe with a joint at the toe; the design being that it should open at each step, with that joint as a centre. Mr. Rogers' horse shoe has a slit near the front, which gives a yielding elasticity something like that of a steel pen. Another horse shoe has been invented with two joints, one on either side. Mr. Turner has devised a mode of nailing the shoe on one side only, so as to leave an expansive action to the foot. Mr. Clarendon has patented a shoe, in which elasticity is afforded by a singular contrivance; the shoe does not differ much from others in shape, and is nailed near the point in the usual way; but all the other nail holes are made large enough to admit of a spreading action of the foot. Specimens of this horse shoe will be sent to the Exhibition.

HOSIERY MANUFACTURE. The principal seat of this manufacture in England is in the three counties of Leicester, Nottingham, and Derby. In the first of these, worsted hosiery forms the principal branch of the manufacture, while in Nottinghamshire the material chiefly used is cotton, and in Derbyshire silk goods are mostly made.

The stocking-frame, by means of which this manufacture is carried on, is, next to the common warp and weft loom, the oldest machine in existence applicable to textile fabrics. It was invented about the close of the 16th century by the Rev. William Lea, of St. John's College, Cambridge, but a considerable time elapsed before the produce of this frame took the place of the trunk hose then worn by all who could afford such an article of dress. For this reason Mr. Lea settled at Rouen, in Normandy, where his manufacture was carried on under the patronage of Henri IV.; but the assassination of the king and the political troubles brought on by that event caused the abandonment of Mr. Lea's establishment, and that gentleman shortly after died in a state of poverty at Paris. From the time of its first invention the stocking-frame has not received any considerable improvement in respect to its principle; but the details have been improved by a long series of patented inventions.

The principal seat of the cotton hosiery manufacture abroad is at Chemnitz, in Saxony, where, owing to the low rate of wages, goods are made, with yarns imported from Lancashire, at prices which have excluded English goods from many foreign markets.

The hosiery or frame-work manufacture is a peculiar kind of interlacing. Instead of being a series of cross threads woven in a loom, it is a series of loops or links, so connected as to possess both strength and elasticity in a remarkable degree. It is a continuous thread which is thus linked around itself; in a way which bears a good deal of resemblance to many kinds of ladies' netting and crochet work. The article made in the stocking frame is not a stocking, but a piece of knitwork cloth, which is afterwards sown up into the form of a stocking by needle and thread. Hence, there are three kinds of operatives engaged; the *winders*, who put the thread into or on the machine; the *frame-work knitters*, who work the thread up into a knitted fabric; and the *seamers*, who make the stockings out of the pieces thus produced. The winders are generally children, who can each wind thread enough for half a dozen machines; the knitters are men, women, and youths, who hire both the winders and the seamers; and the seamers are women. Some of the stocking-frames are owned by the frame-work knitters; some are let out to the men by the owners, at so much per week for each frame; while other persons are the renters of what is termed a 'shop of frames,' containing eight or ten frames; these, with standing-room to work in, they let to the workmen, at so much per frame per week. The master manufacturer gives out his thread, and the workman returns this thread in the form of stockings, the work being paid for at so much per dozen pair.

We have spoken only of hosiery, but many other articles besides stockings are made of this linked fabric. Gloves, waistcoat-pieces, mitts, pantaloons, drawers, braces, webs, comforters, caps, jackets, leggings, and various other articles—are made nearly in the same way, and of the same material. The processes for worsted, cotton, and silk are nearly analogous; those for silk requiring, however, the greatest care. Some progress has been made towards the manufacture of hosiery by means of steam-power; but the extreme lowness of wages in this department of labour has hitherto kept it nearly in the position of hand-loom work.

It is pleasing to find that Ireland is gradually advancing in this as in many other branches of manufacture. At Balbriggan there is a hosiery manufacture, from which specimens of cotton hosiery are to be sent to the Great Exhibition, of a degree of fineness such as has never perhaps been equalled; one dozen pairs of ladies' full sized stockings will weigh only nine ounces. Cotton stockings of a peculiar kind of open work are also manufactured in the same town.

The exports of stockings in 1850 amounted to the following quantities:—

Cotton	234,163	dozen pairs.
Silk..........	4,482	„ „
Worsted......	119,873	„ „

HOT-BED; HOT-HOUSE. A hot-bed is a heap of fresh stable litter in a state of fermentation, upon which a glazed box is placed for the cultivation of certain plants requiring heat and moisture in greater quantity than those agents exist in the external air. For the growth of cucumbers and melons, raising seeds of tender annuals, and of other plants, either culinary or ornamental, hot-beds are advantageously employed. They may be formed of various substances, such as rotting dung, tan, leaves, or a mixture of these with moist litter; in short, any substance capable of producing and retaining fermentation, and which will admit of being built up so as to support a frame with sashes.

A *hot-house* is a structure in which exotic plants are cultivated under circumstances approximating as closely as possible to those under which they naturally exist; or it is used for accelerating the production of flowers and fruits of either indigenous or exotic plants. Hot-houses appropriated to the latter purposes are very frequently termed *forcing-houses.*

The principles by which the construction of hot houses must be governed have reference to the three great agents in vegetation—*heat, moisture* and *light.* There must be means for varying all these to a wide extent. With regard to the means of supplying artificial heat, the old system of using brick flues is now rapidly being superseded by that of hot water. The glass for admitting light to hot-houses is found to be better fitted for its object if it has a slight green tint.

Hot-houses may be classed under four different heads, namely, the *dry stove,* the *damp stove,* the *bark stove,* and the *forcing house.* The *Dry Stove,* as the name implies, is used for the cultivation of plants which do not require much water: such as the different species of Cacti, some Euphorbias, and other succulents of like habits. The temperature of such a house during the winter months should never exceed 55° of Fahr. The *Damp Stove* requires treatment of an opposite description. Instead of being kept dry like the last, its atmosphere should be always excessively humid, except in the winter season; the temperature is made to vary from 55° to 70° according to the season. The beautiful *Palm House* at Kew may be regarded as a damp stove. The *Bark Stove,* when it is of large dimensions, consists of a pit in the middle of the house, surrounded by a brick wall, leaving as much room round the sides as will form a passage to walk in. The pit is filled with bark, and, after being allowed to sink a little and ferment, the pots containing the plants are plunged more or less deep as prudence may suggest. The *Forcing House* is a contrivance of frames and pits, heated with dung, to accelerate the growth and maturation of flowers, fruits, and vegetables.

There are also *hot walls,* or walls with flues in them, constructed in cold countries, in order to afford warmth to trees placed against them. One furnace is allowed for heating about 40 feet of wall, that is, 20 feet on each side of the place where the fire is situated. The flues on either side are made to take four courses, or two returns; the first course being a little above the surface of the ground, and the upper 1½ or 2 feet below the coping. Instead of flues, hot water pipes might be introduced into the cavity of a common hollow wall, a little above the level of the border.

HOUSE. The houses of this country have undergone many changes of form and construction. Three centuries ago they were constructed in a very different manner from the houses of the present century. The chief materials were wood and plaster, and a common but peculiar feature was the projecting upper floors. The internal arrangement was adapted to the wants of that day, and the external architecture had often a picturesque appearance. After the great fire of London the advantage of building in cities with brick or stone became so apparent, as well as the adoption of some regularity, that a great change took place in house-building in the metropolis, which extended by degrees to the houses which were from time to time rebuilt throughout the country. In this gradual change have almost entirely disappeared the projecting floors with large bow windows, the wooden galleries round the quadrangular courts, the boldly projecting dripping eaves, and the high-pitched roofs with their large windows. In London and other large towns, the basement story is for the most part built below the level of the ground, the earth being excavated for that purpose; this floor usually contains the kitchen and the rooms for the use of the domestics. English houses are in general well provided with means for carrying off water and all impurities which require to be removed from the premises; that is, the better houses in the large towns are so provided; but many improvements must be yet introduced before the same can be said of the mass of dwellings. The houses of the poorer classes are too often negligently constructed. In their construction, economy, convenience, and a wholesome ventilation, should be mainly kept in view, and these may be united with as much picturesque beauty as the nature of the materials will admit of without increasing the expense.

The English and Scotch cottages differ in their external appearance and arrangement. The best English cottages of recent construction are built of brick and covered with slate.

The use of these materials has changed the character of this class of dwellings. In many cottages the chimney-stack forms the principal bearing of the floors and roof. The Scotch cottage has not only a different appearance when compared with the English, but, from its being so much wider, it admits of two apartments being formed on the ground floor; this is also a matter of necessity, as they are seldom raised more than one story. The material for the walls is most commonly stone; the roof is large and heavy in appearance, and has but a small projection beyond the walls; the gable walls also run up frequently above the roof, forming a parapet, which is sometimes notched so as to resemble steps, or has a battlement appearance. As the French and Italians of the middle classes do not generally live in separate houses like the English, but on floors containing a series of rooms, it follows that the arrangement of their houses differs from that of the English. The staircase, as in public chambers, is common to each floor. The rooms communicate with each other, and generally with a passage or balcony on one side; chimneys are rare, stoves being most commonly used to heat the rooms. French and Italian houses are mostly built of rough stone and stuccoed; the floors are seldom boarded, being paved with glazed tiles or unglazed bricks. The Spanish houses are very spacious; they have large courts in the interior, and are formed with galleries round the inside of the quadrangular courts: families occupy the separate floors. The houses in many parts of Germany approach nearer to the English in their arrangement than the French and Italian houses. In many places the houses are a framework of wood, and the interstices are filled with unbaked bricks, and are plastered with clay. The city architecture of Russian houses, both in its effect and arrangement, resembles the architecture of Italian and French houses, except that the roofs are covered with sheet-iron painted with vivid colours, mostly green and red. The windows are double.

Many details connected with the building of houses will be found scattered under various headings in this work. With regard to the present state of things in this country, one of the most interesting social features is the attention now being made to the construction of healthy dwellings (at a moderate rent) for the working classes.

HOWITZER, is a short but broad-mouthed cannon. It is employed to project solid and hollow shot, loaded shells, carcasses, and case shot, either in the point-blank direction or at angles of elevation, which hitherto have not exceeded fifteen degrees. It is used against troops in the field, in the attack of redoubts or villages, and both in the attack and defence of regular fortresses. About the year 1820, Colonel Paixhans, in France, constructed what were denominated canons obusiers, for the purpose of projecting solid or hollow shot of great diameter: and in 1824 and 1836 the late General Millar, in this country, executed for the like purpose iron shell-guns, or naval howitzers as they are called, whose calibres are 10 inches and 8 inches respectively. Besides these, 24-pounder and 12-pounder howitzers are employed in the British service.

HUDDERSFIELD, is one of the most notable of the West Riding towns. The manufactures of Huddersfield and the adjacent villages are principally woollens and waistcoatings; indeed fancy productions in which wool is mixed with silk or cotton now form a very large department of the industry of the town. The cotton manufactures are also carried on, though not to a very great extent. In 1765 a commodious cloth-hall was erected for the buyers and sellers of the Huddersfield manufactures by Sir John Ramsden. The trade derives great advantages from its inland navigation, by means of the Ramsden and Huddersfield canals, both eastward and westward, and by the railways which now connect it with the neighbouring towns.

At the Industrial Exhibition, Huddersfield will display specimens of all the leading products of the town.

HUDSON'S BAY COMPANY. This remarkable trading company obtains its name from the great inland sea which lies westward of Labrador in North America. The countries which inclose Hudson's Bay on all sides constitute by far the greatest portion of the British dominions in North America. The area cannot be given, as considerable tracts of the coast are still unknown, but it probably does not fall much short of 3,000,000 square miles. This immense country may be divided into four natural regions. The most eastern is the *Sterile Region*, which lies along the shores of the sea, and extends far inland. The second or *Wooded Region*, extends on both shores of James's Bay, and along the southern shores of Hudson's Bay, as far westward as Cape Churchill. It is generally well wooded, and produces fur-bearing animals. Beyond this is the *Savannah Region*, which extends to the foot of the Rocky Mountains, and northward to the Lake of Athabasca and the Peace River: its surface stretches out in extensive plains, intersected only by the beds of several rivers, which are considerably below the plains. The fourth region, the *Mackenzie Valley*, comprehends the country between the Sterile Region and the Rocky Mountains, north of Lake Athabasca.

The present wealth of the country consists in its animals, especially rein-deer, musk-ox, moose-deer or elk, other kinds of deer, bears, wolves, wolverines, foxes, beavers, otters, racoons, and several smaller animals. Iron, copper, and lead are known to exist, though not yet worked to any extent; and coal has been found at various places, Vancouver's Island being one. The settlements of the Hudson's Bay Company are divided into two districts; the southern comprehends the settlements on the west coast of Labrador, together with the more numerous establishments in the countries inclosing James's Bay, and as far as the banks of the Albany River. The principal depôt is at Moose Fort, near the mouth of Moose River. The northern district comprehends all the others as far north as Fort Good Hope on the Mackenzie River, north of the Polar Circle. Its chief settlement is York, on the Hayes River.

The circumstances which led to the establishment of a trading company in these regions have been noticed under FURS; FUR TRADE. Vancouver Island, on the coast of the North Pacific Ocean, was granted by the British government to the Hudson's Bay Company in August 1848.

HULL. This seaport is the greatest shipping emporium on the east coast next to London. The exports formerly were chiefly wool, woolfells, and leather; its imports, wine and timber. At present the coasting trade is one of its chief branches of profit. It has also an extensive commerce with the Baltic, with the north of Germany, Holland, and Denmark. The Greenland fishery owed its revival, about 1766, and its subsequent importance, to the mercantile enterprise of Hull. The facilities of communication between Hull and the interior of the kingdom are numerous; the Ouse, Trent, Aire, and Calder, all communicate with the Humber, and these means of internal communication are extended by the York, Newcastle and Berwick Railway, the York and North Midland Railway, and the Hull, Selby and Leeds Railway. The prosperity of Hull has been greatly increased by the progress of steam-navigation, and it may be considered as the second great centre of this mode of transit on the eastern coast.

There are large docks and extensive quays. The number of sailing vessels registered at Hull in 1848, was 462 (64,951 tons). The number of steam-vessels was 28 (5658 tons).

The manufactures of Hull are varied. The expressing and refining of oil from linseed is effected by wind-mills and steam-mills; the residue of the seed is prepared as food for cattle. There is a large sugar-house, a soap manufactory, several white-lead works, shipbuilders' yards, turpentine and sail-cloth manufactories, extensive ropewalks, and several breweries. There are also two large joint-stock cotton mills.

Hull is the great port of the Humber, and the outlet for the vast produce of the district watered by that river and its tributaries. Hull is especially the port at which Baltic timber, Russia hemp, and Belgium flax are imported; and at which the Lancashire and Yorkshire manufactures are exported to the continent of Europe.

At the ensuing Exhibition, the Hull manufactures, of oil, oil-cake, tar, turpentine, &c., will be illustrated. There will also be every variety of English and foreign wood in the form of books, showing the grain, quality, and perhaps the bark, with the name of each engraved or sculptured on the back: and a complete series of the imports of the port, which will be arranged by the local committee, and will give a statistical account of the quantity of each imported during a series of years.

HUMIDITY is that property of a substance by which it communicates to a body in contact with it some of a liquid which it may have absorbed. The humidity of the atmosphere is caused in a great measure by the evaporation of water from the seas, lakes, &c., of the earth; and the quantity of moisture which a volume of air is capable of containing depends upon the temperature. Dr. Dalton found by experiment that a body of earth one foot in depth, when saturated with moisture, contains seven inches in depth of water, and that it may lose one-fourth or one-half of that quantity without becoming incapable of supporting vegetation. The effects of humidity on the dimensions of bodies are various: when a watery vapour penetrates between the twisted fibres of cordage which are vegetable materials, the cordage swells out transversely, and thus becomes shortened; while cords made of animal substances become relaxed by humidity and increase in length. Most salts absorb water, and thereby increase in weight.

HUNGARY. The produce and manufactures of this interesting country are briefly glanced at in connection with the Empire of which it forms a part [AUSTRIA].

HUNTINGDONSHIRE. Only a small portion of the county is unproductive. Peat is found in many parts. The farms are mostly of considerable extent. The expense of cultivation on the fen-land, when it is once drained, is small in proportion to the produce. Paring and burning the surface is the general practice. Rape seed is sown, which is fed off with sheep the first year, and left to ripen its seeds the next. The straw of the rape is burned on the land, after the seed has been thrashed out; and this is all the manure required to produce a good crop of wheat. Oats, barley, and beans are also grown. Mustard-seed is grown to some extent, and in good soils gives a good return. On the borders of the Ouse and Nene are some very rich meadows. A great part of the county is still in pasture, although much has been broken up and converted into arable land. In the marshy parts willows grow rapidly, and are profitable, although not ornamental. Although Stilton is in this county, and it is asserted that the cheese which bears that name was originally made there, none of that kind is now produced in any of the dairies; all such cheeses are made in Leicestershire and Lincolnshire.

Huntingdon, the chief town, has a considerable trade in wool and corn. At St. Ives, brewing and malting are carried on, but there are no manufactures. There are a few other towns, but none of manufacturing importance.

HUSBANDRY. The land in England consisted originally for the most part of woods, and of extensive pastures, in which sheep and cattle were bred, which constituted the chief wealth. A very small proportion of the soil was cultivated; and, while the population was thin, there was no difficulty in obtaining land which had never before been broken up, and which with little trouble or manuring produced moderate crops of corn. When the husbandmen began to congregate in villages for mutual defence, the best land nearest to the habitations was cultivated, and the common pastures fed the cattle without much trouble or expense. Manure was seldom made; four times the seed was an average corn crop; and fields were fallowed every second year. Wheat was little cultivated; barley, rye, and oats were the principal produce. Many hogs were fed on acorns and beech-mast in the woods. Bread made of rye, barley, peas, or beans, was the food of the labourers who were attached to the soil. The immediate tenants of the lord cultivated a portion of the lands which they held for their own use, and let the remainder to smaller tenants, who, although born free, were little above the condition of the labourers, and lived much in the same manner. The live stock was frequently hired from the landlord. Oxen drew the ploughs; horses carried the produce to mill and market; and the implements were of the rudest kind.

From these beginnings various systems of husbandry have brought the land of this country into the state briefly noticed under the names of the counties and the chief crops.

HYDRACIDS are such acids as contain hydrogen instead of oxygen as the acidifying power: hydrobromic and hydrochloric acids are examples. Their acidity is in general very strongly marked. All the hydracids are gaseous, and are easily combined with water, forming solutions which possess the well-known and strongly marked properties of sourness, acting upon carbonate, and reddening vegetable blue colours. They are all artificial products. They have not hitherto been of much value in the arts.

HYDRATES, are compounds which contain water in definite proportion, but which do not assume the crystalline form. Thus, when water is added to potash, it may form with it either water of solution, water of crystallisation, or water which constitutes it an hydrate; and it is observable that, while water of solution has comparatively little affinity for the substance with which it is combined, water of crystallisation has more, and water with which the body constitutes an hydrate has the greatest affinity of all.

HYDRAULIC MACHINES. The art of constructing docks, quays, or any buildings whose foundations are laid under water, is denominated *hydraulic architecture;* and all machines in which water is employed as a moving power, or by which water is put in motion, may be termed *hydraulic machines.* No countries in Europe possess more advantages with respect to naval power than Great Britain and Ireland. The islands and headlands on their coasts form excellent natural ports; and these, where necessary, have been converted into secure harbours by every means which the science of the hydraulic engineer could devise. The Breakwater at Plymouth, the lighthouses which have been raised in the ocean, and the vast docks at the principal sea-port towns, are so many practical examples which render the British Isles a complete school for the study, in detail, of every subject connected with this branch of art.

Hydraulic architecture chiefly now involves the construction of masses of masonry whose foundations are laid in the beds of rivers or æstuaries, or in that of the sea, such as the piers of bridges, quays, jetties, and breakwaters; also the formation of artificial harbours and docks for shipping, and locks at the falls on rivers or canals. In the articles BREAKWATER, BRIDGE, CANAL, DOCK, HARBOUR, &c., these matters have been briefly touched upon.

Hydraulic machinery has been brought to its present efficient state by many successive improvements. It may be remarked however that, on account of the high degree of perfection which, within a few years past, the steam engine has attained, the employment of hydraulic machines for raising great quantities of water, or as first movers with respect to extensive works of any kind, has of late considerably diminished. Yet, where the circumstances are favourable, as when a supply of water for working the machine can be readily obtained, the latter, from being less expensive in their construction, are still preferred to the former.

The principal hydraulic machines which are in use for domestic or general purposes are the *Siphon*, the *Screw of Archimedes*, the various kinds of *Pumps*, the *Hydraulic Press*, and *Wheels* turned by water. For the first two see SIPHON and SCREW PROPELLER. The others will be now briefly described.

The common pump is a machine for raising water by the pressure of tho atmosphere. It consists of a cylindrical body, or barrel, from the lower part of which a tube descends into the water contained in the well or reservoir. In the interior of the cylinder is a moveable piston, surrounded with leather, in order that it may be water-tight, yet capable of moving up and down with freedom. The piston is perforated, and the orifice is covered above by a valve which opens upwards: a similar valve at the bottom of the cylinder or barrel covers the upper extremity of the tube which leads to the well. The piston being raised by means of the handle, the air contained in the tube tends by its elasticity to occupy the lower part of the cylinder, which it enters by forcing up the last-mentioned valve; and its elasticity diminishes in consequence of its occupying a greater space than before. Hence the air exerts on the surface of the water within the tube a less pressure than that which the external air exerts upon the water in the well; and the water consequently rises in the tube to a certain height. The valve then falls over the orifice, and, the piston being depressed, the air contained between it and the bottom of the cylinder will be condensed; in which state it will force up the piston valve, and escape at the top of the pump. The valve then falls; and, if the piston be again elevated, the water will rise higher in the tube, for the same reason as before. The operation of raising and depressing the piston being repeated a few times, the water will at length enter into the cylinder through the valves; after which it will, at each stroke of the piston, be forced through the spout.

The *lifting pump* is frequently similar in construction to the common pump above described; but the lower valve is always below the surface of the water in the reservoir, and the piston is so when depressed to the bottom of the cylinder or barrel. On raising the piston, the water above it is lifted up, and the pressure of the external atmosphere forces the water of the reservoir to enter into the cylinder. Then, by successive depressions and elevations of the piston, the water is at length raised to the top of the pump, and discharged by the spout.

The *forcing pump* is one in which the water, when raised in the barrel, is driven through an orifice in its side by the depression of the piston, which is solid, or without a perforation; it is also, in general, provided with an air-vessel, into which the water is forced, and whence, by the elasticity of the condensed air, it is made to issue through a pipe inserted in the upper extremity.

In the *chain pump* a chain, carrying a number of flat circular pistons, passes round a wheel at the upper, and sometimes also at the lower extremity; each piston, as it goes over the wheels, being in part received in the intervals between the radii. The wheel being put in motion, the pistons descend in a barrel on one side, and enter from below into another on the ascending side, when pushing the water before them, they raise it into the reservoir, from whence it escapes by a pipe. Pumps of this kind are frequently fixed in inclined positions; and it is when the inclination of the barrel is about 24 degrees, the distance of the pistons from one another being equal to their diameter, that the greatest quantity of water is raised.

The *Hydraulic Press* was invented by Mr. Bramah, and is a machine of very great power in compressing bodies or lifting weights; or, again, in drawing up trees by the roots, or piles from the beds of rivers. There is an iron cylinder in which a piston works. At the bottom of the former is inserted a tube, whose aperture, under the piston, is covered by a valve. The other end of the tube communicates with a small forcing pump, by which water is driven through the said valve into the lower part of the cylinder, where its hydrostatical action is exerted to raise up the piston. Now suppose the diameter of the cylinder to be 10 inches, and that of the piston in the forcing pump to be one quarter of an inch, then the proportion between the surfaces of the pistons will be that of 1600 to 1; and, on the principle of the equal pressure of fluids in every direction, the force with which the larger piston is raised bears the same proportion to the resistance against the lower surface of that in the forcing pump.

The largest and finest hydraulic presses ever constructed, were those made by Messrs. Easton and Amos, and employed in raising the ponderous tubes of the Britannia Bridge. The ram or larger piston is 22 inches in diameter; the cylinder in which it worked is 9 feet long by six inches thickness of metal; and one of the castings for making the largest press required 21 tons of melted iron.

In *water wheels*, water is made to act as a moving power against wheels by its weight, its momentum, or by both combined. In the first case the wheel is provided with a number of buckets, or troughs, into which the water is received near the level of the axle of the wheel; the vessels thus filled becoming heavier than those on the other side, the wheel is made to revolve by that excess of weight merely. But if the water fall into the troughs from a channel on a level with the top of the wheel, or at least above the axle, the wheel will revolve both by the weight and by the momentum which the water acquires by its fall. This is called an *overshot* wheel. If the lower part of the wheel be placed in a stream of water which is made to act on float-boards fixed on the circumference, the machine has the name of an *undershot* wheel. Lastly, when the wheel is placed in a sort of channel, or *race*, as it is called, which is formed between two projections of masonry below the bed of the upper portion of the stream, and so as to coincide very nearly with the lower quadrant of the wheel's circumference on that side, the water descending from the stream upon float-boards, or troughs, and thus acting both by its momentum and weight, the machine is called a *breast* wheel. It has been determined by experiment that the effect of the wheel is the greatest when its velocity is about half the velocity of the stream; and it is asserted that the efficacy of an overshot wheel is more than double that of an undershot wheel of equal magnitude.

A remarkable application of water power has been recently made in the United States, to work the printing press of a daily paper in Boston. Through a two inch lead pipe, a stream of water is introduced into a meter, which only occupies twenty-four square inches. The fall of water between the Boston reservoir and this meter is about a hundred feet. This two-inch stream will discharge eighty gallons of water each minute, and in passing through the meter will give a motive power equal to what is called three-horse power. This is more than sufficient for driving the press.

HYDROFLUORIC ACID. The properties of this acid (which is a compound of fluorine and hydrogen) are, that it is fluid, clear, colourless, and volatile; and, when it escapes into the air, which it does at about 60°, it forms with the moisture of it white fumes. Its vapour is extremely pungent and irritating, and it acts strongly on vegetable blues. It acts upon and decomposes glass with great facility, on account of its affinity for the silica which it contains. And hence it has, to a certain though not to a very great extent, been employed to engrave on glass.

HYDROFUGAL MACHINE. Under DRYING MACHINE a description is given of certain contrivances, by which drying is effected through the agency of centrifugal force, engendered during the rapid rotation of the articles to be dried. In France much progress has lately been made in applying similar machines to other purposes; and the name of *hydrofugal machines* has been proposed as applicable to them. Sugar has been clarified by rotating in such a machine. Beer has been cooled by a similar rotation. Attempts have been made to produce a sufficiently low temperature by this means to permit the formation of ice; but these have not hitherto succeeded. In Alsace a hydrofugal machine is employed in making starch; the starch particles are separated from the other components of flour by the centrifugal action. It is also conceived that this machine may be advantageously employed in classifying and sorting different qualities or sizes of grain, seed, or ores; since the heaviest particles are driven farthest from the centre of the machine.

HYDROGEN. This remarkable gas is the lightest of all known bodies. It may be obtained in several modes, but it is usually procured by the decomposition of water, by causing some substance to act upon it which has affinity for its oxygen and none for the hydrogen, so that this element is separated, and asumes the elastic or gaseous state. Hydrogen is colourless, inodorous, insipid, and it has resisted all attempts which have been made to condense it by the united agency of cold and pressure. 100 cubic inches weigh only 2.15 grains. This gas extinguishes flame by itself; but when it meets with a supporter of combustion, as oxygen, it burns readily, and with a continuous but feeble flame, and much heat. When mixed with oxygen, a taper causes immediate and loud explosion attended with the formation of water by the combination of the gases. When mixed with oxygen gas, and the mixture gradually burned into a small jet, intense heat is generated. When a very small jet is burned, the flickering nature of the flame causes musical sounds when a tube of glass or metal or even of paper is held over it.

Hydrogen unites with all other elementary gaseous bodies, and forms with them compounds of vast importance and utility: thus with oxygen it forms *water;* with nitrogen, *ammonia;* with chlorine, *hydrochloric* or *muriatic* acid; with fluorine, *hydrofluoric* acid; with bromine, *hydrobromic* acid; with carbon it forms the *fire-damp* of coal mines, the liquid *naphtha*, and the solid *caoutchouc*, according to the proportions and the mode of combination.

It is needless to expatiate on the utility of hydrogen in the arts and manufactures, since scarcely any process goes on without its presence and immediate action.

HYDRO'METER. The principle of the hydrometer is this:—When a body is immersed in a fluid it loses as much of its weight as is equal to the weight of that portion of the fluid which it displaces. Hence, if the same body be immersed successively in two different fluids, the portions of weight which it will thereby lose will be directly proportional to the specific gravities of those fluids. The body in this case is supposed to be specifically heavier than the fluid. If it be lighter it will float upon the surface, so that its tendency to descend, or its weight, will then be entirely counteracted by the fluid; from which it appears that, when a body floats upon the surface of a fluid, the weight of the portion of fluid displaced is equal to the entire weight of the body. Now, since the weight of the fluid displaced by a floating body is constant (being always equal to the weight of the body), whatever may be the density of that fluid, it is obvious that if we can determine how much of the body is immersed we may immediately deduce the specific gravity of the fluid; because, when the weight is constant, the specific gravity varies inversely as the bulk.

Upon this principle is constructed the well-known instrument called Sykes's *Hydrometer*, which is now employed in the collection of the spirit revenue of Great Britain. It consists of a thin brass stem about six inches in length, passing through and soldered to a hollow ball of the same material, and about one inch and a half in diameter. To the inferior extremity of the stem, from which the hollow ball is about one inch distant, a permanent pear-shaped weight is attached; so that, when the instrument is placed in a fluid, the other extremity may float perpendicularly to the surface. There are also ten weights of different magnitudes, nine of which are circular, and one in the form of a parallelopiped. By the successive application of these weights the instrument may be sunk so as to obtain the complete range of specific gravity, from that of pure alcohol to that of distilled water.

See further under ALCOHOMETER and SPECIFIC GRAVITY.

HYDROSTATIC BED. [ARNOTT BEDSTEAD.]

HYDROSTATICS. The laws of hydrostatics and hydrodynamics, or the pressure and motion of fluids, belong to the physical sciences, and not to the object of the present volume. The practical applications of those laws are noticed under HYDRAULIC MACHINES and other headings.

HYGRO'METER. This is an instrument serving to determine the quantity of aqueous vapour in the atmosphere or other gas under examination. M. De Luc employed for this purpose a thin slip of whalebone, the contractions of which indicated the variations of moisture; and De Saussure had recourse to a human hair, by means of which he constructed a far more delicate instrument. Leslie's hygrometer consists of a glass tube, bent so as to form two equal branches parallel to one another, and each terminating with a hollow ball, in which is introduced sulphuric acid coloured. One of the balls is covered with cambric, which is kept constantly moist by water from a neighbouring vessel; and the evaporation of the water, by cooling that ball, allows the air in the other, by its superior elasticity, to depress the acid in the tube below. This depression, being measured by a convenient scale, affords an indication of the relative dryness of the atmosphere.

All these instruments have however been nearly superseded by the hygrometer invented by the late Professor Daniell. It consists of two thin glass balls one inch and a quarter in diameter, connected by a glass tube about 7 inches in length. The tube is bent in two places at right angles, so as to form three arms of unequal length, the longest of which contains a small thermometer, whose bulb descends into the lower of the two glass balls. This ball, after being filled about two-thirds with æther, is placed over a spirit-lamp until the vapour of the æther has expelled the contained air through a capillary tube which is left open for the purpose, and afterwards hermetically sealed. The other ball is then covered with a piece of muslin, and the instrument thus adjusted is placed upon a stand, to which is attached a small thermometer, indicating the temperature of the external air. When about to be used, a small portion of æther is poured upon the muslin, which, by evaporating, lowers the temperature of the glass ball, and thereby occasions a rapid condensation of the æthereal vapour contained within the instrument. The condensation of the vapour within the tube produces a continuous evaporation from the surface of the æther in the lower ball, whereby the temperature of the included æther is continually reduced until a deposit of moisture from the surrounding atmosphere is observed to take place upon the exterior of the glass. At this instant the inner thermometer, which always indicates the temperature of the æther, is observed, and thus the dew point, or that at which the precipitation of atmospheric moisture takes place, is determined with considerable accuracy.

As an illustration of the facts brought out by the use of the hygrometer, we may state that in Great Britain the mean evaporation per minute from each square inch of the surface of water, one inch deep, is 0.01155 grains.

HYPONITROUS ACID. This liquid at common temperatures is green, but at 0° it is colourless; it is very volatile, so that when exposed to the air it is rapidly converted into an orange vapour.

I

ICE-HOUSE. One of the simplest modes of preserving ice consists in enveloping it in a great quantity of straw, above the surface of the ground, in such a position that moisture, which is even more injurious than heat, may drain off freely. But to preserve ice in larger quantity and for a longer period, and to obtain a cool temperature for meat and fish, an *ice-house* is requisite.

Such an ice-house may be simply a large cellar, with hollow or double walls, floor, roof, and doors, and furnished with a trapped drain to allow the escape of such water as may be produced by a partial thaw, without admitting any air. Mr. Loudon gives a ground plan and section of a complete ice-house of approved construction, of the inverted conical shape, with an arched roof, which it is proposed to cover with two or three feet of earth, or more in hot climates, over which he suggests the propriety of training ivy, for the sake of excluding solar heat. In this design a small pump is shown communicating with a well in the drain of the ice-house, for the purpose of raising the thaw-water for drinking or other use. Dr. Ure, in his 'Dictionary of Arts,' gives a section of a similar structure, but with solid walls and a conical roof of timber, which may be simply thatched, or covered with brick-work and thatched, and which should have a gutter round it to collect and conduct to a distance all rain that falls upon it, that the circumjacent ground may be kept dry. Many other forms of ice-house have been proposed by different writers.

ICE TRADE. A remarkable traffic has sprung up within the last few years; viz., the transport of ice from America to various parts of the world. In the East Indies the artificial formation of ice has been long carried on, as the only means of cooling beverages and food. The ground near Hoogley, about 40 miles from Calcutta, is formed into shallow troughs; into these troughs, on a layer of straw, are placed pans of porous earthenware. Shortly before midnight in the winter months, and when the wind happens to be blowing from the north-west, a little water is poured into each vessel or pan; and if all the circumstances are favourable, a film of ice is found in each pan on the following morning; and this ice is collected and stored with the utmost care. The selling price of this ice at Calcutta is about sixpence per pound; but the Calcutta inhabitants were surprised by the arrival, in 1833, of a ship from the United States, laden entirely with ice, which was offered for sale at three-pence per pound, and was understood to yield a good profit even after paying all the expences of a long voyage. Since then the price has been much lowered; and ice has become a regular article of shipment from America.

This remarkable trade is in the hands of the Wenham Lake Company. The company purchased a lake of pure water, and the surrounding land, at Wenham, about 18 miles from Boston; they built storehouses, and formed a railway from Wenham to Boston. The lake is very deep, and is supplied solely by springs, which issue from its bed. During winter the ice which forms on it is very thick, clear, and compact. When the ice is about a foot thick, a number of men, horses, and machines are set to work. The surface is first swept scrupulously clean; an *ice-plane* is drawn over it, to cut away a layer of loose or imperfect ice; an *ice-plough* is drawn over it, to cut a groove across the lake; and other machines are successively employed, until the ice is removed from the lake, in solid blocks weighing from one to two cwts. each. They take two acres of lake surface into operation at one time; this will yield, at the average thickness, abont two thousand tons of ice; and forty men, assisted by twelve horses, will cut and stow four hundred tons of this in a day. The company's store-house, near the lake, is built of wood, and has double walls two feet apart: the intervening space being filled with saw-dust: twenty thousand tons of ice can be stored in this building at one time. The company bring the ice to Boston on their own railway, and thence transmit it to various parts of the world. Large store-houses have been formed in many parts of the United States, as well as in London and Liverpool.

Whether procured from Wenham, or from our own streams and ponds, ice may be conveniently kept in *portable ice-houses* or *refrigerators*, which are now much used in England and America. This consists of a box with two lids, and with perforated sliding shelves; ice is placed under the shelves, meat or other provisions is laid on the shelves, and the box is closed; being air-tight, it allows the ice to cool the other contents of the box with great rapidity. A new form of apparatus has been recently patented by Mr. Ling, under the name of *ice-safe*. The ice is placed in a distinct chamber, in a way that is intended to economize that material. The smaller size, for families, is planned so as to cool two gallons of water at a time, besides meat, &c.

ICELAND. The best inhabited spots on this lonely island are near the *fiords* or creeks, where establishments are kept up for the sake of trade and shipping. Corn is cultivated to a limited extent. Hay is the great harvest of Iceland. Those who live on the coast attend to fishing, which is very productive; and those a little further inland rear cattle. The common food of the people is butter, milk, and fish; fresh meat and rye bread are holiday fare. The exports consist of cod and other dried fish, whale oil, salted mutton, eider-down and sulphur, which is abundant. Turf is the common fuel of the inhabitants; fossil wood, iron, and copper are found. In the northern district there is a kind of town or village, called Eyafiordur, and a factory called Husavik, on the Skialfianda fiord, from which sulphur from the neighbouring mines is shipped. Other factories are scattered about the coast, especially in the west.

ICELAND MOSS. This lichen, though a native of the higher mountains of the northern part of Britain, is procured mostly from Norway and Iceland, on the lava of the west coast of which latter country it abounds and attains a large size. It is imported through Hamburg. When dry it has scarcely any odour, and the taste is bitter and unpleasant. The powder or flower is of a whitish gray. When the bitter principle is removed, the starchy matter differs from wheat-flour in nutritive properties, though some authorities assert that a soup prepared with it is twice as nutritious as one made with flour. Certain it is that the inhabitants of Norway, Lapland, and, above all, of Iceland, use it extensively as an alimentary substance, the latter regarding it as the gift of 'a bountiful Providence, which sends them bread out of the very stones.' Dr. Henderson ('Tour in Iceland') says that a porridge made of this lichen flour is to a foreigner not only the most wholesome but the most palatable of all the articles of Icelandic diet. It is submitted to no other preparation than repeated steepings in cold water, drying, and powdering; after which it is either made into cakes or boiled in milk. The excellence of Iceland Moss depends upon its freshness and freedom from accidental impurities, which should be carefully removed before it is used.

IDOCRASE, is the name of a gem which is sometimes called *Pyramidal Garnet*. The colour exhibits various shades of brown, black, gray, blue, green, and yellow.

ILLE-ET-VILAINE. The soil of this department of France is made to produce all kinds of breadstuffs, in quantity more than enough for the wants of the population. In the rich soils, wheat of excellent quality is raised; tobacco is grown near St. Malo; rye, barley, oats, buckwheat, and mixed grain are produced in the middling and poorer soils. The cultivation of flax and hemp for the manufactures of the department is very extensive; the flax and hemp in the dressed state, as also the seeds, are important objects of commerce. The apple and the pear are extensively cultivated for making cider and perry, the chief drinks of the population; the cider is strong enough to keep for two years, and is considered the best made in France. Excellent butter and cheese are made. The forests of the department contain fine timber: the prevailing kinds are oak and beech; next come chestnut, poplar, and birch. Several iron mines are worked: roofing and clay slate, white quartz for the glass factories, limestone, and granite are quarried: lead and copper ore are found.

The most important manufactures are linen, sailcloth of the best quality, Russia duck, canvas, and shoe and morocco leather; felt and straw hats, sewing thread, thread stockings, ship cordage and ropes, fishing nets, hooks and lines, pottery, cotton and woollen yarn, are also made. There are besides, several bleaching establishments, brandy distilleries, paper mills, iron forges and smelting furnaces, and flour-mills; in the towns on the coast shipbuilding is carried on to some extent. Salt is made in some of the marshes on the coast. The commerce is composed of the various articles named, and of groats, chestnuts, salt pork, hides, oak staves, firewood, &c.

ILLINOIS. A few commercial features relating to this rapidly-advancing state will be found under UNITED STATES.

ILLYRIA, a kingdom and province of the Austrian empire, is slightly noticed in respect to its produce and manufactures, under AUSTRIA. We may here state in addition that the most important town is *Idria*, famous for its quicksilver mines. It is situated at the bottom of a narrow valley surrounded by high mountains, on the banks of the little river Idria, and has 5000 inhabitants, who subsist partly by lace making and straw platting; but the greater part are employed in the mines and in the quicksilver works and cinnabar factories in the neighbourhood. The entrance to the mine is nearly in the middle of the town, by a large iron gate, which opens to a horizontal passage leading to a flight of 757 steps cut in the limestone rock.

IMPORTS AND EXPORTS. Until a time comparatively recent, our official trade accounts were not furnished in such a manner as to allow of any certain deductions being made from them; but the monthly and yearly accounts of the Board of Trade now furnish very complete information on these points. The list of our imports from foreign countries and the colonies comprises almost every article of use and of luxury which cannot be profitably produced within the kingdom; while our exports comprise chiefly mineral produce, and manufactured goods of a very varied description.

We find that in the last five years, the value of British and Irish produce and manufactures exported has been as follows:—

Year.	Total Exports.
1846	£57,786,876
1847	58,842,377
1848	52,849,445
1849	58,910,883
1850	65,756,032

Taking the year 1848 as an example, we find that the largest customers for our manufactures were the following:—

United States	£9,564,909
Germany	5,263,588
East Indies	5,077,247
Holland	2,823,258
Turkey	2,664,281
Brazil	2,067,302
British America	1,990,592
West Indies	1.434,477

The Board of Trade returns respecting Imports give *quantities* of each kind of commodity, rather than *values*; and it is therefore not easy to present an abstract of them. We will however take the year 1850, and show what were the most notable items, both of export and import. First for Export:—

Candles	2,723,531 lbs.
Coals	3,347,607 tons.
Cotton Goods	1,358,238,837 yards.
Cotton Lace	114,095,554 yards.
Cotton Yarn	131,433,168 lbs.
Earthenware	76,952,735 pieces.
Glass	336,614 cwts.
Linen	122,397,457 yards.
Linen Yarn	18,559,318 lbs.
Metals and Machinery (about)	10,000,000*l*.
Oil	3,292,266 gallons.
Salt	15,824,780 bushels.
Silk Manufactures (about)	1,300,000*l*.
Soap	124,038 cwts.
Soda	888,146 cwts.
Wool and Woollens (about)	11,000,000*l*.

Among the items of Import, the following were the most considerable:—

Brimstone	664,630 cwts.
Coffee	50,809,521 lbs.
Corn	7,969,435 quarters.
Corn-meal	3,873,908 cwts.
Cotton	5,934,793 cwts.
Cured or Salted Meat	687,199 cwts.
Hemp	1,048,635 cwts.
Live Stock	217,247 head.
Metals	117,148 tons.
Rice	785,692 cwts.
Saltpetre	529,012 cwts.
Silks (about)	6,000,000 lbs.
Spices (about)	13,000,000 lbs.
Spirits	7,763,279 gallons.
Sugar	1,250,441 cwts.
Tallow	1,241,781 cwts.
Tea	50,513,003 lbs.
Tobacco	35,427,335 lbs.
Wine	9,267,573 gallons.
Wool	74,326,778 lbs.

INCLINED PLANE. In mechanical and mathematical considerations an *inclined plane* is a plane surface making any angle with the horizon. A body placed on it is capable of being moved upwards along it with more facility than it can be raised in a vertical direction. The principle on which it constitutes a mechanical power was first introduced by Stevinus in the sixteenth century.

Among the useful rules ascertained on this subject are the following:—A weight placed upon an inclined plane is propelled down the plane by such a fraction of the whole pressure of the weight as the height of any section of the plane is of its length. The velocity acquired by a body in descending from the top to the foot of a plane, whatever be its inclination, is the same as in falling vertically from the top to a horizontal plane passing through the foot.

INCLOSURES. The amount of common land (land in a state of nature or waste) in England is not known, but it is conjectured that it may be about 8,000,000 of acres; the total area of England and Wales being supposed to be about 37,000,000 acres. There is another class called *commonable lands*, which is commonable or open to all the parishioners during a part only of each year. As common and commonable lands produce relatively little on account of insufficient culture, *Inclosures* of land have now been going on for many years. It is stated that since 1800 about 2000 inclosure acts have passed; and prior to that time about 1600 or 1700. These inclosure acts (with certain exceptions) are private acts, and the expense of obtaining them and the trouble attendant on the carrying their provisions into effect have often prevented the inclosure of commons. In 1836 an act was passed for facilitating the inclosure of open and arable fields in England and Wales. In pursuance of the recommendation of a Committee of the House of Commons, which sat in 1844, an act of parliament was passed in 1845, the object of which is thus stated in the preamble:—'To facilitate the inclosure and improvement of commons and other lands now subject to the rights of property which obstruct cultivation and the productive employment of labour, and to facilitate such exchanges of lands, and such divisions of lands intermixed or divided into inconvenient parcels as may be beneficial to the respective owners.'

Although the local rights of parishioners are somewhat interfered with by these inclosures, there can be little doubt that the general culture of the land, and the wealth of the community, are increased thereby.

INDIA. [East India Company.]

INDIA RUBBER MANUFACTURES. A description of this singular substance, and of the mode in which it is obtained in the East, will be found under Caoutchouc. When the gum became known in England, its elasticity and its imperviousness to water pointed it out as a valuable material for manufactures; and it has gradually come into very extensive use.

Before Caoutchouc can be practically applied, it requires to be brought from its first crude state to that of a cake, a thread, or a liquid, according to its mode of application. The crude substance is cut into shreds, washed, heated, and kneaded by rollers until it assumes a homogeneous consistency; it is then pressed into moulds, which bring it to the form of large rectangular masses. From these masses sheets are cut by machinery to any required thickness; and from these sheets threads or any of the other countless forms of the material are prepared. By the use of petroleum, naphtha, oil of turpentine, or a few other liquids, caoutchouc may be dissolved; and in that dissolved state is an admirable varnish for rendering porous substances water-proof.

As a solid substance, as a woven material (with or without any fibrous ingredient), and as a varnish, caoutchouc is now applied to countless purposes, in dress, in machinery, and in other ways. Every reader will be able to verify this assertion.

Mr. Hancock, who has probably done more than any other person to vary the modes in which caoutchouc may be employed in manufactures, took out a patent in 1845 for removing three inconveniences which are often presented by this substance. These inconveniences are, a clammy adhesiveness; a tendency to stiffen and harden by cold; and a tendency to become softened or even decomposed by heat or by oil. To remove the clammy adhesiveness, Mr. Hancock brings the caoutchouc to the state of a sheet by the pressure of iron rollers, and forces into this sheet twice its weight of powdered French chalk, or silicate of magnesia, by repeated pressure. Other processes then incorporate the two substances completely; and the compound is ready to be applied to varied purposes. For some purposes powdered black lead, or powdered dry asphalte, are used instead of the silicate.

To enable caoutchouc to resist heat, cold, air, grease, oil, and various solvents, is the purport of Mr. Hancock's Vulcanized India Rubber. This is a compound of caoutchouc and sulphur. The sulphur is either pounded and pressed into the sheets of caoutchouc in the same manner as the silicate; or the sheets are steeped in melted sulphur until they become thoroughly impregnated with it. The compound is then made into a paste, or a so-

KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 26.

lution, or thin sheets or threads, or any of the numerous forms in which it is employed. The caoutchouc loses some of its extent of elasticity, but acquires more perfect elasticity, the longer it remains in the melted sulphur; that is, it becomes less easily stretched, on account of its increasing toughness, but its elasticity is more intense so far as it goes. Some of the Vulcanised India Rubber now used is wonderfully elastic.

In 1846 Mr. Parkes patented many improvements in the caoutchouc manufacture. One of these is a new kind of vulcanised India rubber. The change which has obtained this name is produced, according to this patent, by immersing thin sheets of caoutchouc in a solution of chloride of sulphur or bisulphuret of carbon, heating them to a temperature of 80 Fahr., boiling them in a caustic ley, and drying. Vulcanising in the dry way, Mr. Parkes effects by kneading or pressing fine chloride of sulphur into the substance of the soft caoutchouc. Another part of the patent relates to the dyeing of caoutchouc. The following are the ingredients named, for forming the various dyeing liquids:—For black; sulphate of copper and caustic ammonia. For green; sulphate of copper, muriate of ammonia, and caustic lime. For purple; sulphates of copper and of potash, and sulphate of indigo. For merely colouring the surface, without dyeing the substance, many ingredients may be employed, and many tints produced.

It would carry us beyond our limits even to name the various patents which have been brought out for india rubber manufactures, and the improvements suggested therein. We may however briefly glance at a few.

Mr. Lorimer, in 1848, among other novelties patented a waterproofing material, made of caoutchouc combined with oxide of copper and slaked lime acidulated with oxalic acid. Another patent in the same year was for imparting certain qualities to caoutchouc by combining it with carbonate of magnesia. Mr. Nickells in 1849 introduced a mode of combining sulphur with caoutchouc. The caoutchouc is placed in what is called a masticating machine, flowers of sulphur are added, heat is applied, and a roller passes to and fro over these substances, until they are kneaded into a uniform mass. Simpson and Foster's patent, in the same year, was for a mode of dissolving caoutchouc by the use of bisulphuret of carbon combined with pentachloride of antimony. Burke's patent, about the same time, was for giving permanent elasticity to caoutchouc by the application of antimony and carbonate of soda. Newton's patent, in 1850, is for combining caoutchouc with gum lac, as a means of removing its odour.

Notwithstanding the large use of caoutchouc, it must be admitted that Gutta Percha has lately been outstripping it in public favour.

INDIANA. A few industrial statistics of this State will be found under UNITED STATES.

INDIGO. This well-known and beautiful blue vegetable colour is extensively employed in dyeing and calico printing. The plants from which it is mostly obtained belong to the genus *indigofera*, of which the chief species grow in India. When the plant is in full flower, it contains most colouring matter. After being cut, it is put into vats, and covered with water; fermentation takes place, accompanied with the evolution of carbonic acid and probably other gaseous products, and the yellow liquor is covered with a froth which in a little time becomes of a violet colour, and a substance is dissolved which is rendered blue by absorbing the oxygen of the air, and being then rendered insoluble it is precipitated; and this, when collected and dried, is indigo.

The usual appearance of indigo as it occurs in commerce is that of nearly cubical cakes of an intense blue colour and earthy fracture. Indigo seldom contains more than about half its weight of pure colouring matter, and frequently much less.

When common indigo has been treated with dilute acids, alkalis, and alcohol, the remainder is *indigotin*, or indigo, nearly in a state of purity.

The quantity of indigo imported into Great Britain in 1850 was 70,482 cwts.

INDRE. This department of France produces corn in quantity more than enough for the consumption; buck-wheat, hemp, flax, chestnuts, and fruits are also grown. The annual produce of wine is six to seven million gallons, about one-half of which is exported. Sheep are a source of great profit to the farmers, on account of the fineness of their wool: the quality of the wool of the *Champagne* district especially is very superior. Several iron mines are worked; marble, millstone, limestone, mica, flint, lithographic stones, granite, quartz, spar, marl, potter's clay, variegated marbles, &c., are found. The cloth manufactures of Châteauroux and some other places are important; linen, hosiery, scythes, paper, porcelain, and earthenware are made. There are also numerous establishments for the manufacture of woollen yarn, leather, beer, parchment, &c. The most important iron-works are those of Clavières. The commerce of the department is composed of the various agricultural and industrial products named.

There is another department, called *Indre-*

et-Loire, one of the most important products of which is wine; of which 14 or 15 million gallons are made yearly; next come hemp, walnuts for making oil, plums, beans, leguminous plants, liquorice, anise, and coriander; citrons, melons, almonds, apples, pears, truffles, &c. Bees and silkworms are carefully tended. Iron mines are worked; stone, especially a tufaceous sandstone, of which most of the houses are built, is quarried out of the hills near the Loire, and excavations thus formed are occupied as dwelling places by the poorer inhabitants. Millstone grit, marl, potter's clay, and brick-earth are found. Copper ore is met with, but no mines are worked. The chief industrial products are bar iron, powder, and files; woollen cloth, of which manufacture Tours is the centre; silk, leather, paper, and pottery, are also made, but the manufacture of these articles is not so important as formerly. The exports consist mostly of agricultural products, the imports of colonial produce, glass, cotton stuffs, fine linen and woollen cloth, furniture, haberdashery, &c.

INFUSIONS are solutions of some of the principles of vegetables, generally in water, but occasionally in other vehicles. When water is employed it may either be hot or cold. It is customary to use warm water, but in many instances cold is preferable. Sometimes alcohol is added, after straining, to assist in keeping the infusion, or to increase its powers. Hard water should, if possible, be avoided in the preparation of infusions.

INK. The writing ink of the ancients was essentially different from that which is now employed. Its basis was finely divided charcoal, mixed with some mucilaginous or adhesive fluid: it was much less destructible than modern writing ink, and somewhat more resembled printer's ink. Writing ink is now a chemical compound, and not a mere mechanical mixture. Its basis is proto-gallate and proto-tannate of iron, which by oxidisement become per-gallate and per-tannate; and it is owing to the oxygen of the air effecting this change gradually that recent writing is of a comparatively light colour, and that it subsequently becomes black. Many processes have been given for preparing writing ink. The common ingredients are galls and sulphate of iron; in fact, while printers' ink may be considered as a black paint, writing ink may be regarded as a black dye. The following, which is recommended by Mr. Brande, gives, he says, an excellent ink, and it possesses the merit of greater simplicity than most others:—Aleppo galls, bruised, 6 ounces; sulphate of iron, 4 ounces; gum arabic, 4 ounces; water, 6 pints. Boil the galls in the water, then add the other ingredients, and keep the whole in a well-stopped bottle, occasionally shaking it. In two months strain and pour off the ink into glass bottles, to be well corked. To prevent mould, add one grain of corrosive sublimate, or three drops of creosote, to each pint of ink. Modern writing ink, unlike the ancient, is readily destroyed by chlorine, acids, and alkalis. Red, blue, and other coloured inks have nearly the same chemical properties as black ink, and depend for their colour on the kind of ingredients employed. A *Magic Sand* has been recently introduced, to 'write without ink,' and to avoid spilling and spotting. The magic consists probably in sand being saturated with ink.

Indian Ink.—The cakes of this ink are made of lamp-black and size, or animal glue, with the addition of perfumes or other substances not essential to its quality as an ink. It is used in China with a brush, both for writing and for painting upon paper of Chinese manufacture. It is used in Europe for designs in black and white, in which it possesses the advantage of affording various depths of shade, according to the degree of dilution with water.

Printers' Ink is of two kinds: for letter-press printing and for copper plate printing. Printers' ink is prepared by boiling linseed or nut oil in an iron pot; and, if it does not take fire of itself, it is kindled, and suffered to burn for about half an hour; the flame is then extinguished by closely covering the vessel, and the oil is by this operation found to have acquired the necessary drying quality, after being again boiled. It is then mixed with a proper quantity of lamp-black, when black ink is required; if red ink be required, the colouring matter employed is vermillion for finer works. Copper-plate printers' ink is made with oil which is less boiled, and the charcoal used is Frankfort black, made from vine twigs.

Marking Ink is employed for marking linen: it is a solution of nitrate of silver, written with a pen upon the fabric to be marked after it has been moistened with an alkaline solution, as potash or soda. By this process oxide of silver is precipitated upon and combines with the cloth so as to be scarcely removeable by any reagent which does not also destroy its texture. There are other chemical preparations used for this purpose.

Sympathetic Inks are such as are invisible until heat is applied, and then, by the chemical change induced, the writing becomes visible. The most remarkable of these is that prepared from cobalt, called Hellot's Sympathetic Ink, which is a chloride of the metal. When the written paper is held to the fire so as to evaporate the water, the letters become green.

INTA'GLIO. This name is given to small works of the gem class, in which the design is indented or engraved, to distinguish them from those in which the subject or device is raised, called *Cameos*. The Greeks carried this branch of the fine arts to the same perfection which their genius and feeling for the beautiful enabled them to reach in all others to which they devoted their attention; but we do not trace its existence among them to a very remote date. We have no information respecting the process by which the ancient intagliatori (or sculptores) executed works which are now justly referred to as the best examples of the art. The modern practice of cutting stones in intaglio is by an apparatus similar in principle to the turning lathe, which gives the cutting tool, placed horizontally, a quick rotatory motion, and, the stone on which the design is to be engraved being brought in contact with it, the surface is ground away or indented, till the effect required is produced. Instruments of various sizes are used, which can easily be removed and replaced, and it is usual, during the process of engraving, to supply the points of the tools with diamond dust mixed with a little sweet oil. As the work proceeds, proofs are occasionally taken in wax.

Die-Sinking or the engraving of dies is an important branch of the art of intaglio, and requires great care and skill for its perfection. The die is made of finely prepared and tempered steel. When the first intaglio, or original die, is executed, it forms a *matrix* (or mould), into which a conically formed block of softer steel is compressed, the matrix first undergoing a process by which it is hardened. An impression taken in this way is called a *puncheon*. When this is completed (and frequent annealing and restriking are necessary before it is perfected), the engraver retouches the work, now in relief, and gives it all the delicacy of the original model; the metal is then hardened, and, by pressing this puncheon into other steel which is soft (by almost a repetition indeed of the before-mentioned process), it serves for the purpose of making the dies for coining.

INVENTIONS. A few words on the present state of the law respecting patents (or what may be termed copyright) for mechanical inventions, will be found under PATENT LAWS.

INVERNESSHIRE. By far the greater part of the surface of this Scotch county is covered with heath; but a good deal of the heathy ground is arable, and a considerable extent of it has been brought into cultivation during the present century. Limestone is found in several districts, and in some districts approaches to the nature of marble. Sandstone is also frequently met with. Some veins of lead and silver have been discovered, and also iron ore in small quantities. The soil is for the most part light and sandy, with a subsoil of gravel or clay: but in the neighbourhood of the town of Inverness it is enriched by a fine loam deposited by the waters which fall into the adjoining firth. Formerly there were a great number of small arable farms only a few acres in extent; but these have much decreased since the introduction of sheep-farming. The attention of the farmers is chiefly directed to the rearing of sheep and cattle. The fir woods in Glenmore and those of Strathspey in the adjoining county of Elgin are supposed to be more extensive than all the other natural woods in Scotland together. Glen Morrison, which opens into Glenmore, also contains much fine timber. Those which grow naturally are the oak, fir, birch, ash, mountain ash, holly, elm, hazel and the Scotch poplar. Those which are planted are the larch, spruce fir, silver fir, beech, plane, and fruit-trees. Formerly a good deal of hemp, worsted, and linen yarn was made in this county; but this has greatly declined since the establishment of the large manufactories of the south.

The only important town in the county, Inverness, is noticeable rather in a picturesque than an industrial point of view; there is a small import of hemp, timber, and tar, and an export of oats.

IODINE. This remarkable non-metallic elementary body was discovered by M. Courtois in 1812. Iodine exists in the water of the ocean and mineral springs, and in marine molluscous animals and sea-weeds; but it is principally obtained from kelp, or sea-weed which has been burnt for the purpose of obtaining alkali. It is a soft opaque solid, of a blueish black colour and metallic lustre. When moderately heated, it rises in vapour of a violet colour, and hence its name from the Greek word for violet. On cooling, it again crystallises unchanged, nor is it decomposed or altered by being subjected to very high temperatures; and it has resisted all attempts to decompose it.

Iodine has a strong disagreeable odour and taste; it stains the skin of a brownish colour, but not permanently. It is readily dissolved by alcohol, but scarcely at all by water. It is very poisonous. Its characteristic property is that of giving an intense blue colour when added to a solution of starch. It unites with metals to form compounds, which are termed *Iodides;* and, like chlorine and bromine, it forms acids both with hydrogen and oxygen.

Iodine, though only obtained in an isolated state of late years, has been long employed as the efficient principle of other preparations and therapeutic agents, namely, burnt sponge and certain mineral waters. It is only since it has been procured as a distinct principle that its action has been ascertained with precision. In the present day it is administered rather in some artificial compound than as pure iodine, owing to its very sparing solubility in water. Its value in medicine is very great. In photographic processes and in other processes connected with the arts, iodine is also very useful.

At the Dublin Exhibition of manufactures in 1850, the Messrs. Bullock, manufacturing chemists of Galway, exhibited specimens of Irish iodine. It appears that iodine is found in large quantities in the sea-weed which covers the rocks for miles round the west coast of Ireland; it has been hitherto collected by the peasatns for manure; but Messrs. Bullock have found that it will yield iodine in sufficient quantity to pay for the extraction. This affords one among many exemplars of the advancing spirit of manufactures in Ireland.

IONIAN ISLANDS. This name is given to the islands of Corfu, Cephalonia, Zante, Santa-Maura, Theaki, Paxo, Cerigo, and some small islets, all situated in the Ionian Sea, off the west coast of Albania and the coast of Greece. Oil, wine, corn, cotton, the small species of grape called currants, and other fruits, and flax, are the chief productions; the olive is extensively cultivated in all the islands; the currant is grown in the greatest perfection in Cephalonia and Zante, but of late years the cultivation of this fruit is diminishing in the islands and increasing on the main land of Greece. Earthenware, salt, soap, and some coarse woven goods, are the principal industrial products; ship-building and the fisheries give employment to a considerable number of hands. The coasting trade is important. The imports, consisting of sugar, coffee, and drugs, raw and manufactured cotton and silk; wool and woollen cloth, glass, hardware, staves and hoops; iron, timber, wheat, Indian corn, rice, cheese, flour, fish, cattle, sheep, tobacco, &c., average in value about 630,000*l*. a year. The import and export is almost entirely carried on in British ships.

The British produce and manufactures imported into the Ionian Islands in 1849 amounted in value to 165,805*l*.; those from other countries amounted to three or four times this value, but mostly in British shipping.

Of these several islands *Cephalonia* depends chiefly on its culture of currants, of which there are about 6000 acres planted. *Corfu* produces oil, wine, cotton, fruit, flax, and corn; oil is the chief produce, the annual produce being about 200,000 barrels. *Cerigo* and all the other islands produce nearly the same crops, varying a little in richness.

IOWA. This member of the United States confederacy, which attained to that honour only so late as 1846, is too young a state to present us yet with any marked industrial developments.

IPECACUANHA. This emetic substance is the root of several plants growing in South America. All the kinds have nearly the same ingredients, but differ in the amount of the active principle which they respectively contain, termed *emeta*. The best is the annulated, yielded by the *Cephaëlis Ipecacuanha*, a small shrubby plant, native of Brazil and of New Granada. Of this sort there are three varieties, namely, the brown, red, and gray, or gray-white, called also greater annulated ipecacuan. As this is the only sort sent from Rio Janeiro, it is sometimes called Brazilian or Lisbon ipecacuanha. It is sent in bales and barrels.

IRELAND. This beautiful and naturally rich portion of our Empire contains six coal districts: the Leinster, or Castlecomer district; the Slieve Arda, or Tipperary district; the Munster district; the Lough Allen district, round the source of the Shannon; and the Monaghan and Tyrone districts; there is also a coal district of small extent in Antrim. The coal raised in the southern districts is anthracite, or blind-coal; that raised in the districts north of Dublin is bituminous. In addition to these the central district of Ireland contains upwards of one million acres of bog, comprehended for the most part within that portion which would be embraced by lines drawn from Wicklow to Galway, and from Howth-head to Sligo. In respect to lakes and rivers, it has been estimated that the water power afforded by the different rivers and natural dams of Ireland is greater than in any equal extent of accessible country in Europe: this is a very important feature in connection with the future industrial progress of Ireland.

Of the 20 millions of acres of land in Ireland, it has been estimated that 5¼ are arable and garden ground; 6¾ meadows, pastures, and marshes; 5 improveable wastes; and the rest unimproveable wastes. In 1841 there were about 350,000 acres of plantations in Ireland. In 1847, about one-fourth of the whole area of Ireland was under crop, comprising about 5,000,000 acres; of which two-thirds were under corn-crops, and one-third under crops of beans, potatoes, turnips, clover, flax, &c. The corn produce in that year was about 16,000,000 quarters; comprising wheat, oats, barley, bere, and rye; and giving about

5 quarters average per acre. The Irish fisheries are carried on upon a considerable scale, under the management of the Board of Works. The whole coast of Ireland has been divided by the commissioners into 28 fishery districts, in which are registered about 20,000 vessels and boats, and about 100,000 fishermen and boys.

Among the manufactures of Ireland, that of linen takes the lead; it gives a flourishing character to the district around Belfast and Coleraine. Cotton spinning and weaving, and calico bleaching and printing, also occupy many hands. The woollen and silk manufactures, once carried on to a respectable extent, have greatly declined within the last few years. In grinding, malting, brewing, and distilling, a considerable trade is carried on. The malt made in Ireland in 1850 was 1,682,102 bushels. The quantity of spirits charged with duty in Ireland in the same year was 7,408,086 gallons. There are numerous paper-mills, glass-works, and tobacco manufactories.

The inland traffic is kept up by tolerably good roads, rivers, canals, and railways. The chief canals are the Grand Canal, Royal Canal, Shannon Navigation, Limerick Navigation, Lagan Navigation, Newry Navigation, Tyrone Navigation, Boyne Navigation, Slaney Navigation, Barrow Navigation, and Ulster Canal, giving about 620 miles of available navigation. Railways will very shortly cross the island from east to west and from north to south. The external traffic is greatly aided by steam power; steam vessels of large size run from London, Plymouth, Bristol, Holyhead, Liverpool, Fleetwood, Greenock, and Glasgow, to Cork, Waterford, Wexford, Dublin, Belfast, Londonderry, and other Irish ports.

Every one at all interested in the welfare of Ireland is anxious to see her great industrial capabilities developed. That her manufacturers can produce manifold and excellent specimens of skill was sufficiently shewn at the Dublin Exhibition of Manufactures in 1850, noticed in our '*Introduction*.' That Ireland is not insufficiently supplied with mineral wealth is exemplified in the black and white marbles of Galway, the slates of various districts, the coal of her various beds, and the peat which—though now an incumbrance and an eyesore—may yet become a mine of resources. That the Ulster cultivators and manufacturers are not blind to improvements is shewn by the eagerness with which the investigations concerning flax are now being regarded. That the merchants of Ireland are alive to the energy of commercial enterprise, let Cork and Limerick, Waterford and Dublin, Belfast and Derry, bear witness. The castings for an iron bridge for the South Wales Railway have just been made at Dublin—a feature which has excited well-merited attention. When we find that 19 Irish counties contain iron, 17 copper, 18 lead, and 16 coal, we cannot but hope that a brighter future is in store for that country.

At the forthcoming Industrial Exhibition, Ireland will occupy about 10,000 square feet of floor and counter, and 14,000 of wall space. In the section relating to manufactures there are more exhibitors than in the other three combined. From Cork the contributions will comprise marble, pottery clay, fine sand and silex for glassmaking, wool, leather, friezes, blankets, ginghams, models of inventions in machinery, and cabinet work. From Clonmel—cutlery, ivory turning, crochet and other work; woollens, models of agricultural implements. From Tipperary—coal, copper ore, &c. From Kilkenny—the marbles for which it is so celebrated, Kellymont flags, anthracite coal, hunting breeches, and friezes, and specimens of the leather used in making them; together with an interesting cabinet of the materials used in the manufacture of artificial flies for angling, flies and fishing tackle. From Wexford—porphyry, sand for glass, clay, the herring nets made by the fishermen of that locality, models of machinery, architectural models, and philosophical instruments. From Limerick—the beautiful Limerick lace, gloves, brushes, cutlery, army clothing, fishing tackle, worsted work, leather, and tobacco; in raw materials, alumina, silex, pottery clay, fire-clay slates, flagstones, building stone, marbles, copper and iron ore; in fancy woods, bog oak, bog yew, and arbutus; and in the mechanical section, models of machinery and inventions; and from Mountmellick, the bits and stirrups for which it is famous. These are from the south and west of Ireland; the north and east will contribute yet more largely.

IRI'DIUM. This rare metal is found combined with platinum in the ores of the latter metal, from which it may be separated by a complex chemical process. A few minute grains of native iridium have been found, but it is rarely so met with. Iridium is brittle, and when carefully polished has the appearance of platinum. When heated to redness in the air, if in a state of fine division (which is obtained by precipitation), it is oxidised, but not if in mass. Iridium is with difficulty acted upon by acids. It combines chemically with many simpler substances; but its usefulness has not yet become very great.

IRON AND ITS ORES. Of all the metals iron is the most widely diffused, the most abundant, and the most useful. It is found not only intermixed with soils, and contained in rocks and minerals, but it is even met with in some animal and vegetable bodies, and also in mineral waters. It occurs rarely in nature in the metallic state, for almost the whole of it that has been found occurs as meteoric iron containing nickel, or in meteoric stones. It is mostly found either combined with oxygen, oxygen and carbonic acid, or sulphur. The best iron ores are oxides, which occur in primitive countries, where they generally form very large beds; such are those of Sweden: but the greater part of the iron ore of Britain is an impure carbonate.

When separated from its ores, the colour of iron is grayish white with a tint of blue. It is extremely ductile, so that it may be drawn into wire finer than the human hair, but it cannot be beaten into very thin leaves. It is of all metals the most tenacious, for a wire $\frac{1}{15}$th of an inch in diameter is capable of supporting a weight of about 550 lbs. It is susceptible of a high polish. It is combustible when minutely divided, as in the state of filings. It is very hard at common temperatures, and this property may be increased by its being heated and then suddenly cooled; it then however becomes brittle. It requires a most intense heat to melt it; but when heated to redness it becomes soft and pliable, and possesses the valuable property of *welding*, that is, two pieces of red-hot iron may be made to unite by hammering. Its texture is fibrous. Its specific gravity is about 7.77; but this varies in some degree according to the extent to which it has been drawn, rolled, or hammered, and it is increased by fusion. Iron, or rather steel, is capable of being rendered permanently magnetic. Iron has great affinity for oxygen and sulphur, and some other elementary bodies, and combines with them in various proportions.

The chief ores of iron are the following:—*Oxydulous* or *Magnetic; Specular* or *Micaceous; Goethite; Iron Froth; Red Hematite; Brown Hematite; Carbonate of Iron*, or *Spathose Iron Ore;* and *Clay Iron Stone*. The last named is the most abundant in this country.

Of the valuable chemical substances in which iron forms an ingredient, it is difficult to give even a list: so numerous and varied are they. *Steel* and *black lead* consist of iron and carbon; *green vitriol* is sulphate of iron. The presence of phosphorus in iron is said to give it what iron manufacturers call the *cold short* quality. The *acetate of iron* is much used in calico printing.

The *Alloys of Iron* are much less useful than might be expected from the extreme utility of the metal itself. *Potassium* and iron, and *sodium* and iron, combine when heat is applied to them: the alloys are more fusible than pure iron, especially when in contact with the air; and they are decomposed by air and water. *Silicium* and iron form an alloy which is ductile or brittle according to the quantity of charcoal which it contains. *Arsenic* and iron form an alloy which has a grayish white colour, does not obey the magnet, is very brittle, and much more fusible than iron. *Chromium* and iron form an alloy very little known. With *columbium* a hard brown alloy is formed. *Zinc* gives a white and brittle alloy with iron. *Tin* and iron form the alloy seen on tin-plate ware. *Antimony* and iron unite when heated together in close vessels: the alloy is white, hard, brittle, and its specific gravity is less than that of the mean of the two metals. No metal appears to deprive iron more of its magnetic property than antimony. *Cobalt* and iron form a hard magnetic alloy. *Nickel* and iron form the meteoric alloy. *Bismuth* combines with difficulty with iron. *Molybdenum* forms with it a blueish gray brittle alloy. The alloy of *copper* and iron is magnetic. *Silver* combines readily with iron when they are fused together, but they separate on solidification, and globules of silver appear on the surface of the alloy. With *mercury* a white tenacious alloy is formed. *Lead* and iron combine with difficulty. *Rhodium, iridium, tungsten*, and *platinum* may all be made to form alloys with iron. *Gold* and iron combine with facility; a compound of eleven parts of gold and one part of iron is nearly white, and very ductile.

IRON MANUFACTURE. The art of smelting iron was practised in this country during the time of the Roman occupation, and in many ancient beds of cinders, the refuse of iron-works, Roman coins have been found. The principal ancient seats of the iron manufacture in this country appear to have been Sussex and the Forest of Dean, or Arden, as it was then called. Remains of ancient iron-furnaces have been noticed in Lancashire, Staffordshire, and Yorkshire. The art of working in iron and steel was much practised in this island before the Norman Conquest. At the present day the chief iron manufacturing districts in this country are the Lanark district of Scotland, South Wales, and South Staffordshire; the works distributed in other parts of the kingdom are much less extensive, though many even of these are of great importance.

There are two distinct qualities into which this metal is commonly divided, viz. *pig-iron* and *malleable* or *bar iron*, the second being the result of an extension of the processes necessary for the production of the first kind.

The first process is that of reducing the iron-stone or ore, or, as it is technically called, the *mine*, into a metallic state by means of fusion. This operation is conducted in a *blast-furnace* or *smelting-furnace*. [FURNACE.] The furnace is charged from the top with certain proportions of iron ore, coke, and limestone. The ore is previously roasted in a kiln, in order to drive off the water, sulphur, and arsenic, with which it is more or less combined in its native state: by this process it loses one-sixth part of its weight. A furnace of the size commonly used in Wales will produce from 5 to 6 tons of pig-iron in twelve hours. For the largest quantity the furnace is charged progressively with 15 tons of roasted iron ore, 22½ tons of coke, and about 6 tons of limestone. These ingredients are supplied at 50 charges, and are intimately mixed together in the furnace. The limestone is broken into small pieces, and is used to act as a flux to the ore and promote its fusion. The heat that would be produced in any furnace by merely setting fire to the fuel which is contained in it would be altogether insufficient for the fusion of the ore, if its intensity were not promoted by the forcing in of a current or blast of air. For this purpose it is necessary to use a strong mechanical force, and of late years the agency of steam has been most commonly employed for this purpose. The blast is carried into an intermediate chamber of a spherical or cylindrical shape, called a regulator; and, as the air is in a state of condensation when admitted, its effort to expand itself again to its natural volume causes the continuous and regular supply to the furnace which is necessary. The air thus forced into the furnace keeps the heat at a degree of intenseness which is indispensable for the smelting of the ore. A most important improvement was made by Mr. Neilson, some years ago, in using the *hot blast* instead of the *cold*, that is, drying and highly heating the air before it is forced into the furnace. This has proved to be the most valuable and economical of all modern inventions in the iron manufacture.

The iron is run from the furnace every twelve hours, by tapping the front of the furnace on a level with the bottom of the hearth. When the furnace is tapped, the metal is allowed to run into channels formed in the sand of the smelting-house floor. The names of *sow-metal* and *pig-metal*, which were originally given by the workmen, signify in one case the blocks of iron which are formed in the large main channels, and in the other case the smaller blocks which are formed in smaller side channels communicating with the larger ones.

The quality of pig-iron varies according to the purposes for which it is intended, and depends not only upon the quality of the ore, but also upon that of the fuel. The principal division is into *foundry-iron* and *forge-iron*, the former being used for castings, the latter for conversion into malleable iron. Foundry-iron is further divided into three qualities, distinguished by the numbers 1, 2, and 3, and differing in the amount of carbon combined, the fluidity when melted, and the hardness when cooled. Forge iron is divided also into three qualities, and is distinguished as *bright iron*, *mottled iron*, and *white iron*, which names are indicative of the appearance which each quality presents to the eye; they have less carbon, less fluidity, and more hardness, than foundry iron.

Forge or bar iron is pig-iron freed from carbon and oxygen. The first operation for producing this change is called *refining*, and is performed in small low furnaces, about three feet square at the base, having the bottom, or hearth, of fire-bricks, and the sides of cast iron, made hollow to allow a stream of water to pass constantly through, which prevents their being quickly burnt away; near the top are holes for the insertion of blast-pipes. The iron is kept in a state of fusion in the refinery for some time exposed to an intense heat produced by a strong blast, and is then run out into a flat mould twenty feet long by two wide, placed over a cistern of water, where it speedily cools into a bright brittle state.

The first process employed for making bars is called *puddling*, and is performed in a *reverberatory* or *puddling furnace*. [FURNACE.] The quantity of refined metal put into this puddling-furnace at each charge is from 3½ to 4 cwt. In about half an hour from the charging of the furnace the metal begins to melt. The puddler then observes, through a small hole provided for that purpose and for the introduction of his tools, the progress of the work. The business of the puddler is so to dispose of the pieces of metal, moving them by means of his tools, as to ensure an equable application of heat to the mass. When the whole quantity is fully melted, the puddler stirs the metal about briskly, changing his tools continually, that they may not be melted. By means of this agitation the metal gives off an elastic fluid, and after a time becomes thick, and grows increasingly so, until it loses all fluidity and forms into lumps. The contents of the furnace are then divided into five or six portions by the puddler, and each is made up by means of his tools into a spherical form. These balls are technically called *blooms*. Being taken from the puddling-furnace, they are subjected each to ten or twenty blows from a heavy hammer (called shingling), or to an intense pressure by a machine called a *squeezer*, which makes them more compact and gives them a shape more convenient for going through the rollers. These rollers consist of two cylinders working in contact, and having on their surfaces a series of grooves, varying in size. The iron is passed through all these grooves in succession, until it is reduced to the requisite width and thickness. It is thus converted from a fusible, hard, and brittle substance, to a tough and elastic bar which is hardly fusible, and which, from its property of yielding and altering its form under the hammer, has acquired the name of malleable iron.

The bars, when they have been passed through these rollers, and while yet hot, are cut into convenient lengths and taken to the balling-furnace, the shape and construction of which resemble those of the puddling furnace. In this balling furnace the bars are piled evenly, so that one bar does not project beyond another. Several of these piles, each of which is composed of five or six bars, are placed at once in the furnace, and when sufficiently heated, so that they will weld together, the piles are taken out separately, and are passed again through rollers similar in construction to those described above, but differing from each other in the form of their orifices and grooves, so that either round or flat or square rods and bars may be produced at the pleasure of the maker, and these, when weighed and put up into bundles, are ready for sale.

The progress of the Iron Manufacture in this country has been astonishing. The quantity of iron made in different years presents the following results:—

1740	..	17,300 tons.
1750	..	22,000 „
1788	..	68,000 „
1796	..	125,000 „
1806	..	250,000 „
1820	..	400,000 „
1830	..	677,417 „
1840	..	1,396,400 „
1848	..	1,998,568 „

The quantity of nearly two million tons in 1848 was thus made up:—

England	..	735,800 tons.
Wales	..	722,800 „
Scotland	..	539,968 „
		1,998,568 tons.

The near approach of Wales to England in produce is remarkable, and shews how rapidly the iron manufacture of South Wales must have been extending.

In 1796 each furnace throughout the kingdom yielded an average produce of about 1000 tons of iron annually; in 1849 the average yield was about 6000 tons: so great have been the improvements in the manufacture. In 1848 the total number of furnaces, in and out of blast, was 623. The price of *bar iron*, at the close of ten successive years, was as follows:—1840, £8½; '41, £6½; '42, £6; '43, £5; '44, £6½; '45, £10; '46, £8½; '47, 9½; '48, £5½; '49, £5½. Best iron, angle iron, rail iron, sheet iron, and hoop iron, all exceed the above prices by 5*s*. to 40*s*. per ton. The highest price of *pig iron* for the last twenty years has been £6¾ per ton; and the lowest about £2.

A few further details of the iron districts will be found under GLASGOW, MERTHYR, STAFFORDSHIRE, WALES, &c.

Our Exports of iron are very large. In 1849 the quantity of Bar, Pig, Bolt, Rod, Wire, Cast, and Wrought iron exported was 772,865 tons; besides iron in the forms of steel, cutlery, hard ware and machinery, to the value of 4,077,151*l*.; making altogether a value of about nine millions sterling.

The various manufactures in which iron or steel are employed to considerable extent are noticed under their proper headings in this work; such as CUTLERY, FILES, NAILS, NEEDLES, SAWS, &c.; see also STEEL MANUFACTURE. We may notice here the modern and very useful form of *galvanized tinned iron*, as prepared under the patent of Messrs. Morewood and Rogers. The sheets are rolled in the usual way, to any required degree of thinness; some are kept in the original flat state; while others are *corrugated*, or brought to the form of alternate ridges and hollows. Both surfaces are covered with a layer of tin by the galvanic process, analogous to those noticed under ELECTRO-METALLURGY. This material, either in the flat or the corrugated form, is used for roofing, ships' bolts and sheathing, carriage roofs, tunnel linings, gutters, pipes, cisterns, chimney pots, cowls, baths, cans, buckets, coal-boxes, stove pipes, and numerous other articles. Temporary houses and stores, made of corrugated iron, are sent out to the colonies and California.

It is to be hoped, and reasonably expected, that every department of a manufacture on which so much of the prosperity of England depends, will be well represented at the approaching Exhibition. Nor is it less to be desired that foreign countries should shew their strength in the same direction.

IRRIGATION. In China and in India, as well as in Egypt, ingenious modes of watering lands have been adopted from the most remote ages. No expense has been thought too great to secure a supply of water, and to distribute it in the most advantageons manner.

The whole art of irrigation may be deduced from two simple rules: first, to give a sufficient supply of water during all the time the plants are growing; and, secondly, never to allow it to accumulate so long as to stagnate. The supply of water must come from natural lakes and rivers, or from artificial wells and ponds, in which it is collected in sufficient quantity to disperse it over a certain surface. As the water must flow over the land, or in channels through it, the supply must be above the level of the land to be irrigated. But there must also be a ready exit for the water, and therefore the land must not be so low as the natural level of the common receptacle of the waters, whether it be a lake or the sea, to which they run.

When there is a considerable fall and a sufficient supply of water, a series of channels may be made, so situated below each other, that the second collects the water which the first has supplied, and in its turn becomes a feeder to irrigate the lower parts of the declivity: a third channel receives the water and distributes it lower down, until the last pours it into the river. This is called *catch-work*, because the water is caught from one channel to another. When the surface to be irrigated is very flat and nearly level, it is necessary to form artificial slopes for the water to run over; the whole of the ground is laid in broad beds, undulating like the waves of the sea; and the water, carried along the ridge of each bed, is allowed to flow down the slopes. When it is intended to form a water-meadow on a surface which is nearly level, the whole of the land is laid in beds about 20 or 30 feet wide, the middle or crown of these beds being on a level with the main feeders, and the bottoms or drains on a level with the lower exit of the water, or a little above it. Grass-seed being sown over these beds, the water may be let on for a very short time, to make them spring. As soon as the grass is two or three inches above ground, a regular flooding may be given and in a very short time the sward will be complete. Instead of sowing seed, tufts of grass cut from old sward may be spread over the newly formed beds, and they will soon cover the ground.

The rules for adjusting the time and mode of irrigation to the growth of the plants are among the studies of practical agriculture.

ISÈRE. This French department has a more than usually varied produce, including wheat, rye, barley, maize, buckwheat, peas and beans, potatoes, fruit of all kind, walnuts, mulberries, almonds, medicinal plants, hemp, &c. Vines are mostly grown in the fertile valleys, trained either to greenwood supports of maple or cherry-tree, or to dry tall poles of chestnut wood; vines thus grown are called high vines (hautins). But on the hill slopes in favourable situations and in the Rhône district, the low vines, as they are called when unsupported, produce a stronger better-keeping wine, and more fitted for transport. The produce of wine in ordinary years is 5 to 6 million gallons, the best of which is produced in the neighbourhood of the Rhône. The mulberry grounds are extensive; the number of trees exceeds a million.

In mineral wealth the department is very rich. Iron, lead, copper, and coal mines are worked; gold and silver mines have been worked, but are now abandoned. In the year 1837 a vein of platina was discovered in the valley of the Drac. Marble, granite, porphyry, gypsum, slate are quarried. Antimony, zinc, cobalt, rock-crystal, vitriol, sulphur are found.

The indnstrial products consist of sailcloth, table and household linen, gloves, soldiers' uniforms, calicoes, printed cottons, oil, turpentine, liqueurs, and mineral acids. There are iron, copper, and lead foundries, steel works, zinc and copper rolling factories, marble sawing mills, paper and vellum works, naileries, dyehouses, glass-works, cotton yarn manufactories, magnaneries, and silk throwing establishments.

Of the manufacturing towns of this department, *Vienne* is among the most conspicuous. It is one of the principal seats of the woollen manufactures in the south of France; common cloth, pasteboard, soap, leather, glass bottles, paper, chemical products, &c., are also made; and there are establishments for reeling and throwing silk, dye-houses, iron furnaces, steel works, sheet copper and lead works, copper and brass foundries.

ISINGLASS. This remarkable substance, one of the purest kinds of glue, or animal gelatin, is made chiefly in Russia, from the dense membrane which forms the air-bladder of the sturgeon and other fishes of the same family.

1591 cwts. of isinglass were imported in 1848.

ITALY. Brief sketches (for they can only be brief in this work) illustrative of the produce, manufactures, and commerce of this beautiful country, will be found under the names of the chief states and cities which compose the Italian peninsula; such as LOMBARDY, NAPLES, VENICE, &c.

IVORY. This delicate substance, derived from the tusks of elephants, is extensively used for the handles of knives and forks, and for making or embellishing numberless small articles in general use. The principal supplies of elephants' tusks to this country are from the west coast of Africa and from Ceylon. The remaining imports are from the coast of Barbary, the Cape of Good Hope, Madagascar, and Siam. The quantity imported annually is about 5500 cwts., of which about 4500 cwts. are retained for consumption.

The demand for ivory has much increased within the last few years, and the supply can scarcely keep up with it. A great quantity is now brought over by the Peninsular Company's steamers from Alexandria, sometimes as much as 20,000*l.* worth in one cargo. This portion of the trade consists chiefly of wild elephants' tusks which have been shed in the deserts of Arabia, and bought up by the Pacha of Egypt for sale to English buyers.

The teeth and tusks of the elephant, hippopotamus, wild boar, and narwahl, all form ivory of various kinds; though the tusk of the elephant is that which usually goes by the name. Ivory was used for some of the colossal statues of the ancients, especially the far-famed statue of Jupiter by Phidias. Among the moderns, the Chinese show great skill in working ivory, especially in the production of elaborate carvings. Ivory is used for billiard and bagatelle boards; for veneers; for scales connected with mathematical instruments; for artificial teeth; for miniature tablets; for combs; for flutes; and for numerous other purposes. Ivory is worked into form by saws, files, and edge-tools, used with great care and delicacy. It may be etched by using an etching ground of nearly the same kind as that employed by engravers; and it may be stained or dyed of various colours.

Mr. Cheverton in 1850 patented a mode of making what he terms artificial ivory. It consists in giving an ivory-like surface to gypsum or alabaster. The ornaments or other articles made of this material, are exposed for forty-eight hours to a temperature of 300° Fah., by which the moisture is driven off. They are then immersed till saturated in olive oil or in white hard varnish; and after being steeped several times in warm water, they are polished with whiting or putty powder, by which they obtain an ivory-like surface.

J

JACQUARD LOOM. The Jacquard Loom, or more correctly Jacquard appendage to the loom, is the most beautiful of all contrivances connected with weaving. We will say a few words of the inventor and of the machine.

Joseph Marie Jacquard was born at Lyon in 1752, of humble parents, both of whom were employed in operations connected with weaving. His parents died, leaving him a small property, which he employed in the attempt to establish a business in the weaving of figured fabrics. The undertaking failed, and he was compelled to sell his looms in order to pay his debts. He subsequently married, and occupied himself with ingenious schemes for improvements in weaving, cutlery, and type-founding, which produced nothing for the support of his family. In 1792 he assisted in the defence of Lyon against the army of the Convention. Being denounced after the reduction of Lyon, he was compelled to fly. When he was enabled to return, and Lyon began to rise from its ruins, Jacquard applied himself with renewed energy to the perfection of the beautiful apparatus for figured weaving which bears his name. He had conceived the idea of such an apparatus as early as 1790, and he now succeeded, though but imperfectly, in accomplishing his end. His machine was presented, in September 1801, to the national exposition of the products of industry, the jury of which awarded him a bronze medal for its invention. In the same year he obtained a patent, or 'brevet d'invention,' for a term of ten years. About the same time his attention was accidentally directed to the construction of a machine for weaving nets for fishing and maritime purposes. He accomplished the desired object, but, having amused himself and his friends with his contrivance, he threw it aside. His machine-made net however fell into the hands of the préfet at Lyon, and the result was that, according to the arbitrary fashion of the time, he and his machine were placed under arrest and conveyed to Paris, where the invention was submitted to inspectors, amongst whom were Napoleon and Carnot, and a gold medal was awarded to him in February 1804. In 1804 Jacquard returned to Lyon, where he was long engaged in superintending the introduction of his inventions for figured weaving and for making nets, in which he was powerfully aided by Camille Pernon, a rich manufacturer. For some years Jacquard had to struggle against much opposition and prejudice on the part of the Lyonese weavers; but before his death, in 1834, he had the pleasure of knowing that his ingenious invention had become extensively employed.

The apparatus which cost Jacquard so much thought and anxiety is intended to facilitate the weaving of figured patterns on cloth of any kind. In plain weaving the weft or cross threads pass alternately under and over the warp threads, forming a perfectly regular interlacing; but in pattern or figure weaving, the device is made by irregularities in these alternations; sometimes two or more threads are crossed over at one time, without any intermediate under-crossing. When the shuttle with the weft thread has to be thrown from edge to edge of the warp or web, some of the warp threads have to be lifted up to allow it to pass; and the Jacquard apparatus assists in this elevation, which depends (in every throw of the shuttle) on the pattern to be woven. There are numerous cards (as many as 500 for a complicated pattern), formed of pasteboard, and pierced with holes. Every card has a certain relation to one throw of the weft-thread; and the number and arrangement of the holes determine which warp threads shall be drawn up to let the weft pass. The cards are linked together into an endless chain, which is passed over a hollow box at the top of the loom. The chain is made to rotate slowly, one movement for every weft thread thrown; and each card in turn acts upon a series of levers by which the warp threads are raised: the blank part of each card acts upon the levers; while the perforated parts allow the levers to pass into the holes without being affected.

Mr. Mackenzie has recently patented a machine for punching the holes in the Jacquard cards. Hitherto this operation has required two workmen; one to 'read the pattern,' as it is termed, and one to arrange the punches; but in Mr. Mackenzie's arrangement, the person who reads off the pattern plays at the same time on a set of keys, each of which inserts a punch into its proper place.

An ingenious variation of the Jacquard apparatus has lately been patented, in which the device is marked by pins on a rotating barrel, instead of by holes in a chain of cards. The principle is the same as that of the barrel organ and the musical snuff-box; and there would seem to be no reason why it should not apply efficiently to the weaving apparatus.

JAGGERY. This is the name given to various kinds of sugar, made and used in the east. It is procured by evaporating and granulating cocoa-nut toddy, Palmyra toddy, Malabar toddy, and Mysore toddy—toddy being a general name for the fermented juice of the palm. Ten gallons of the toddy yield nearly thirty lbs. of jaggery.

JALAP, is obtained from the *Convolvulus Jalappa*, an American plant. It is chiefly shipped from Vera Cruz, and takes its name from the town of Xalapa, or Jalapa, in the interior. The large root, which often weighs 50 pounds, is divided into portions, which are hung in nets over a fire, and dried in ten or twelve days. It occurs in commerce in irregular round or pear-shaped masses, which, when good, are dry, hard, with a brown shining fracture, resinous, not light, somewhat tough. It is often adulterated with portions of the root of white bryony, which however are white, or when old, gray, not heavy, very brittle, fracture not resinous, spongy, without smell, but with a very bitter taste. Dried pears are also often substituted for it; but they may be detected by being laid open, when the core will be seen, containing the seeds.

Jalap is a well-known and powerful medicine; but it is not used, so far as we are aware, in other arts. 68,829 lbs. of Jalap were imported in 1848.

JAMAICA. The staple produce of this the most important of our West India Islands, are sugar, rum, and molasses, which form by far the most important articles of export. The sugar plantations are very numerous and extensive, especially in the lower and warmer tracts of the island. On the hills and their declivities coffee is cultivated to a great extent. Next to these the pimento plantations supply the most important article of export. Arrowroot, indigo, (which formerly was much more cultivated than at present,) ginger, turmeric, and cacao are also cultivated, as also a little tobacco. Indian corn is universally cultivated, and yields an abundant produce; two and even three crops of it can be raised within the year. Guinea corn is cultivated, as are also yams, cassava, sweet potatoes, a few grasses, and a great variety of delicious fruits. The forests contain mahogany, satinwood, cedar, fustic, logwood, bamboo, cocoa, and various other trees.

The horned cattle are very numerous. The horses are of a middle size, hardy and active, but only fitted for the saddle and harness. Mules are numerous, and employed on the sugar estates. Sheep, goats, and hogs abound.

All kinds of poultry are raised in the greatest abundance, excepting geese and ducks.

The greatest part of the produce of the southern districts is sent to *Kingston*, the chief town, and hence exported to Europe or America. A railway from Kingston to Spanish Town was completed and opened in 1846.

The abolition of slavery, and (twelve years afterwards) the change in the sugar duties, have greatly shaken the prosperity of Jamaica. It was so essentially a protected slave-holding state, that, being now left to its own resources, it is found wanting in the energy which free labour and free competition engender. Its sugar plantations have fallen away, and much of its commerce has gone to Cuba. Attempts are, however, now being made to establish, or rather to increase, the cotton culture. Specimens have been sent to England within the last twelve months, illustrating the kind of cotton which Jamaica is capable of growing. The great experiment has, however, yet to be made: can free-grown cotton be raised as cheaply as slave-grown? Almost the whole of the cotton (nine-tenths at least) used in this country, is slave-grown: if Jamaica can raise good cotton by free labour, and derive a remunerating profit therefrom, it would be a great result.

The British Produce and Manufactures exported to Jamaica in 1849 amounted in value to 624,568*l.*

JANEIRO, RIO DE, the capital of the empire of Brazil, has perhaps the finest, safest, and most capacious harbour in the world. Most of the inhabitants are engaged in commerce. There are numerous sugar refineries, tanneries, cotton factories, rum distilleries, train-oil factories, and diamond-cutting establishments. The commerce is extensive, and on the increase. The principal exports are coffee, sugar, hides, rice, tobacco, rum, tapioca, ipecacuanha, manioc flour, gold, diamonds, &c. The quantity of coffee exported is immense: amounting in some years to nearly 200 million of lbs. The imports, more than one-half of which in value are derived from Great Britain, include cotton, woollen, linen, and silk manufactures, wines, ironmongery, flour, meat, fish, butter, spirits, earthenware, paper, &c.

JAPAN. This remote Asiatic Empire is almost unknown to us. It is certain, however, from the scanty information obtained, that agriculture is carried to a high degree of perfection in Japan. Nearly all the declivities of the hills are formed into terraces, and these terraces are cultivated with the utmost care. The produce comprises rice, wheat, barley, rye, maize, millet, batatas, potatoes, cotton, silk, hemp, and a very great variety of fruits and esculent vegetables. Japan abounds in mineral wealth. Gold seems to be very plentiful in several provinces, but is only partially worked. Silver, iron, and tin exist in small quantities; copper is more plentiful. Salt and porcelain clay abound. The Japanese, in manufacturing industry and in scientific knowledge, seem to be nearly equal to the Chinese, and in some articles the Japanese are superior. Their manufactures in metals, silk, cotton, china, glass, and paper, and their cabinet-work, are highly esteemed. The inland trade is very considerable. The coasting trade is much favoured by the great number of small harbours, and the interior communication by well-planned and well-maintained roads, which are always thronged with carriages and people. The foreign commerce is chiefly with the Chinese.

How many ages will elapse before Japan will take part in any Exhibition of Industry, where other nations (not to say all nations) will be represented, it would be difficult to surmise. At present the Japanese go beyond even the Chinese, in rejecting intercourse with foreigners.

JAPANNING is the art of producing a highly varnished surface on wood, metal, or other hard substance, sometimes of one colour only, but more commonly figured and ornamented. The process has received its name from that of the island of Japan, whence articles so varnished were first brought to Europe; though the manufacture is also extensively practised by the Chinese, Siamese, Birmese, and other nations of eastern Asia, among whom it was suggested most probably by the possession of a tree, which affords with little preparation a beautiful varnish, exceedingly well adapted for the purpose, and which hardens better than those prepared in Europe.

The appearance of japanned work is as various as the taste and fancy of the artists employed in it. Sometimes it is a plain black or red, with a gilded or painted border; or it is an imitation of marble, of fine grained or rare wood, or of tortoise-shell; sometimes a drawing, with high finish, brilliant colour, and showy patterns; and occasionally fine copperplate engravings are applied to a japanned surface with good effect. In all cases the work is highly polished and varnished. Japanning is applied to ladies' work-boxes and work-tables, to toilet-boxes, cabinets, tea-caddies, fire-screens, tea-trays, bread-baskets, snuffers and trays, candlesticks, and a variety of other articles.

Three processes are usually required in

japanning: laying the ground, painting, and finishing. In addition to these processes, whenever the article to be japanned is not sufficiently smooth to receive the varnish, or when it is too soft or coarse, it is sometimes prepared or primed before any of the proper japanning processes are applied. Almost every workman has his own peculiar modes of working, and his own receipts for making and mixing his varnishes. In whatever manner the work has been painted or printed, or if all addition to the plain colour of the ground has been dispensed with, nothing now remains but the finishing. This is a very simple process: the workman chooses a suitable varnish, and passes it over the work with a brush several times, until he judges the coating to be thick enough to bear the polish.

JASPAR. [Quartz.]

JAVA. This large and important island, in the Eastern Archipelago, yields abundantly the yam, the sweet potato, the Java potato, arrowroot, the common potato, artichokes, cabbages, and peas. The Javanese also cultivate cucumbers, onions, capsicums, cocoa-nuts, ground-nuts, Areca palm, betel, tobacco, coffee, sugar, pepper, cardamom, ginger, cotton, and great varieties of dye-stuffs, and fruits. They procure oil from many of their trees, and make toddy from the palm. Few minerals are known to exist in Java; but iron, sulphur, salt, and saltpetre are obtained.

Java is extremely well adapted for an extensive commerce. The island itself is rich in productions, and its northern coasts, which are accessible to vessels all the year round, lie opposite the richest countries of Asia. Besides this, the Dutch government has made it the centre of all the trade which Holland carries on with its extensive settlements in the Indian Archipelago. Hence the transmission of native produce to other countries, and the importation of foreign commodities, are both very large. The exports of British produce and manufactures to Java, in 1848 amounted to 336,843*l.*, of which by far the largest items were cotton and linen goods. The produce of the Dutch possessions in Java was in 1848—coffee 144,861,372 lbs., sugar 112,000 tons, indigo 1,151,368 lbs., cochineal 146,000 lbs., tea 988,529 lbs., pepper 461,680 lbs., cinnamon 250,550 lbs., tobacco 1,500,000 lbs. In the year 1828, the island supplied Great Britain with only 15,000 tons of sugar; in 1847, the quantity of sugar imported from Java into Great Britain amounted to 75,000 tons.

JERSEY. The agriculture of Jersey is backward, which is partly owing to the minute subdivision of property, arising from the custom of gavelkind. Wheat is the principal grain crop; barley is grown, and some oats, parsnips are extensively grown and used for fattening hogs and bullocks. Potatoes for exportation are widely and increasingly cultivated. Lucerne is one of the most valued crops. A considerable portion of the land is laid out in orchards. The trade of Jersey, owing to the privileges possessed by the islanders, is very considerable. The agricultural produce of the island, potatoes, apples, cider, butter, cows, and other live stock, are sent to England; the articles required for the consumption of the island are in a considerable degree supplied from France.

JEWELLING OF WATCHES is the art of setting diamonds, rubies, sapphires, chrysolites, or other hard stones, in the frame-plates and other parts of watches, in such a manner that the pivots of the watch may act in holes made in these stones. The province of the watch-jeweller is to select the stones, and (except in the case of diamonds) to grind, polish, turn, drill, and set them into the frames or other parts of the watch in such a manner that the holes in the stones may correspond exactly in position with holes previously made by the watch-finisher or escapement-maker. Jewelling is an operation which, when well performed, adds materially to the durability, and not a little to the elegance of the machine. The apparatus necessary for the jeweller to carry on his business are, a small lathe: small gravers for turning brass and steel; a quantity of rough diamond in fragments, technically termed *bort;* small mills or circular disks of metal (usually copper) for grinding the stones into shape; diamond-powder of various degrees of fineness for polishing; and turning-tools, made by cementing small pieces of bort into a notch made in the end of small brass wires and fixed in proper handles.

JEW'S-HARP. This simple musical instrument consists of an iron frame, resembling in form the handle part of an old fashioned corkscrew, in the centre of the upper and wide part of which is riveted at one end an elastic steel tongue. The extremity of this tongue, at the free end, is bent outwards to a right angle, so as to allow the finger easily to strike it when the instrument is placed to the mouth and firmly supported by the pressure of the parallel extremities of the frame against the teeth. The action of this instrument is very remarkable; the elastic spring gives the sound by its vibrations; but this sound undergoes musical modifications by varying the cavity of the mouth of the performer, which he does by slight movements of the lips and jaws. The late M. Eulenstein produced exquisite music from this instrument.

JOINERY. This name is given to the handicraft of joining pieces of wood together, for the interior fittings of buildings, for making articles of furniture, and for numerous purposes requiring greater neatness of workmanship than the operations of the carpenter. As carpentry and joinery are in many cases carried on in the same establishment, and even by the same workmen, it would be difficult accurately to define the limits of these two kindred arts. The proper object of carpenter's work in a building is to give firmness and stability to the structure; and within its proper range may be embraced all the rough timber-work necessary for the support, division, or connection of the several parts of a building. Carpentry thus includes the construction of the framing of floors, partitions, and roofs. Joinery has for its object the addition of all the fixed woodwork necessary for convenience or ornament. Cabinet-making, or that department of woodwork which relates to the making of furniture, has little affinity with joinery, although the same materials and tools are employed in both descriptions of work. The line of demarcation, however, between joinery and cabinet-making seems to be even more difficult to define than that between carpentry and joinery; and, with the exception of such matters as veneering and polishing, which relate only to the use of the harder and more valuable woods, the operations of the cabinet-maker and the joiner are nearly identical, the same means being adopted by both for the production of heat and strong joints, and for evading the injurious effects of shrinkage and warping in the material operated upon. A few details on these subjects will be found under CARPENTRY; FURNITURE MANUFACTURE.

JUNIPER. There are about twenty species of this plant, three or four of which are valuable in the arts and in medicine. The *Common Juniper* grows wild in all the northern parts of Europe. The fruit is used in considerable quantities in the preparation of gin, and in medicine. *Oil of Juniper* is said to be the most powerful of all diuretics in doses of four drops. The *Juniperus Sabina*, or *Savin*, is found wild in the middle of Europe and the west of Asia, inhabiting the most sterile soil, and is frequently met with in this country in shrubberies. The *Oil of Savin*, and other preparations of the plant, are powerful medicines. The *Juniperus Bermudiana*, or *Bermuda Red Cedar*, is very little known in Great Britain, in consequence of its not bearing the climate without protection. It is a native of the Bermudas, where it becomes a large tree, with a soft fragrant wood, the value of which is well known from its use in cabinet work and the manufacture of pencils.

JURA. On the more elevated parts of this mountainous department of France, there is abundant pasture, on which during summer, from June to October, great numbers of cattle and horses are fed. During that season the châlets, or solidly constructed huts, on the heights, serve as habitations for the herds, stores for the dairy produce, and as sheds for the cattle; in these the cows are milked, butter and cheese are make. There is one herdsman for every 20 cows, and one cheese-maker for every 80. The agricultural produce of the department is barely enough for the consumption. The produce of wine amounts to about 8,000,000 gallons annually, the best growths being those of the districts about Arbois, Château-Chalon, and Lons-le-Saulnier. Several iron mines are worked; gold, copper, lead, and coal are found; the peat beds are dug for fuel; marble, alabaster, and lithographic stone are quarried. There are important salt-works at Salins and Montmorot. The manufacture of iron and iron wares, carried on in about a hundred smelting furnaces, forges, and foundries, is the most important object of industrial activity. The other manufactures are paper, watch and clock works; turnery in wood, bone, ivory, and horn; coarse woollens, linen, mineral acids, salt, casks, steel, scythes, nails of all kinds, tiles and leather.

K

KALEIDOSCOPE. This beautiful optical instrument was invented by Dr. (Sir David) Brewster, and made public in 1817. The essential parts of the instrument consist of two plane mirrors of glass, having their hinder surfaces blackened in order to prevent any reflection of light from thence. Each mirror is from six to ten inches long, and of a trapezoidal form; the larger end about an inch and a half wide, and the shorter end about three quarters of an inch; and the two are placed in contact with one another at the wide end of each, so as to form a dihedral angle, the like ends being placed together. The object to be viewed is disposed contiguously to the larger ends, and the eye should be near the opposite extremity, but a little above the line of contact. The effect produced by the reflections of the light from the two surfaces is singularly beautiful; the objects viewed undergo multiplied reflections, and assume graceful symmetrical forms. Sir David Brewster found means to obtain multiplied images of such objects as flowers, trees, and even persons or things in motion: and thus the importance of the instrument was greatly increased. Some kaleidoscopes have been executed in such a manner that the two mirrors may be placed at any required angle with one another; by which means the images in the visible field of view may be varied at pleasure. The instrument is capable also of being constructed so that the multiplied image may be projected on a screen, and thus made visible at one time to many spectators. Again, Dr. Roget has shown that the properties of the instrument may be greatly extended by employing, instead of two, three and even four plain mirrors, united together at their edges so as to form a hollow prism, or a frustum of a pyramid, the reflecting surfaces being towards the interior. These are called polycentral kaleidoscopes.

KAMTCHATKA. In this remote corner of Asia there are a few spots which yield rye, barley, buckwheat, potatoes, white cabbages, turnips, radishes, and cucumbers, but these articles are only cultivated by the Russian settlers. The natives formerly lived chiefly on the produce of the chase; but since the number of wild animals has considerably decreased fishing is more attended to. Fish is very abundant on the coasts. The forests contain many fine timber-trees, which are little used, but might be employed in ship-building. The mineral wealth is little known: in some places there is iron ore, and sulphur in immense beds is found in the vicinity of the volcanoes. The manufactures and commerce of such a country are of course extremely limited.

KAOLIN. This is the Chinese *porcelain clay*. It occurs massive and disseminated in disintegrating granite rocks, and is generally supposed to be derived from the decomposition of the felspar which they contain. Its colour is either white, yellowish, or reddish-white. Kaolin is found in China, France, Saxony, &c.; and in England a large tract of this substance occurs near St. Austle in Cornwall, on the south side of the granite range. It contains crystals of felspar, quartz, and mica. From this source the porcelain manufactory of Worcester is supplied.

KELP. [Ashes; Soda.]

KENT. This fruitful county is well circumstanced in respect both to commerce and its productions. It has a most abundant steam traffic from Dover, Deal, Ramsgate, Margate, Herne Bay, Sheerness, Gravesend, Greenhithe, Erith, Woolwich, Charlton, and Greenwich, to London; from Rochester to Sheerness; from Ramsgate and Dover to Ostend; from Dover to Calais and Boulogne; and from Folkestone to Boulogne. The whole of the railways of the county belong to one company—the South-Eastern. They comprise lines from Red Hill to Ashford; Ashford to Hastings; Ashford to Dover; Ashford to Canterbury; Canterbury to Ramsgate and Margate; Canterbury to Whitstable; Minster to Deal; Paddock Wood to Maidstone; Tunbridge to Tunbridge Wells (now being extended to Hastings); the Greenwich and Bricklayers' Arms' Branches; and the North Kent line (London to the Medway).

Kent produces several crops which are peculiar to it, such as canary and radish seed. Other seeds are likewise raised for the London seedsmen, such as spinach, cresses, and white mustard. Kidney beans are cultivated to a considerable amount in the neighbourhood of Sandwich, and produce from ten to twenty bushels per acre. Woad and madder were formerly much cultivated. The marshes produce most of the hay consumed in winter. Romney Marsh, which is well known for the richness of its grass, contains about 44,000 acres; on the borders of the Stour are 27,000; and along the Medway, Thames, and Swale, about 11,500 more. A great many sheep are reared and fattened in these marshes. Hops are grown to a very great extent in this county, and, with the exception of those which are raised at Farnham in Surrey, are the most esteemed of any in England. Near London there are many extensive gardens; and about Deptford hundreds of acres are laid out in asparagus beds. Great quantities of peas are also raised for the London market on the line of road from London to Rochester. Apples, pears, plums, and cherries are raised in orchards, and the produce sent to London markets. The cultivation of filberts is peculiar to Kent, and well managed, especially in the neighbourhood of Maidstone. The Kentish woods are diminishing every year; and the produce of bark and timber is much reduced from what it formerly was.

Ashford is becoming an important town in this county, on account of it being the depôt of the South-Eastern Company. Chatham, Dartford, and Dover are briefly alluded to elsewhere. *Folkestone* harbour, owing to the accumulation of shingle, is not capable of affording anchorage to many vessels, but has been considerably improved by the engineers of the South-Eastern Railway Company, who purchased it when they extended the line of railway from Folkestone to Dover. Steam-packets ply between Folkestone and the opposite ports of France; and the town is acquiring commercial importance. *Gravesend* and *Greenwich* are both important for their steamboat traffic. *Maidstone*, the assize-town of the county, is situated on a declivity on the west bank of the Medway. A lock has been made at Allington, about a mile below Maidstone, to improve the navigation of the river, previous to the formation of which the tide ascended to Maidstone. There is much traffic on the river, in coals, timber, iron, groceries, &c., upwards, and in Kentish ragstone, paper, hops, fruit, &c., downwards. *Margate* and *Ramsgate* have much active commerce arising out of their pleasure-traffic. *Milton* has considerable trade, arising from its oyster fishery, and from its being the port of communication with London for the surrounding agricultural district. At *Sheerness* the dockyard is sufficiently capacious to receive ships of war of the largest size. There are large storehouses, a mast-house, rigging-house, sail-loft, &c. At *Tunbridge Wells* there are considerable manufactures in turned wood. At *Whitstable* the inhabitants are engaged in the oyster fishery. *Woolwich* derives its main importance from its dockyard, from the government foundry for cannon having been established there, and from its having been made a great depôt for naval and military stores. The Royal Dockyard contains two large dry docks, a basin 400 feet by 300 feet, capable of receiving the largest vessels, together with extensive storehouses, mast-houses, &c. The foundry for cannon forms one of the principal departments of the Royal Arsenal. In the Rope-yard, at the east end of the town, cables of the largest size are made.

KENTUCKY. The produce and manufactures of this important American state receive a few illustrations under United States.

KERMES MINERAL is a peculiar sulphuret of antimony, formerly much but now little used in medicine. It is obtained in the form of a brownish red powder.

KERRY. Mountain ridges, bounding valleys of greater or less width, form the distinguishing features over the greater part of this Irish county. The whole coast line, from the Shannon to the Kenmare, contains many good harbours, of which that of Valentia might be made of high commercial value. The roads in the south-western parts of Kerry up to the year 1820 were scarcely passable for wheel-carriages, and there are some parts of the coast between Kenmare and Cahirciveen still inaccessible, except on foot or horseback. But great exertions have been made to establish good roads across the county; and these roads have been very instrumental in developing the resources of the district. The mountains of Glanbehy abound with iron-ore, which was formerly smelted in considerable quantities at Blackstones, in works erected by Sir William Petty; but, the supply of timber having failed, these works were given up about the year 1750. Iron has been worked in other parts, and copper and lead also exist in the county. The slate quarry in Valentia produces flags and slates to a large amount; the flagging, which is of a very superior description, is transported to London.

Cider is made in the county in considerable quantity. The chief trade consists in exports of agricultural produce, chiefly oats and butter. The manufacture of linen is carried on with some activity in the neighbourhood of Dingle. There is also a general manufacture of coarse woollens throughout the county for home consumption. Fishing is carried on extensively on the coasts.

Situated in the south-west corner of Ireland, it may yet be a long time before Kerry rises into commercial importance; it has however many of the requisite elements, when more propitious days for Ireland shall arrive.

KERSEYMERE. In the woollen manufacture, *broad-cloth* is an example of plain weaving, followed by the process of fulling; while the name of *kerseymere* is given to a fulled cloth which is woven into the peculiar *twill* pattern. These differences are explained under WEAVING.

KETCHUP. This well-known preparation from the mushroom and other plants used as a condiment for flavouring, differs greatly in its ingredients and manufacture, according to the chief substance which gives it its name. There are camp ketchup, cucumber ketchup, sea ketchup, mushroom ketchup, Pontac ketchup, Tomato ketchup, walnut ketchup, wine ketchup, and two or three others. Mushroom ketchup is prepared (according to one among many recipes) from mushroom juice, pimento, cloves, pepper, mustard, ginger, salt, and shalots.

KEY. [LOCKS and KEYS.]

KHERSON. In this province of Asiatic Russia agriculture is in a backward state; the breeding of cattle and sheep is the chief occupation of the population. Corn, hemp, flax, tobacco, liquorice, saffron, and mustard are grown. The vine is cultivated, and much attention is paid to horticulture. Oxen and buffaloes are numerous, and used for draught. The fisheries on the sea-coast and in the rivers are important. The minerals are—fine potter's clay, freestone, slate, chalk, talc, saltpetre, agates, and garnets. The province is well situated for trade; and the foreign commerce of the country is very important and rapidly increasing.

KIACHTA, a town in Siberia, is commercially very important on account of the traffic of this place with *Maimaitchin*, the Chinese emporium, which is less than a mile from the town. The Russians bring to Kiachta furs of the sable, black fox, and ermine; hides, woollen cloth, and other coarse woollen fabrics; glass, looking-glasses, and cattle. They receive in return from the Chinese, manufactured silk and cottons, tobacco, china, furniture, and several kinds of toys; but the principal commodity taken in exchange is tea.

KIDDERMINSTER CARPETS. The relation which the carpets so called bear to other varieties is explained under CARPET MANUFACTURE. Kidderminster mostly depends on its carpet trade; and the manufacturers have sent specimens of their skill to the Great Exhibition, of carpets, tapestry, and rugs.

KILDARE. This Irish county, in the districts near the Liffey, is in a high state of cultivation, and much of it in demesne. The Grand Canal, which crosses the Liffey by an aqueduct near Naas, is carried through a tract of bog which comprises about 40,000 statute acres of peat-moss, in some places 40 feet deep, reposing on limestone gravel, which rises in low cultivable ridges between the principal fields of morass. The north-western part of the county, extending from the Bog of Allen to the Boyne, is open and chiefly in pasture. Portions of the Great Southern and Western Railway, and the Midland Great Western Railway, pass through this county. The soil of the county is generally a rich loam, resting on limestone or clay-slate. There are rich fattening lands in the baronies of Carberry, Clane, and North and South Salt, which occupy the north western and north eastern portions of the county. An improved system of agriculture has been introduced by the resident proprietors, and is practised to some extent by the smaller farmers. Oxen are in general use both for draught and the plough. There are many corn-mills in the county. The only manufactures carried on within the county are of cottons and woollens, but to a very limited extent.

KILKENNY. We here have another Irish county, which, like Kildare, is wholly inland. The surface of Kilkenny is mostly occupied by the limestone of the central plain, overlaid in the hilly districts north of Kilkenny city by shale and sandstone. The coal formations are nearly co-extensive with the hilly districts. These coal-beds would be of great commercial value, if the natural resources of Ireland were better developed. The general colour of the limestone is a bluish gray. Near Kilkenny it passes into a fine black marble, containing a great variety of shelly impressions. These beds are extensively quarried, and the blocks dressed on the spot by a saw-mill driven by the Nore. The marble, which is sometimes procured of a jet black, is manufactured into chimney-pieces, tombstones, &c.; it bears a very high polish, and can be raised in large blocks. In the coal-tract the soil is a moory turf lying over a stiff whitish clay, which is the poorest district out of the mountain region; but many districts have deep rich soils. Some of the best wheat and meadow lands in the south of Ireland are situated in the level tract along the Suir. About one-third of the level districts is in tillage. There are two districts almost wholly occupied by dairy-farmers, the Walsh Mountains and the southern part of the Castlecomer tract. In the southern dairy district the sour milk is used for fattening pigs for the Waterford market: in the northern district the milk is sold, there being no convenient market for pork.

The manufacture of carpets, diapers, and tapestry was introduced into the county by the Countess of Ormonde in 1359. James, Duke of Ormonde, about the middle of the 17th century, established and encouraged, at a great expense, both linen and woollen manufactures; and about the close of the same century the Bessborough family introduced the manufacture of linen into the southern parts of the county. None of these branches of trade, however, nor that of blankets, introduced about a century ago, have continued on anything like an extensive scale. A coarse frieze for home consumption is made among the peasantry. There are many flour-mills in the county.

KINIC ACID, sometimes called Cinchonic Acid, is obtained from cinchona bark. It has a very sour taste; it reddens litmus paper strongly, is unalterable in the air, dissolves in 2½ times its weight of water at 48°, and is also soluble in alcohol. It combines with many of the alkalies and metals to form salts, which are more used in medicine than in the manufacturing arts.

KINO. This astringent substance is the concrete juice of one or more plants, the identification of which is a matter of dispute among botanists. From India, Africa, Australia, and the West Indies, concrete juices are brought, which, correctly or not, obtain the name of Kino. These different extracts differ in their chemical habitudes with reagents, but they all agree in possessing a strong astringent power. Kino most commonly occurs in grains of a shining aspect and rich ruby-red colour; they are easily reduced to powder. It is nearly entirely soluble in water and in alcohol.

KNIFE MACHINES. The manufacture of knives is noticed under CUTLERY. It affords a curious illustration of the extent to which the saving of labour by mechanical aid has been carried, that a machine has been invented to perform the operation of cleaning table-knives; in which the cleaner has simply to turn a handle, instead of bestowing arm-movement in a somewhat laborious way. There are two rival patented machines for this purpose, Kent's and Masters'; both relate to a machine which was invented by an American, and was introduced into this country, under certain arrangements, by the parties above-named. The machine consists of a flat cylinder, or drum, in the inside of which are brushes placed in contact; holes are made round the drum, in which are placed from four to twelve knives, according to the size of the machine. The blades of the knives pass between the brushes; and when the brushes are made to rotate by a handle worked from without, the blades of the knives are exposed to an amount of friction sufficient to clean their surfaces. The machines are sold from about two guineas upwards.

KÖNIGSBERG, one of the two governments into which the province of East Prussia is divided, is a place of considerable commercial enterprise. *Memel*, the most northern town in Prussia, is well situated for commerce: the exports consist of timber, hemp, flax, corn, hides, tallow, bristles, &c., most of which are brought from Poland and Russia; the imports are chiefly salt, colonial produce, and manufactured goods. The number of ships that frequent the port amounts to between 700 and 800. In the town there are several breweries, distilleries, soap factories, oil and saw mills, &c. *Tilsit* has a trade in corn, linseed, timber, beer, spirits, leather, &c. *Insterburg* has manufactures of cloth, linen, woollen stockings, and spirits, and trades extensively in corn and flax. *Gumbinnen* has woollen and linen factories, distilleries, and tanyards; the trade in corn and flax-seed is important. *Königsberg*, the capital of the province, has communication by the Friedrichs-Gruben Canal with the Memel, by which river, the Oginski Canal, and the Dnieper, it has the advantage of a complete interior navigation into Poland, Lithuania, and even to the Black Sea. The manufactures consist of woollen cloth, linen, silk, leather, tobacco, sugar, beer, and spirits. The exports are composed of corn, flax-seed, flax, hemp, linen yarn, linen cloth, oil cakes, bristles, feathers, and hides. The imports are chiefly sugar, coffee, spices, dyewoods, tobacco, salt, various raw materials and manufactured goods.

L

LABORATORY. This name is given to the room in which chemical operations are performed. The requisites for the proper arrangement of and the necessary instruments for a laboratory may be seen at length in Professor Faraday's 'Chemical Manipulation.'

LAC, is a resinous substance, which in the East Indies flows from certain trees in the state of a milky fluid, on account of the puncture made by a small insect, the *Coccus ficus*, in their branches, in order to deposit its ova. The trees are principally the *Ficus indica*, *Ficus religiosa*, and *Rhamnus jujuba*. There are three kinds of lac known in commerce, distinguished by the names of *Stick Lac*, *Seed Lac*, and *Shell Lac*. Stick Lac is the substance in its natural state; it is of a reddish colour, and incrusts small twigs; when broken off and boiled in water, it loses its red colour, and is then termed Seed Lac; and, when melted and reduced to the state of thin plates, it is called Shell Lac, which has a yellowish brown colour.

Several chemical substances are produced from Lac. *Laccin* is the substance which remains after the lac has been repeatedly digested in alcohol and water. It is insoluble in water, alcohol or ether. *Laccic Acid* separates from solution in water, by spontaneous evaporation, in crystalline grains. With the alkalies and with lime it forms salts which are soluble in alcohol and in water, and are deliquescent. *Cochinellin*, or the colouring matter of stick-lac is similar to that of cochineal, is used for the same purposes, and yields a scarlet colour little inferior to it.

Lac Dye and *Lac Lake*, two preparations of lac which are manufactured in the East Indies are used to a very considerable extent in scarlet dyeing.

LACE MANUFACTURE. This very pleasing branch of industry exhibits instructive features in respect to the application of machinery to what was before mere hand-labour. We must glance at the subject in its two aspects of *pillow-lace* and *bobbin-net*.

Pillow Lace:—Real lace, such as that which often obtains so high a price, is mostly made of flax thread, and is produced in the following way. The lace-worker sits on a stool or chair, and places a hard cushion on her lap. The desired pattern is sketched upon a piece of parchment, which is then laid down upon the cushion; and she inserts a number of pins through the parchment into the cushion, in places determined by the pattern. She is also provided with a number of small bobbins, on which threads are wound; fine thread being used for making the meshes or net; and a coarser kind, called gymp, for working the device. The work is begun at the upper part of the cushion by tying together the threads in pairs, and each pair is attached to one of the pins. The threads are then twisted one round another in various ways, according to the pattern; the bobbins serving as handles as well as for a store of material, and the pins serving as knots or fixed centres around which the threads may be twisted. The pins inserted in the cushion at the commencement are merely to hold the threads; but as fast as each little mesh is made in the progress of the working, other pins are inserted, to prevent the thread from untwisting; and the device on the parchment shews where these insertions are to occur.

The kinds of lace which have obtained different names have certain peculiarities in the character of the mesh. *Brussels point* has a network made by the pillow and bobbins, and a pattern of sprigs worked with the needle. *Brussels ground* has a six-sided mesh, formed by twisting four flaxen threads to a perpendicular line of mesh. *Brussels wire-ground* is of silk; the meshes are partly straight and partly arched, and the pattern is wrought separately by the needle. *Mechlin lace* has a six-sided mesh formed of three flax threads twisted and plaited to a perpendicular line: the pattern being worked in the net. *Valenciennes lace* has a six-sided mesh formed of two threads, partly twisted and plaited: the pattern being worked in the net. *Lisle lace* has a diamond-shaped mesh, formed of two threads plaited to a perpendicular line. *Alençon lace* has a six sided mesh of two threads. *Alençon point* is formed of two threads to a perpendicular line, with octagonal and square meshes alternately. *Honiton* lace is distinguished by the beauty of the devices, worked by the needle. *Buckingham* lace is mostly of a commoner description, and somewhat resembles that of Alençon.

Pillow lace, such as we have just described, is supposed to have been first made in Saxony in the 16th century: the earlier Italian lace having been wrought by the needle. From Saxony it extended to Flanders and France. In Brussels alone there were 10,000 females employed at lace-making at the close of the last century. The art was introduced into England soon after its invention in Saxony; and it is curious that Honiton has produced the best kinds from that time to this. Throughout the midland counties, especially Bedford, Buckingham, and Northampton, almost every town and village exhibits this manufacture; but hand-made lace has suffered severely from the invention next to be noticed.

Bobbin-net:—About 1770 a stocking weaver at Nottingham, named Hammond, made the first attempt to imitate lace by a slight adaptation of his stocking-frame; and many other persons gradually introduced improvements in the art; but it was Mr. Heathcoat who, early in the present century, gave the chief impulse to the trade by the invention of his bobbin frame, which gave the name of *bobbin-net* to machine-made lace. The manufacture sprang up into wonderful activity in and around Nottingham; and though it has suffered many fluctuations since it still constitutes a very notable department of Nottingham industry.

The cotton used in making bobbin net is mostly spun in Lancashire. The machines are very costly and are seldom or never owned by the actual worker. They are among the most complicated apparatus employed in manufactures; and when adapted for steam-power, and provided with the Jacquard apparatus for the production of figured net, the machines are sometimes worth 1000*l*. a piece. One set of threads, which we may call the warp, is stretched in parallel lines up and down the machines; another set, equivalent to the weft, is wound round small bobbins; and the meshes of the net-work are produced by these bobbins twisting in and around and among the vertical threads. After being woven or made, the net is gassed or singed to remove the little hairy filaments; then embroidered or 'run' by females, if the better kind of net; then mended if any of the meshes have given way; then bleached; then dyed, if it be black net; then dressed or stiffened with gum or starch; and finally rolled and pressed.

Besides the specimens from Belgium, lace will form an important item in the number of things sent over from France to the Great Exhibition. The greatest in amount, and most remarkable for beauty, will be contributed from Nancy. Besides several pieces of minor importance, one especially is intended to attract great attention. It is a counterpane, three yards long and two and a half broad. In the middle is embroidered a bouquet of roses and poppies, and a garland all round of the same flowers, of a large size, all embroidered *au lancé* with cotton of size No. 120, the appearance created being that of a white satin texture. The leaves are embroidered on what is termed a sanded ground. The tracery cost three months of labour.

LACQUERING. [JAPANNING.]

LACTIC ACID. This substance exists in milk, and in larger proportion when it has become sour; it also exists in various other animal fluids, and in many vegetable juices. Lactic Acid is colourless, inodorous, and very sour; it attracts moisture from the air, and dissolves in water and alcohol in all proportions. The combinations which it makes with alkalies and oxides are not of much importance in the arts.

LACTUCA'RIUM is obtained from the *Lactuca virosa*, or Acrid Lettuce; being the inspissated milky juice of the plant, and which is at first white, but afterwards, by exposure to the air and sun, concretes and becomes brownish. The juice of the leaves only should be collected before the flowering has begun; puncturing the leaves is the best mode of procuring it. The inspissated concrete juice resembles opium in its action, and is used in medicine.

LAKE. This is a general name for an animal or vegetable colouring substance, precipitated in combination with oxides of tin or alumina. Most persons consider a beautiful crimson to be the proper colour of lake; but according to the chemical definition, it includes pigments of various colours. Most of these are prepared by causing alum to act in an infusion or decoction of the substance employed. *Blue Lake* is prepared from Indigo, and from the blue flowers of some plants; *Brazil-wood Lake* from Brazil-wood; *Florentine Lake* from cochineal; *Madder Lake* from madder; *Green Lake* from a mixture of blue and yellow lakes; *Orange Lake* from arnotto; *Red Lake* from cochineal, differently employed from that required for Florence lake; *Yellow Lake* from quercitron or turmeric; and there are a few others, presenting other tints.

LAMP-BLACK, is a fine charcoal prepared from certain kinds of fir containing much resin, and the refuse and residuary resin left by the distillation of turpentine. The furnace chimney is long, and the greater part of it nearly horizontal, and its exit is covered with old sacking; or the smoke containing the charcoal is carried into chambers, where it is deposited on coarse cloths. The purest lamp-black is procured by the combustion of oils, but that is much too expensive for common use. Lamp-black is extensively employed as a black colour, and mixed with other pigments.

LAMP, SAFETY. It has been long known that coal mines, and especially such as are deep, are occasionally infested with carburetted hydrogen, known to the miners as *fire-damp.* Several contrivances have been proposed for safely lighting coal mines subject to the visitations of this gas; but the safety-lamp of Sir H. Davy is the only one which has ever been judged safe, and been extensively employed.

Davy found that this gas requires an admixture of a large quantity of atmospheric air to render it explosive; that explosions of inflammable gases are incapable of being passed through long narrow metallic tubes; and that this principle of security is still obtained by diminishing their length and diameter at the same time, and likewise diminishing their length and increasing their number, so that a great number of small apertures will not pass explosion when their depth is equal to their diameter. This led to trials upon sieves made of wire gauze: and he found that, if a piece of wire gauze was held over the flame of a lamp, or of coal gas, it prevented the flame from passing; and he ascertained that a flame confined in a cylinder of very fine wire gauze did not explode even a mixture of oxygen and hydrogen, but that the gases burnt in it with great vivacity.

These experiments enabled Davy to determine the principles of a new safety-lamp. It consists of a cylinder of wire gauze, formed of iron wire about $\frac{1}{50}$ of an inch in diameter, the meshes being about $\frac{1}{24}$ of an inch. The wire cylinder is strongly jointed, and is defended by three upright strong wires, which meet at the top, and to them a ring is fixed, from which the instrument is suspended. The lamp is screwed on to the bottom of the wire gauze, and is supplied with oil by the pipe projecting from it, when the top is unscrewed and removed. A wire, bent at the upper end, is passed through the bottom of the lamp for raising, lowering, or trimming the wick.

When the lamp is lighted and introduced into an atmosphere gradually mixed with fire-damp, the first effect of the fire-damp is to increase the size and length of the flame. When the inflammable gas forms as much as $\frac{1}{12}$ of the volume of the air, the cylinder becomes filled with a feeble blue flame, but the flame of the wick appears burning brightly within the blue flame, and the light of the wick continues till the fire-damp increases to one-sixth, or one-fifth, when it is lost in the flame of the fire-damp, which in this case fills the cylinder with a pretty strong light; and, when the foul air constitutes one-third of the atmosphere, it is no longer fit for respiration.

The operation of the wire gauze in preventing the communication of flame is thus explained:— Flame is gaseous matter so intensely heated as to be luminous, and the temperature requisite for producing it exceeds that of the white heat of solids. When the flame comes into contact with wire gauze, it loses so much heat in consequence of the conducting power of the metal which conveys it to the surrounding air, that it is cooled below the point at which gaseous matter can remain luminous, and consequently the flame of the gaseous matter burning within the lamp is incapable of passing through it so as to set fire to and explode the mixture of fire-damp and air by which it is surrounded; and this cooling power is exerted, even though the wire gauze, by effecting it, is rendered and remains red-hot.

Much discussion has arisen concerning the safety of this instrument; it is admitted that there are situations where it would not be danger-proof; but it is also admitted that no other invention is yet equal to it in respect to safety. A form of the instrument devised by Dr. Clanny is that which is now most frequently employed.

The original model of the safety lamp, made by Sir Humphrey Davy's own hands, has been lately placed among the collection of scientific instruments belonging to the Royal Society.

LAMPS. The chief varieties of artificial lights are noticed in earlier articles [ARGAND LAMP; BENZOLE LIGHT; BUDE LIGHT; CAMPHINE LAMP; CANDLE MANUFACTURE; DRUMMOND LIGHT; ELECTRIC LIGHT; GAS MANUFACTURE; LAMP, SAFETY]. Most of the oil-lamps are now on the argand principle, that is, having a ring-formed wick, so as to admit air within and without. Some lamps have been formed for burning solid instead of liquid fuel; such as the *Soho* lamp, which is adapted for burning tallow or fat. One variety of lamp is the *Carcel lamp,* in which the oil is raised through tubes by clock-work, so as continually to overflow at the bottom of the wick, and thus keeping the wick thoroughly soaked. In Parker's *hot oil lamp* the oil is kept between two concentric tubes near the flame, so as to become heated before it reaches the wick. The *meteor lamp* is intended to burn rape oil. The *camphine lamps* are described in an earlier article. In the 'Peerless Self-generating Gas Lamp,' registered by Mr. Holliday in 1849, the arrangement is such that the oil is heated and converted into vapour before it reaches the burner.

The manufacture of brass-work for lamps and chandeliers forms one of the most important departments of Birmingham. The brass tubing is drawn, and the ornaments cast, on a scale of great magnitude; and the various processes of stamping, planishing, lacquering, burnishing, &c., all employ a large number of hands in the lamp trade. All our exhibitions of manufactures contain specimens of Birmingham lamps. Many of those which are ordinarily considered to be made in London are of Birmingham manufacture, put together in London.

LANARKSHIRE. The wonderful energy of this iron-smelting, cotton-spinning county has already engaged a little of our attention [GLASGOW]. In addition to the industrial statistics there given, we may state that there were in Lanarkshire, in 1850, 94 cotton factories, 9 woollen and worsted factories, 4 flax factories, and 4 silk factories; that these contained about 930,000 spindles, and about 19,000 power looms; that the steam and water power employed to work these factories was equal to about 6,300 horse-power; that the number of persons employed in the factories was about 25,000; and that of these persons, nearly 20,000 were females.

LANCASHIRE. To the coal-field of South Lancashire this county owes its manufacturing pre-eminence. It occupies a large irregular tract between the Ribble and the Mersey. The pits in the northern coal field are chiefly in the neighbourhood of Hornby. The principal mineral production of Lancashire is coal. Lead and iron occur to some extent, copper in small quantity, slate, flag-stones, freestone, scythe-stones, brick clay, and pipeclay are among the mineral products of the county.

The county of Lancashire is richly provided with those highways of commerce—canals. The Sankey Canal was the first executed in England; it extends from St. Helens to Warrington, about 12 miles. The Duke of Bridgewater's Canal, one of the most celebrated of Brindley's works, extends from Leigh to Manchester, with extensive tunnels and underground works at Worsley. The Leeds and Liverpool Canal, one of the most extensive in the kingdom, connects those two important towns, and passes near Colne, Burnley, Blackburn, Wigan and Ormskirk. The Lancaster canal begins near Kendal in Westmoreland, and runs to Wigan. The Ashton Canal commences on the eastern side of the town of Manchester, and runs to Fairfield, about 4 miles from Manchester; it has branches to Stockport; to the Huddersfield Canal at Dukinfield; to the collieries at Hollingwood, near Oldham; and to the Rochdale Canal. The Huddersfield and Peak Forest canals belong rather to Yorkshire and to Derbyshire respectively than to Lancashire. The Rochdale Canal commences in the Calder and Hebble Navigation in Yorkshire, and proceeds by Todmorden and Rochdale to Manchester. The Manchester, Bolton, and Bury Canal commences in the Mersey and Irwell Navigation at Manchester, and runs to Bolton, with a branch to Bury.

Nor is Lancashire less richly provided with railways. The first locomotive line in England was the Liverpool and Manchester. Since the opening of that railway in 1830, the railways of Lancashire have taken the lead of those in every other county. The lines open are the following:—Liverpool to Manchester; Warrington to Newton; Warrington to Heyton; Runcorn to St. Helens; Runcorn to Heyton; Liverpool to Bury; Liverpool to Preston; Manchester to Preston; Newton to Preston; Kenyon to Bolton; Bolton to Clitheroe; Clifton to Colne; Manchester to Todmorden; Manchester to Stockport, to Ashton, and to Oldham; Preston to Accrington; Preston to Fleetwood; Preston to Lancaster; and many minor branches. They form a complete network, the proprietorship of which we need not here disentangle.

From the moist nature of the climate, Lancashire is more productive in grass than in corn. Oats are more cultivated than wheat. Potatoes were early cultivated in the fields in Lancashire, and they retain their celebrity. Meadows and pastures are very extensive. Even the extent of grass which is kept for the purpose of bleaching linen on is very considerable, especially in the neighbourhood of Manchester, of Bolton, and other manufacturing towns. A great quantity of new milk is required in the manufacturing towns, and much butter and cheese are also made in the county.

Lancashire is the most important manufacturing county in England. Not only is the cotton manufacture the largest branch of industry, but it has probably no parallel in any other country. The cotton factories are exceedingly numerous, and are spread over most parts of the county. Silk, woollen, and flax manufactures are also carried on, but to a much smaller extent than cotton. Engineering of every description, and ship-building, are other branches of Lancashire industry. Iron and brass manufactures; hat factories; glass,

KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

bottle, and pottery works; alkali, soap, and chemical works; pin manufactories; watch movement manufactories—are among the numerous branches of Lancashire industry.

The commerce of Lancashire consists mainly in the immense trade carried on at Liverpool: the shipping at Lancaster and Fleetwood is of no great amount. The canals and railways conduct a vast inland traffic with other parts of England.

Many of the great towns occupy some of our attention in separate articles, in respect to their industry and produce [ACCRINGTON; ASHTON; BLACKBURN; BOLTON; BURY; CLITHEROE; LIVERPOOL; MANCHESTER; PRESTON]. *Fleetwood* stands at the mouth of the æstuary of the Wyre. The town, harbour, docks, warehouses, and pier were planned under the auspices of Sir Hesketh Fleetwood, about the year 1836, on ground which before that time was little else than a rabbit-warren. It was expected that this port would attract a large amount of traffic to and from Belfast, Londonderry, Drogheda, and other Irish ports; and to and from Glasgow and Ardrossan; but Liverpool still commands nearly all the Irish traffic. The port of *Lancaster* formerly had a considerable share of the West India trade, which is now in a great degree transferred to Liverpool; but it still possesses a portion of foreign commerce, and a considerable coasting trade. The cotton manufacture was introduced not many years ago into the town and neighbourhood, where it has considerably increased. At *Leigh* the townspeople are engaged in the manufacture of cambrics and fustians; there are collieries and stone quarries in the parish. *Oldham* has rapidly risen in prosperity, mainly owing to its being in the neighbourhood of extensive coal mines, which give employment to a large portion of its population, and to the great increase of cotton manufactures since the middle of the last century. The manufacture of fustians, cotton, and woollen and silk goods is very extensive; and there are more hats produced here than in any other part of England. *Prescot* is celebrated for its manufactures of small files, and the movements and other parts of watches. In *Rochdale* the manufactures are very important. In the time of Edward III. some Flemings introduced the woollen manufacture into the town; it has continued to flourish, and now forms its staple commodity. Calico, cotton yarn, and hats are also manufactured. Coal is dug, and slates, flagstone, and freestone are abundantly quarried in the parish; and there are also iron-works. *St. Helens* has risen into importance chiefly by means of the large establishments of the British Plate-Glass Company at Ravenhead, in the adjacent township of Sutton, and of the copper-works belonging to the proprietors of the Parys Mine, in Anglesea, who brought their ore here to be smelted. In *Todmorden* the inhabitants are engaged in the cotton and woollen manufactures, both of which have greatly increased. The principal branches of industry in *Warrington*, are cotton-spinning, the manufacture of flint glass and glass bottles, machinery and mill-work, and many branches of iron manufactures. There are steam flour-mills, tanyards, malt-houses, one or more paper-mills, and several breweries. *Wigan* from its situation on the Lancashire coal-field, has increased with the development of manufacturing industry. The manufactures of the place comprise linens, calico, checks, fustians, the spinning of cotton yarn, and other branches of the cotton manufacture.

In addition to the details under COTTON and FACTORIES, we give the following statistics of Lancashire factories in 1850. In that year there were in the county 1,235 cotton factories, 37 woollen and worsted factories, 9 flax factories, and 29 silk factories. In these factories were about 15,000,000 spindles, and about 185,000 power looms. The machinery was moved by steam-power equivalent to about 50,000 horse power, and by water power to the extent of 4,000 horse power. The persons employed at the 1,310 factories were about 240,000 in number, of whom 130,000 were females. Of the persons so employed, about 12,000 were children under 13 years of age.

LANDES. This department of France calls for a little notice here on account of the extraordinary mode in which some of the inhabitants are obliged to pursue their industrial avocations. Much of the department consists of a loose ashen-gray sandy soil. Numerous flocks of wretched half-starved sheep wander over this desert waste, tended by shepherds who walk on high stilts to enable them to pass dry-footed over the marshes that occur in all directions. Clothed in sheepskins, perched on his lofty stilts, and seated on a high staff with a flat broad end, the shepherd of the Landes watching his sheep, and knitting woollen stockings, his constant occupation, presents to the stranger unprepared for the sight an extraordinary appearance. Not only the shepherds, but the charcoal burners, and almost all the scanty population of the Landes, are accustomed to the use of stilts, on which they walk with astonishing rapidity. The most important produce of the Landes are the pine forests which cover nearly one-fourth of the surface, and which, besides the value of the timber, yield a great quantity of resin. The more fertile districts of the department yield wheat, maize, millet, hemp, flax, madder, saffron, &c. About 10,000,000 gallons of wine are produced annually, of which about a third goes to supply the home consumption; the rest is exported, or distilled and sold as Armagnac brandy. Mines of iron and bitumen are worked; mica, coal, marble, granite, lithographic stones, chalk, ochre, potters' clay of superior quality, crucible earth, &c., are found. Peat fuel is dug. The industrial produce is composed of coarse woollens, pottery, liqueurs, bar iron and ironware, resin, pitch, tar, glass, paper, leather, brandy, beer, oil, &c. There is also a considerable trade in timber, deals, linseed oil, fruits, wool, pork, &c.

LANTERNS. It is said that we are indebted to Alfred the Great for the invention of lanterns, or lanthorns. Before the invention of clocks, Alfred caused six tapers to be made for his daily use; each taper contained twelve pennyweights of wax, and was twelve inches long. The whole length was divided into twelve parts or inches, of which three would burn for one hour; so that each taper would be consumed in four hours, and the six tapers, being lighted one after another, lasted twenty-four hours. But the wind, blowing through the windows and doors and chinks of the chapel, or through the cloth of his tent, in which they were burning, wasted the tapers, and caused them to burn irregularly. He therefore designed a lantern, made of ox or cow horn cut into thin plates, in which he enclosed the tapers; and being thus protected from the wind, the period of their burning became a matter of comparative certainty.

The translucent part of a lantern is made of cow-horn. The horn is softened and separated into thin leaves, by following the natural layers of the substance. The thin leaves are flattened, scraped with a blunt-edged knife, smoothed with a woollen rag dipped in charcoal dust, and finally polished with horn shavings.

LAPIDARY. The work of the lapidary is the shaping, cutting, and polishing of precious stones. He uses mortars for crushing and grinding diamond powder; cutting instruments for reducing stones to thin layers; instruments for giving flat and curved surfaces to gems; lathes for turning, and drills for piercing holes; apparatus for making the facets of brilliants, &c. A few details bearing on this subject will be found under CAMEO; DIAMOND; GEMS; INTAGLIO.

LAPIS LAZULI. [ULTRAMARINE.]

LARCH. A few words have been said concerning this valuable tree, in connection with the genus to which it belongs [ABIES]; and we will here add a little detail concerning the uses of the tree in the arts.

Larch wood seems to be more and more valued as its qualities become known: and it will probably supersede others which have hitherto been held in greater repute. The Germans find larch wood almost indestructible for wine-casks. In many parts of France houses are built of larch, and water-pipes made of the same material. In Switzerland it is used for vine props. In all cases where timber is exposed to alternations of wet and dry, larch is particularly valuable. As naval timber the larch is rising rapidly into note. As sleepers for railways, axles for mill work, hop poles, stakes for plants, and numerous other useful articles, larch is a most valuable material. It is rather too difficult to work to be used much in the carpentry of English houses.

The qualities which render larch so serviceable for the above purposes are the following:—It is much clearer of knots than fir-wood; it is more durable than fir; it is much less liable to shrink than common deal; it will not crack with any moderate degree of heat, when in the form of planks or boards; it is more tough than foreign deal; as an ornamental wood it often presents a very beautiful colour, and will receive a high polish.

LASER, was the name given by the ancients to a gum-resin highly esteemed by them, and which was sometimes called *Silphium*. It is supposed to have been procured from certain species of the genus *Loderpitium;* the root of which is extremely bitter, and yields an aromatic resinous substance. The gum-resin was employed medicinally by the ancients, and was an article of some commercial value.

LATA'NIA, is a genus of Palms. The leaves, like those of other palms, are employed by the natives of the Isle of France for covering their huts, as well as for making fans and umbrellas. The leaf-stalks are split, and employed for making baskets, sieves, &c.

LATHE. [POTTERY; TURNING.]

LAUDANUM. [OPIUM.]

LAUREL. The fruit of the laurel or *Sweet Bay* is endowed with aromatic properties as well as the leaves, whence both, as well as a fatty oil expressed from the seed, have long been used in medicine as stimulants and carminatives.

From the laurel is obtained *laurine*, an acrid and bitter principle contained in the berries; its smell resembles that of laurel oil.

LAVAL, the capital of the French department of Mayenne, is the centre of a large manufacture of table and household linen and linen-yarn, for the sale of which there are weekly markets; calico, flannel, cotton handkerchiefs, serge, soap, leather, &c., are also made; and there is a good business done in flax, wine, brandy, clover-seed, timber, iron, marble, &c.

LAVENDER. Lavender plants are hoary, narrow-leaved, fragrant bushes, inhabiting the south of Europe, the Canaries, Barbary, Egypt, Persia, and the west of India, with generally blue flowers. Twelve species are described, of which two only are of general interest, namely, the common lavender and Spike Lavender, both natives of sterile hills in the south of Europe and Barbary. The common lavender yields the *Oil of Lavender*, so extensively employed in the preparation of perfumes; and its flowers are employed in medicine. The spike lavender yields the *Oil of Spike*, or foreign oil of lavender; this is less fragrant than the other oil, and is used to adulterate it, and also as a material in painting.

LEAD. This very useful metal has a blueish gray colour, and considerable brilliancy when fresh surfaces are formed by cutting. If it has not been cooled too rapidly, it is so soft that, even when in pieces of considerable thickness, it may be easily bent. It soils slightly, and leaves on paper or cloth a mark after friction resembling that of plumbago. Its specific gravity is 11.4. Lead may be reduced to thin laminæ; but its tenacity is extremely slight, so that a wire about $\frac{1}{10}$th of an inch in diameter breaks with a weight of 30 pounds. It fuses at about 612°, and crystallises when slowly cooled. It is not a volatile metal, for in close vessels it may be heated to whiteness without subliming. When exposed to the air, it absorbs oxygen and carbonic acid slowly, and acquires a superficial coating of carbonate of lead. If it be exposed to air and water, it is oxidised and converted into carbonate of lead with considerable rapidity; this carbonate has the appearance of minute shining brilliant scales. Though at common temperatures lead is slowly acted upon by the oxygen of the air, it is readily oxidised when the heat is raised.

The ores of lead, strictly speaking, are few in number. Indeed the only one which can properly be considered as a working ore is the *Sulphuret*, or *Galena*. This almost universally diffused ore occurs in attached crystals and massive. The crystals are opaque and leaden gray. The massive varieties have a granular structure. By the blowpipe on charcoal the sulphur is first dissipated, and then metallic lead is obtained. In Cornwall and Scotland the veins of this ore traverse primary rocks; in Derbyshire it occurs in veins or beds in transition rocks. It very commonly contains a considerable portion of silver. There are many minerals in which lead forms a component ingredient, but most of the lead of commerce is procured from the sulphuret.

Lead forms many useful substances in combination with other bodies. Protoxide of lead is *massicot*, and the deutoxide is *Minium*, both used as colours. Oxychloride of lead forms *patent yellow*. Carbonate of lead forms *White Lead*. Acetate of lead is *Sugar of Lead*. Di-acetate of lead forms *Goulard's Extract*. Chromate of lead is a beautiful yellow pigment. The manufacture of RED LEAD and WHITE LEAD will be noticed in separate articles.

Of the *alloys* of lead, three are of some importance. Alloyed with antimony, lead forms *Type-metal*. *Pewter* consists of about 80 parts tin and 20 lead. Equal parts of tin and lead form *Plumber's Solder*.

LEAD MANUFACTURE. Lead was known to and used by the Greeks and Romans for various purposes. Among others it was employed for pipes to convey water, just as it is now. The lead-mines of this island were worked by the Romans. The chief of them are in Cornwall, Devonshire, Somersetshire, Derbyshire, Durham, Lancashire, Cumberland, Westmoreland, Shropshire, Flintshire, Denbighshire, Merionethshire, and Montgomeryshire; in Scotland, in Dumfriesshire, Lanarkshire, Ayrshire, and Argyleshire. Lead is also found in Ireland, in the counties of Armagh, Wexford, Wicklow, Waterford, Clare, and Down.

The ore of lead, when extracted from the mine, is called *Galena*, and is combined with various earthy matters. The first processes subsequent to its extraction are those of crushing or pounding and washing the ore. The ore is then smelted, sometimes in a common smelting furnace and sometimes in a reverberatory furnace; and the melted metal is allowed to run into a large iron pan, from which it is ladled into cast-iron moulds. It then constitutes what is called *Pig-Lead*. In this state lead always contains more or less of silver. The proportion is sometimes exceedingly minute, varying from 1 to 30 ounces in a ton of lead. The extraction of the silver is always performed when it exists in a proportion sufficient to pay the expense of the process, which varies in different localities according to the cost of fuel. The process of extraction, which is called refining, depends upon the well known circumstance, that lead, when heated to redness, absorbs a large portion of oxygen from the air, and is converted into an oxide; while silver does not undergo any such change, but retains its metallic form at almost any temperature. Mr. Pattinson, of Newcastle, has introduced an improved process, in which the crystallising properties of melted lead are brought into requisition.

The most extensive use of lead is in the forms of sheets and pipes. To make sheet-lead, the pigs are brought to a state of fusion in a large pot or cistern, near which is placed the table on which the sheet is to be cast. This table, which is usually from 18 to 20 feet long and 6 feet wide, is made either of wood or cast iron. The wooden table has its surface protected by a layer of fine sand, which is wetted and spread evenly and firmly over it before the melted lead is poured on. To prevent the lead from running over the sides, a ledge is provided, two or three inches thick, and two inches high, which forms the margin of the table. An instrument called a strike is also provided to regulate the thickness of the sheet, and to spread the melted metal evenly over the table. In casting the sheet the fused metal is taken from the cistern with an iron ladle, and put into a triangular-shaped iron shovel or peel, placed at the head of the table, which peel being raised so as to pour out the lead upon the table, the strike is brought into use to spread it evenly over the whole surface: the surplus, if any, falling into a vessel placed for its reception at the foot of the table. A sheet of lead weighs 9 cwts., so that its length and breadth will be greater in proportion to the diminution of its thickness. The thickness of sheets of lead is frequently reduced by means of heavy rollers worked by steam power. Rolled sheet-lead is made by the repeated compression, between steel rollers, of a block of lead several inches in thickness.

Lead pipes are sometimes made, when great exactness of shape is not required, by bending a length of sheet lead of the necessary width over a mandril, and soldering the edges together; but the more usual method of manufacture is by casting and drawing. The casting-box employed is an iron cylinder made in two parts, and put together longitudinally with flanges; inside of this cylinder is placed an iron rod or core, which is so fixed as to be concentric to the cylinder, without touching it; a space is thus left, into which the melted lead is poured. When this is set, the core is removed, and the cylinder opened, so as to withdraw the pipe, which is much thicker than is needed, and must be lengthened, while its substance is reduced, by drawing it through a succession of holes in steel plates, diminishing gradually in diameter. The making of lead shot is described elsewhere [SHOT MANUFACTURE.]

In a purely metallic state, lead produces no action on the human system except such as arises from its mechanical properties; but, as soon as it becomes oxidised, it can combine with the contents of the stomach, and produce different effects, according to the nature of the substances it meets with. Painters are exposed to a distressing disease from the use of white lead, called *Painter's Colic.* The lid or cover of cisterns should never be made of lead, as the vapour which condenses on it possesses all the solvent power of distilled water. It is also unsafe to use water which has flowed over leaden roofs, more particularly in towns, as the surface of the lead is almost invariably coated with some soluble salt. No kind of adulteration or impregnation with lead, from accident or ignorance, is more common than that of wine or cyder. Even a single shot of lead left by accident in a bottle after cleaning has produced severe colic; and the more extensive use of the salts of lead to *fine* wines, as it is termed, that is, to remove their acid taste and make them sweet, has occasioned most serious consequences.

In the year 1848 lead ore was raised from sixteen counties in England and Wales; viz., Cornwall, Devon, Cumberland, Durham, Northumberland, Westmorcland, Derbyshire, Shropshire, Somerset, Yorkshire, Cardigan, Caernarvon, Caermarthen, Flint, Montgomery, and Merioneth. The quantity of ore raised in that year, and of lead smelted from the ore, in the United Kingdom, was as follows:

	Ore.	Lead.
England	55,638 tons.	39,142 tons.
Wales	16,305 ,,	11,122 ,,
Scotland	2,588 ,,	1,736 ,,
Ireland	1,912 ,,	1,188 ,,
Isle of Man..	2,521 ,,	1,665 ,,
	78,964	54,853

From this we learn that three tons of ore produce about two tons of metallic lead. The richest English mines are in Durham. The richest Welsh in Flintshire.

The pig and sheet lead imported in the three years 1848, 1849, and 1850, were 3,789, 7,216, and 11,977 tons, respectively. The quantities exported in the same three years were 6,129, 170,27, and 22,083 tons, respectively.

LEAGUE. In modern English a league means the 20th part of a degree of latitude, or three geographical miles, each of which is the 60th part of a degree. The league of our sailors may be described and easily remembered as 3.456 statute miles of 1,760 yards each. The same marine league is used by the French and other nations: besides which, the French have among their itinerary land measures, two distinct leagues (or *lieues*; in some of the provinces *lègues*), the first of 2000 toises, or 2.42 English miles, which is the legal posting measure; the second of 25 to the degree, or 2.77 English miles.

LEATHER MANUFACTURE. This remarkable substance, which is universally employed throughout the civilised world, is prepared from the skins of animals, or, it would perhaps be more correct to say, consists of that substance after it has been chemically changed by the process of tanning. This change is effected by means of a substance residing in several vegetable matters, to which the name of *tannin* has been given. When this tannin, which is soluble in water, is applied to the hides of animals from which the hair, epidermis, and any fleshy or fatty parts adhering to them are removed, and which hides then consist wholly of *gelatin*, also soluble in water, these two soluble substances so unite chemically as to form the wholly insoluble substance called leather. Of the ox-hides which are converted into leather, those supplied by bulls are thicker, stronger, and coarser in the grain than those of cows; while the hides of bullocks are intermediate between those of the bull and the cow. Such leather is employed for the soles of boots and shoes; for most parts of harness and sadlery; for making leather trunks, buckets, hose for fire-engines, and pump-valves; for the thick belts used in military accoutrements; and for the gloves of cavalry. The thick *buff-leather*, formerly used as armour, and which was pistol proof, and would resist the edge of a sword, was made from the hide of the urus or wild bull. The skins of *calves*, though thinner than those of cows, are thicker than most other kinds of skin which are converted into leather.

The process necessary to convert hides into the thick hard leather used for the soles of boots and shoes is as follows:—The horns are removed from the hides; and the latter are scraped, steeped, and sweated, and the hair removed. The hides are then immersed for a few days in a liquid which opens the pores and fits them for the action of the tanning ingredients. In the old method of tanning, which is not yet entirely abandoned, the hides and powdered bark were laid in alternate layers in the tan-pit, which was then filled with water to the brim. After some months the pit was emptied and re-filled with fresh bark and water, and this process was repeated whenever the strength of the bark was exhausted. In this way the time required for impregnating the hides varied, according to their thickness and other circumstances, from one to four years. The process has been expedited by the use of a concentrated solution of bark instead of mere layers of bark in water. The variations of practice among different tanners extend to the substance used as an astringent, as well as to the manner of applying it. Ground oak-bark, which was formerly the only material in common use, and is still the most general, produces good leather of a light fawn-colour. Valonia, of which considerable quantities are imported for the use of tanners, produces leather of great solidity and weight, the colour of which is inclined to gray, and which is more impervious to water than that made with oak-bark. Catechu, or Terra Japonica, the inspissated extract of the *Acacia Catechu*, produces leather of a dark reddish fawn colour, which is light, spongy, and very pervious to water. Another substance which has been used of late years is a kind of bean-pod called *divi-divi*. These substances may be used either individually or in various combinations; and they are prepared with plain water or with ooze, with hot water or with cold, according to the judgment of the tanner. In whichever way the tanning is effected, the hide is subjected to the action of solutions increasing progressively in strength, until it is so perfectly penetrated, that when cut through it presents a uniform brown colour; any appearance of a light streak in the middle of its thickness being an indication of imperfect tanning. When the process is complete, the hides are hung up in a shed, and allowed to dry slowly, and, while they are drying, they are compressed by heating or rubbing, or by passing them between rollers, to give them firmness and density.

Several schemes have been devised for forcing a tanning solution through the pores of the hide by mechanical pressure. Mr. Spilsbury patented a method of forcing the tan liquor into the pores of the hide by hydrostatic pressure, but in a mode which was found to produce leather of unequal quality. Another process, by Mr. Drake, consisted in sewing two skins together (after they had received a slight tanning in the ordinary way), so as to form a water-tight bag, which was filled with tan-liquor, and compressed so as to force the liquor through the skin. In another plan, which has been tried under several forms, the tanning liquid is applied to both sides of the hides, which are placed in an air-tight vessel, and is forced into their pores by hydrostatic pressure, the air being previously pumped out. In the plan patented by Messrs. Herapath and Cox of Bristol, a number of hides are connected together by strings, so as to form a continuous belt, and passed between rollers turned by steam or other power; there are several pairs of rollers, each pair erected over a pit. The pits contain tanning liquors of different degrees of strength. The hides are dipped first in the weakest liquor and so on to the strongest, passing between and being compressed by the rollers after each dipping. This process is said greatly to expedite the conversion of hide into leather; but it is not yet settled whether the leather is of quality equal to that prepared by the old method.

The thinner hides or skins for the upper leathers of boots and shoes are tanned with the same materials as the thicker, but by a quicker and less elaborate process.

Of the thin skins prepared for ornamental purposes, many are tanned with a substance called *sumach*, prepared from a plant of the same name. After a preparatory cleansing, &c., the goat-skins for morocco leather are sewed up into the form of a bag, with the grain or hair-side outwards; they are nearly filled with a solution of sumach, inflated with air, the aperture tied up, and the bags then thrown into a cistern of hot sumach liquor. Being thus acted on, both within and without, the skins are soon impregnated with sumach. The bags are then opened, the liquor removed, and the skins washed, rubbed, dried, dyed, and wrinkled by pressure with a grooved instrument. Cheap or imitation morocco is made of sheep-skins.

Tawing is the name applied to the process by which the skins of sheep, lambs, and kids, are converted into soft leather by the action of alum. Of this kind of leather gloves are usually made. Skins intended for tawing pass through a series of operations resembling those by which skins are prepared for tanning; but the tawing materials consist of alum, salt, flour, and yolk of eggs (chiefly the first two), which are applied in various ways. The skins require a great deal of stretching and rubbing after the steeping, to give them the requisite softness.

In making *Chamois Leather* or *Shamoyed Leather*, of which wash-leather is a cheap example, the skins of deer, goats, and sheep, are impregnated with oil instead of with the ingredients hitherto mentioned. After a certain preparation, the skins are beaten for many hours with heavy wooden machines, and cod-oil is forced into the pores.

Sheep-skins, when simply tanned, are employed for inferior bookbinding, for leathering bellows, and for various other purposes for which a cheap leather is required. All the *whit-leather*, as it is termed, which is used for whip-lashes, bags, aprons, &c., is of sheep-skin; as are also the cheaper kinds of *wash-leather*, of which gloves, under-waistcoats, and other articles of dress, are made. Mock or imitation morocco, and most of the other coloured and dyed leathers used for women's and children's shoes, carriage-linings, and the covering of stools, chairs, sofas, writing-tables, &c. are also made of sheepskin. *Lamb-skins* are mostly dressed white or coloured for gloves; and those of *goats* and *kids* supply the best qualities of light leather, the former being the material of the best morocco, while kid leather affords the finest material for gloves and ladies' shoes. Leather from goat-skins, ornamented and sometimes gilt, was formerly used as a hanging or covering for walls. *Deer* and *antelope* skins, shamoyed or dressed in oil, are used chiefly for riding breeches. *Horse-hides*, which, considering their size, are thin, are tanned and curried, and are used by the harness-maker, especially for collars; and occasionally, when pared thin, for the upper leathers of ladies' walking shoes. *Dog-skins* are thick and tough, and make excellent leather. *Seal-skins* produce a leather similar but inferior to that supplied by dog-skins; and *hog-skins* afford a thin but dense leather, which is used mostly for covering the seats of saddles.

Currying is the general name given to the various operations of dressing leather after the tanning is completed, by which the requisite smoothness, lustre, colour, and suppleness are imparted. The processes of the currier are various. The first is styled *dipping* the leather. It consists in moistening with water, and beating upon a trellis-work of wooden spars, with a mallet or mace. After this beating, by which the stiffness of the hide or skin is destroyed, it is laid over an inclined board, and scraped and cleaned, and, wherever it is too thick, pared or shaved down on the flesh side, by the careful application of various two-handled knives; and then thrown again into water, and well scoured by rubbing the grain or hair side with pumice-stone, or with a piece of slaty grit, by which means the *bloom*, a whitish matter which is found upon the surface in tanning, is removed. The leather is then rubbed with the *pommel*, a rectangular piece of hard wood, about twelve inches long by five broad, grooved on the under surface, and fastened to the hand. The currier uses several of these instruments, with grooves of various degrees of fineness, and also, for some purposes, pommels of cork which are not grooved at all. The object of this rubbing is to give grain and pliancy to the leather. The leather is then scraped with tools applied nearly perpendicular to its surface, and worked forcibly with both hands, to reduce such parts as may yet be left too thick to a uniform substance. After this, it is dressed with the *round knife*, a singular instrument which pares off the coarser fleshy parts of the skin. In addition to these operations, the currier uses occasionally polishers of smooth wood or glass for rubbing the surface of the leather; and, when the leather is intended for the use of the shoemaker, he applies to it some kind of greasy composition called *dubbing* or *stuffing*.

Leather is occasionally dressed 'black on the grain,' or having the hair or grain side instead of the flesh side coloured. The currying operations in such a case are similar to those above described, but the finishing processes are somewhat modified. The leather is rubbed with a gritstone, to remove any wrinkles and smooth down the coarse grain. The grain is finally raised by repeatedly rubbing over the surface, in different directions, with the pommel or graining board.

Japanned Leather of various kinds is used in coach-making, harness-making, and for various other purposes. *Patent Leather* is covered with a coat of elastic japan, which gives a surface like polished glass, impermeable to water; and hides prepared in a more perfectly elastic mode of japanning, which will permit folding without cracking the surface, are called *Enamelled Leather*. Such leather has the japan annealed, something in the same mode as glass: the hides are laid between blankets, and subjected to the heat of an oven at a particular temperature during several hours.

In making *Russia leather*, the skins are freed from the hair or fleece by steeping them in an ash-lye, then rinced, fulled, fermented, and cleaned. They are then soaked for forty-eight hours in a bath composed of water mixed with a paste of rye-flour. The skins, when taken out of the bath, are left in tubs for fifteen days, then washed, and immersed in a boiler containing a hot decoction of willow bark, in which they are handled and pressed for half an hour. This manipulation is repeated twice a day for a week, after which the tanning infusion is renewed, and the process is repeated on the same skins for another week, after which they are exposed to the air to dry, and are then dyed and curried.

Shagreen, a peculiar kind of leather, or rather of prepared skin, formerly much used for the covers of watch-cases, mathematical-instrument cases, &c., is produced by soaking, scraping, rubbing, softening, salting, and dyeing. The unevenness of surface is produced in a singular way. The grain side of the skin is strewed with the hard round seeds of the Goose-Foot (*Chenopodium album*). A felt being laid over these, they are trodden deeply into the soft-yielding skin; and when dried, the seeds may be shaken out without violence, leaving the skin in a hard horny state, covered with deep indentations.

It has been recently stated that Dr. Burnland, of Vienna, has discovered a method of making leather out of certain refuse animal substances; and that the substance is at one stage of its process in a state of fluidity, and can be *cast* into boots and shoes and other articles.

Leather-splitting machines, by which even very thin skins may be divided into two thicknesses, each of which is capable of being dressed as a perfect skin, have called forth much ingenuity of contrivance. In one machine of this kind, the skin is drawn between two revolving rollers, and presented, as it emerges from their grasp, to the edge of a long and very sharp knife, which is kept continually moving a little backwards and forwards with great velocity

As there are attempts now being made to revive the beautiful art of carving, in its higher artistic branches; so does the art of embossing and gilding leather seem likely to meet with some revival. Embossed leather, ornamented in gold, silver, and colours, was largely manufactured some centuries ago, first in Spain, Italy, and Flanders, and then in Germany, France, and England. It was much used as tapestry for rooms; and some of our old English mansions still present specimens of it. The Alhambra in Spain still contains some very rich examples. The leathers so employed were made of calf, goat, and sheep-skins. Mr. Leake has recently introduced machinery which bids fair to produce embossed leathers in high relief, and presenting patterns of great beauty.

The untanned hides imported into this country in 1850 amounted to 591,920 cwts. The leather manufactures imported in the same year, comprised about 3,260,000 pairs of gloves, and about 780,000 pairs of boots, shoes, and boot fronts. The English-tanned leather, and English made leather goods exported in

1850, comprising saddles, harness, gloves, and other articles, had an aggregate value of 608,656*l*.

LEECH TRADE. The traffic in leeches is a remarkable one, alike for the gatherer and the dealer. The leech is met with more abundantly in the south than the north of Europe. The country about La Brienne in France is famous for its supply of leeches; and here is exhibited the wretched nature of the employment of a leech-gatherer. He has his arms and legs bare, and walks about in the marshes where the leeches abound. They attach themselves to his legs as he moves along, and he picks them off from time to time; he seeks for them also about the roots of the bullrushes and sea-weeds. He can on some days gather a gross in three or four hours; and he puts them into a small bag suspended round his neck. Such is the leech-fishery in spring; but in summer it is still worse. The leeches then go into deeper water; and the gatherer strips naked to go after them. These poor fellows are exposed to fogs, mists, and fœtid vapours, and are subject to agues, catarrhs, and rheumatisms; but the trade is tolerably lucrative, and thus there is no scarcity of leech gatherers.

A large portion of our leeches are imported from Hamburg, to which port the dealers bring them from different countries. They are sometimes imported in bags, but more usually in small barrels containing about 2000 each; the head being made of stout canvas to admit the air. Some years ago it was stated that four principal dealers in London imported about 7,000,000 leeches annually. It is estimated that the consumption in Paris is about 3,000,000 annually.

LEEDS, the principal emporium of the woollen manufactures in the West Riding of Yorkshire, is one of the most important of our northern towns. Though the spinning of worsted and the manufacture of worsted stuffs is not extensively followed at Leeds, vast quantities of these goods are brought there to be dyed and finished. The dye-houses and dressing-shops at Leeds are very extensive. In these establishments both the woollen and worsted goods are finished, after being purchased in the rough at the cloth-halls and piece-halls of the clothing towns. The mills at Leeds for the spinning of flax for canvas, linen, sacking, thread, &c., are very extensive. There are also large manufactories of glass, earthenware, steam-engines, locomotives, and all kinds of machinery. These and the other operations of the district are facilitated by the abundant supply of coal, produced from the mines in the vicinity of the town.

The largest commercial buildings in Leeds are the cloth-halls. The Coloured Cloth Hall was built in 1578; the White-Cloth Hall in 1775. In the cloth-halls, the principal sales of woollen cloths in their rough state from the country manufacturers to the merchants are effected. The cloth markets are held on Tuesdays and Saturdays, and last only one hour and a quarter at each hall.

There is a School of Design at Leeds, to improve the taste of the workmen. Some exquisite specimens of communion cloths, made of silk warp and flax weft, elaborately damasked have recently been woven at Leeds.

LEGHORN. This enterprising free port in Tuscany is, in the western district, intersected with canals, by which goods are carried in boats from the shipping in the harbour and landed before the warehouses of the merchants. Many of the private houses are handsome. The outer mole is about a mile in length. The harbour is tolerably large, but not sufficiently deep for large vessels, which lie in the roads, where the anchorage is safe and good. The Darsena, or interior harbour or dock, is only fit for smaller vessels. Leghorn is rather a commercial than a manufacturing town; it has however tan yards, rope-walks, soap and candle factories, glass-works, establishments for the manufacture of coral ornaments, woollen caps, cream of tartar, borax, and sulphur. Steamers and sailing vessels are built. A railroad connects the town with Pisa, Pontedera, Empoli, and Florence.

The imports into Leghorn are either for consumption or for deposit. They consist of corn, tissues of cotton, hemp, and wool, sugar, raw and manufactured silk, bronze work and jewellery, salt fish, hides, hemp and flax, coffee, raw cotton and cotton yarn, wool, spices and drugs, dye-stuffs, porcelain, gum, wine, brandy, rum, spirits, tobacco, &c., to the value of about 3,000,000*l*. annually. Many of these articles of course enter into the exports, for the transit trade is very extensive. Other exported articles are—oil, anchovies, paper and rags, straw hats, marble and alabaster, works of art, timber, cork, coral, tallow, potash, &c. The total value of the exports amounts to about 2,000,000*l*. a year. The number of vessels that enter the harbour annually is over 4000, with about 400,000 tons cargo. The number of ships that clear out annually are about the same in number, but the freights are somewhat less. About 2000 of these vessels are Tuscan. Steamers ply regularly to Civitâ-Vecchia, Naples, Sicily, Genoa, Nice, and Marseille.

LEGU'MIN, is a peculiar vegetable product obtained by Braconnot from peas, and which he considers as a vegetable alkali. It appears to be a substance intermediate between gluten and vegetable albumen; it differs from the first in being insoluble in alcohol, and from the last in readily dissolving in the alkaline carbonates. It contains some sulphur and also azote, but less than animal albumen. It exists in peas and beans, to the amount of about 18 per cent.

LEICESTERSHIRE. This county has coal-fields near Ashby, which furnish a cheap supply of fuel; and there are also procured within the county coarse slate, gypsum, limestone, freestone, and brick-clay. The county is supplied with canals and railways, in amount quite adequate to its traffic. In respect to agriculture, the most fertile soils are almost invariably kept in pasture, for which this county is pre-eminent. Out of above 500,000 acres of surface, fully one-half is in permanent grass. Grazing and breeding cattle and sheep are the chief objects of the Leicestershire farmers, and they have succeeded admirably both with oxen and sheep. Most of the improved modern instruments, such as scarifiers, spiked rollers and drills, have been introduced and are used in the larger farms, which are chiefly in the hands of the proprietors. The county contains many large dairies, and produces excellent cheese, especially the Stilton cheese.

Leicestershire is the centre of the worsted hosiery manufacture, nearly all of which is conducted within this county. Leicester is the chief town both of the county and of the manufacture. Most of the principal manufacturers are connected with the hosiery or wool trades. Some of the larger firms employ 2000 to 3000 hands; and one or two spinning mills recently built would rival those of Lancashire. There are worsted spinners, lambs'wool spinners, wool staplers, &c., to supply the raw material; there are frame-smiths, needle-makers, sinker makers, &c., to supply the working apparatus; and there are thousands of persons to weave and sew the stockings. Market Harborough, Lutterworth, Hinckley, Market Bosworth, Loughborough, and most of the villages between these towns, and between them and Leicester, are inhabited by the stockingers (as they are often called). See farther on this subject under HOSIERY MANUFACTURE. The other departments of industry in Leicestershire are not very extensive. There were 35 spinning mills in this county in 1850.

LEIPZIG. This busy city, the second in rank but the first in commerce in Saxony, has extensive manufactures in oil, paper, musical and optical instruments, bronzed articles, hats, leather, hardware, &c. The town has a tribunal of commerce, an exchange, savings' bank, a discount bank, and several assurance companies. There is a considerable trade in American and Russian furs; and the wool fairs, especially that held in June, are very important. Leipzig, though comparatively small, has become one of the most important cities in Europe, owing to its university, its fairs, and its book trade. These fairs have laid the foundation of the prosperity and wealth of Leipzig. The concourse of merchants from various countries is very great, and the value of the manufactured goods of all kinds sold annually is estimated at upwards of three millions sterling.

The singular concentration of the German book-trade in Leipzig has been a main cause of the celebrity and wealth of that city. The first two booksellers, who were also printers, that settled in Leipzig were Steiger and Boskopf, in 1545. There are now 110 publishing establishments, and 23 great printing houses, with 14 printing machines and 260 presses. Above 40 millions of sheets are annually printed at Leipzig, and the bales of books brought thither every year amount on an average to 30,000 cwt. For the transaction of business, and settlement of accounts, there is a handsome building called the Booksellers' Exchange, which was opened in 1836.

At the Leipzig fairs of 1850 it was remarked that the attendance of great buyers had somewhat slackened: the increased facilities for travelling having enabled merchants to visit the manufacturing towns, and make some of their purchases there.

LEITH. The chief manufactures of this important Scotch seaport are ropes, cordage, sailcloth, bottles, soap, and candles. There are several breweries, ship-building yards, and a distillery.

There are two commodious dry docks for the repairing and building of ships, and two wet docks, each of which is 300 feet wide and between 700 and 800 feet long, and of sufficient depth to admit vessels of from 200 to 250 tons' burthen. They are surrounded by well-constructed quays, upon which are erected appropriate warehouses for the reception of merchandise. Extensive additional wet docks are now being constructed, to accommodate increasing traffic. Steamers ply to and from Leith; but the new pier at Granton is found to be more available for this kind of traffic. Leith is the most important naval station on the east coast of Scotland, and its commerce is large. The gross customs receipts in 1848 were 563,452*l.*, ranking next after London, Liverpool, Dublin, Bristol, and Glasgow. The vessels which entered the port of Leith in 1848 were 1028 with an aggregate tonnage of 122,675 tons. 386 boats, and 2064 persons, were engaged in the Leith and Burntisland fisheries in 1846.

LEMBERG, the capital of the kingdom of Galizia, has manufactures of woollen cloth and linen. Lemberg has an important commerce with Russia and Turkey. The commission trade is very extensive, and an immense amount of business is done at the annual fair; it commences on Jan. 6, and for some weeks afterwards a vast concourse of strangers resort to this place.

LEMNIAN EARTH is an earthy substance soft, dull, opaque, yellowish white, and falls to pieces when put into water. It was formerly used in medicine under the name of *Terra Sigillata*. Two-thirds of its weight consist of silica.

LEMON. For a few details relating to this fruit, see the article ORANGE.

LENS. This name is given to a glass, or other transparent medium, ground with two spherical surfaces. If one side is flat and one convex, it is called *plano-convex;* if both are convex, it is *double convex;* if one is flat and one concave, it is *plano-concave;* if both are concave, it is *double concave;* if one is convex and one concave, it is *meniscus*, or concavo-convex. All these lenses, for optical purposes, are ground to the proper curve by revolving wheels.

LEVELLING. The relative heights of a series of points on the ground are obtained by means of their vertical distances from others which, on the supposition of the earth being a sphere, are equally distant from its centre; and these, which are called level-points, must be found by an instrument constructed for the purpose. [SPIRIT LEVEL; THEODOLITE.] In general, a choice is made of any convenient stations on the line of operation, and the distances between them are determined by actual admeasurement. The instrument is then set up at or near the middle of the interval between every two such points in succession. When the telescope thus placed has been rendered horizontal by means of the adjusting screws, an assistant at each of the adjoining stations, holding what is called a station staff in a vertical position, moves a vane or index along the staff, upwards or downwards according to the directions of the observer at the telescope, till it appears to coincide with the intersection of two wires in the telescope. The points thus determined on the staves are level points or points equally distant from the centre of the earth; and the difference between the height of the index on the two staves will give the relative height of the ground at the two stations.

It is frequently the practice to execute a sort of double-levelling; which consists in placing the instruments successively at each of the stations, a staff being held up vertically at the other, when, the axis of the telescope being at equal heights from the ground at both stations, half the difference between the heights read on the staves will express the difference in the height of the stations.

The profile of the ground is usually expressed on paper, in portions of any convenient length, for the purpose of enabling the engineer to determine the depths of his excavations, or the heights of the masses of earth to be raised, when it is proposed to execute a canal or road. A right line being drawn to represent one parallel to the horizon, and passing through the highest or the lowest point of the natural ground; the heights and depressions of the remarkable points, with respect to such line, are obtained by additions or subtractions from the numbers in the field-book, and are, by a proper scale, set out from that line on others drawn perpendicularly to it at intervals equal to the horizontal distances between the same points. The series of points thus obtained, being joined by hand or otherwise, give the figure of the required vertical section of the ground.

LEVER. This simple but invaluable mechanical instrument consists merely of a bar of wood or metal, by fixing one point of which called the *fulcrum*, a pressure at the end more distant from the fulcrum is made to counterbalance a larger pressure at the nearer end; or, if both ends be equally distant from the fulcrum, equal pressures are made to balance each other.

The first explanation of the lever was given by Archimedes, and in a simple and correct form. It assumes two principles; firstly, that when a system is in equilibrium, the state of rest will not be disturbed if additional pressures, such as compensate each other, and would by themselves produce no motion, be introduced or removed; secondly, that, when a weight is made to rest by being attached to an immoveable point (say it is suspended by a string), the point or pivot of suspension undergoes a pressure equal to the weight of the system, whatever may be the form of that system, or the dispositions of its parts. Thus, a cylindrical or prismatic bar of uniform material will necessarily rest if a pivot be passed through a section in the middle of its length, since there is no reason why it should preponderate on either side; now, divide the bar into any two parts, and, from their middle points, suspend weights equal to the weights of the parts; also apply counterpoises of equal weights at the same points, by means of strings passing over pulleys; the equilibrium will then be undisturbed; take away from the system the parts of the bar and the counterpoises (which are equal and opposite to one another), and the equilibrium will subsist between the remaining weights, which are those first suspended. The points of suspension being in the middle of the lengths of the two parts are at distances from the pivot (at the middle of the whole length of the bar), which are inversely proportional to the suspended weights.

This may be briefly illustrated thus. When a straight and uniform bar is supported on a central pivot, if weights on either side of the pivot keep the bar exactly horizontal; then the weight on one side, multiplied by its distance from the pivot will be equal to the other weight similarly multiplied by its distance. If a weight of eight lb. balances another of sixteen, the former must be twice as far from the pivot as the latter. It is on this principle that the *Steelyard*, and other kinds of weighing machines, act.

In English treatises on mechanics it is customary to call one of the pressures which balance on a lever, the *power*, and the other the *weight*. Levers are thus distinguished as of the first, second, or third kind, according as the fulcrum, the weight, or the power, is in the middle.

LEYDEN. In this Dutch city the manufactures of linen and woollens have declined considerably, but are still the most important in Holland. The woollen manufacturers are especially famed for the production of very soft blankets with scarlet borders. A great wool fair is held annually. There are likewise extensive manufactories of soap and indigo, tanneries, salt-works, &c.

LI'BER, the inner bark of a plant, is a layer consisting of woody tissue, cellular substance, and vessels, forming a compact zone immediately applied to the wood. The woody tissue of which it is composed quickly becomes thick-sided, by the addition of internal ligneous strata, the consequence of which is, that such tissue in this part is more tough than elsewhere. Hence it is usually from the liber that are extracted the fibres employed in making cordage or linen thread: this at least is its source in hemp, flax, the lime tree, the lace-bark, and many other exogens which furnish thread; but in endogens, which have no liber, as the cocoa-nut, it is the ordinary woody bundles of the leaves, stem, and husks of the fruit from which the fibre used for ropes is procured. In many plants a new layer of liber is formed annually, contemporaneously with a new layer of wood; but this is by no means universal; on the contrary, the oak and the elm increase their liber slowly and irregularly.

LI'CHENS. This large and important natural order of imperfectly organised plants contains numerous species employed in the arts as pigments, and as articles of food. It is principally in the former respect that they are of economical interest, in consequence of the great consumption of orchal, or archil [ARCHIL], Cudbear (*Lecidea tartarea*), and others by the dyer. Lichens are distributed over all parts of the world, forming in the polar and similar regions a food for animals and man. *Cladonia rangiferina* supports the reindeer; *Cetraria islandica* furnishes the nutritious Iceland moss of the druggists' shops; and various species of *Gyrophera*, under the name of Tripe de Roche, form a part of the supply of food scantily furnished by nature for the Canadian hunter. In warmer countries they acquire a firmer consistence, and appear to form secretions of a peculiar kind in much greater abundance than in the northern parts of the world.

LIEGE. This very important Belgian province produces hops, corn, and a little wine; the pastures are good, and maintain great numbers of horned cattle and sheep. The mineral wealth of the country is considerable; there are mines of calamine, alum, lead, and iron ore; but more important than all these together are the numerous coal mines of the province. The manufactures, which are conducted on a large scale, consist of all kinds of steam-machinery for railroads and factories, mil castings, fine woollens, merinoes, linen, cotton stuffs, cutlery and surgical instruments, fire arms, glass, hardware, &c. The number of steam-engines of different kinds in the province is between 400 and 500.

The manufacturing towns are numerous. *Glons* is the centre of a great straw-hat manufacture, which gives occupation to upwards of 6000 people. *Herstal*, or *Heristal*, has important coal-mines, iron and steel works, and iron-foundries. *Herve* has manufactures in woollen cloth, stockings, and shoes. At *Huy*, beer, spirits, paper, leather, linen, and cast iron are manufactured. *Seraing* has coal-mines, important iron-foundries, and glass-works. *Spa*, famous for its mineral springs and baths, exports about 150,000 bottles of mineral water annually from the Pouhon spring, which is the strongest. Spa is famous also for the manufacture of elegant wooden toys, workboxes, writing-desks, &c. *Verviers* is famous for the manufacture of fine and ordinary woollen cloths and kerseymeres, giving employment to 40,000 hands in the town and neighbourhood; the Belgian army is clothed principally from the looms of Verviers, the total produce of which is estimated at 1,000,000*l.* sterling annually. Flannels, serges, tickings, coverlets, mouselines de laine, merino, &c., are also manufactured. The dyes of Verviers are said not to be surpassed in Europe. There are also establishments for the manufacture of steam machinery, ironmongery, soap, beer, &c.

But the most important town in the province is *Liège*, from which the province itself has been named. The extensive coal-mines near the town; its numerous iron-works, royal cannon foundry, and establishments for the manufacture of fire-arms, hardware, broadcloth, glass, and leather; its engine-factories, zinc-rolling mills, and naileries; its linen and cotton factories, steel-works, and breweries; together with a flourishing commerce in colonial produce and manufactured goods,—render it one of the most important towns in Belgium, and one of the most industrial spots in Europe.

LIFE-BOAT; LIFE-PRESERVER. Many ingenious plans, more or less practicable, have been proposed for saving from drowning those who may be in peril by shipwreck or otherwise. These contrivances may be classed as *Life Boats*, *Life Buoys*, and *Life Dresses*.

Life Boats.—A life boat is a boat constructed with great strength to resist violent shocks, and at the same time possessing sufficient buoyancy to enable it to float, though loaded with men and filled with water. Such boats are maintained at most of the ports of this kingdom, always ready to put to sea when vessels are seen in danger of shipwreck, and provided with means for being conveyed to the shore, and launched as rapidly as possible. As early as the year 1785, a patent was granted to Mr. Lukin for a life boat with projecting gunwales and hollow cases or double sides under them, as well as air-tight lockers or inclosures under the thwarts: these contrivances increased the buoyancy of the boat, and the air-tight cases under the gunwales, by their weight when raised above the surface of the sea, and their resistance when depressed beneath, greatly prevented rolling. Mr. Lukin's boat was strong and buoyant, but it was liable to be disabled by having the sides staved in. This defect was obviated in Mr. Greathead's boat, which was invented soon after; its prevailing feature is that the boat is lined inside and outside with cork. Mr. Greathead's boat was instrumental in saving the lives of 300 persons in five years, near Tynemouth.

In 1839 Mr. Mackintosh of New York took out a patent for a sort of temporary life boat. It consists of canvas rendered impervious to water by being saturated with a solution of caoutchouc. A square piece of this canvas is so hemmed at the edges as to leave a hollow tube or channel, which, when filled with air, may act as a buoyant cell or air-chamber. The opposite edges of the piece of canvas are partially sewn together, so as to give to it the semblance of a boat, the sewn edges being cemented with caoutchouc to render them air and water tight. Mr. Adams shortly afterwards contrived a boat lined with cork in the inside, and having air-vessels under the decks or seats. Holcroft's pontoon, or safety boat, also of recent origin, has some peculiarities about it, on account of its portability. It is formed of a skeleton frame, easily detached and folded into one-sixth of the space which it occupies as a boat. The frame is covered with layers or folds of strong canvas saturated with India-rubber; and in various parts are cases or air-cells, partitioned off one from another. The portability of the boat is brought about by having the framework hinged to the keel, so that the sides close together like a portfolio. Captain Smith's paddle-box boats, for steam-vessels, originated from that officer having observed that there is room, upon such paddle boxes, for a life boat, without encumbering the ship in any way; and builders of steamers have devised a mode of making the inverted boat a covering for the paddle box.

Every year brings forward some new projects relating to life boats. There was a singular suggestion made a year or two ago by Mr. Bateman, for the construction of a wooden boat, having as many vertical cylinders as there were to be persons accommodated; each cylinder was to be 36 inches deep by 16 in diameter. Each cylinder was to have a cover when not in use; but when the cover was removed, a man was to get into each cylinder, and thus seek for safety. The interstices were to be filled up with cork, and other arrangements made for lightening, strengthening, and rowing the boat.

The Duke of Northumberland has recently offered a prize for the invention of the most efficient form of life boat; and this offer has led to the exercise of much ingenuity on the subject. One of the inventions proposed to compete for the prize is that by Messrs. Russell and Oswald of the Isle of Man. The boat is on the double or twin principle; both boats being divided into ten air-tight compartments, and completely decked over, by which arrangement they cannot be swamped. The boats are placed three feet apart; and upon them is fixed a framing, with seats and row-locks for eight rowers. The bottom of each boat is a curve, rising up at both ends to a considerable height above the water. There are arrangements for masts and sails. This boat is, we believe, to be exhibited at Hyde Park.

Life Buoys.—Besides those life boats which have been constructed for the especial purpose, there have been several inventions for converting ordinary ships' boats into life boats upon a sudden emergency, which may be applied by the crew of a ship in distress. Mr. Bremmer, about the year 1800, proposed that empty casks should be strongly fixed in ships' boats upon a plan described by him, which on trial was found to answer perfectly. Captain Gordon's life buoy consists of a series of bamboos of different lengths fastened together; the uppermost piece is the longest, the others diminish gradually to the lowest, which is the shortest of all; thus forming a triangle, which is covered with pieces of sound cork, strongly fixed to the bamboo rods. Two of these triangles are intended to be fastened to a boat, one on each side, the long pieces being close to the gunwale, the shortest near the keel. Well-tarred sheepskin bags, inflated with air; air-tight copper tubing fitted under the seats of boats; and many other contrivances have been partially used. Cork mattresses have been found useful, but it was alleged that they gave sailors facilities to desert, and they were discontinued; floating ropes lined with cork have also been suggested, but, like fire-escapes, these contrivances are never at hand when most wanted. Boyce's life buoy is intended to be kept suspended at a ship's stern, to be dropped into the water in case a man falls overboard. It is composed of two hollow wooden cylinders, either made air-tight or else filled with cork, and connected by a wooden grating so as to form a sort of raft. It has been suggested to convert the warping buoys which abound in our harbours into a sort of life buoys, by fitting them up with wooden battens placed lengthwise from end to end upon their circumference. Cooke's life buoy is formed of two hollow copper spheres, connected by a horizontal rod; and from the middle of the rod rises a vertical stem containing a fuse at the top. The fuse is lighted, the buoy is lowered, and the person in the water, attracted towards the buoy by the light (if at night), seeks safety by clinging to the floating mass. Captain Beadon's buoy consists of a metal tube, eight feet long by one foot in diameter, tapered at its after end; it is divided into water-tight compartments, and has a keel ten or twelve inches deep. There is a kind of saddle across the cylinder, on which a man may sit; a staff, on which a light may be kindled; and a paddle to work the buoy, or two oars hinged to it. Irvine's safety-portmanteau, which will support two persons clinging to it in the water; Henvey's cork float; and Taylor's deck chair, are among the numberless modern contrivances for a similar object.

Safety Dresses.—Among these contrivances is the life hat. The upper part of the crown of the hat is made air-tight and water-proof, so that, in the event of the wearer falling into the water, its buoyancy may (according to the intention of the inventor) save him from being drowned. The lining of the hat is capable of being loosened, and the vacant space expanded by air being blown into it, so as to form a buoy capable of being grasped by any one immersed in the water, instead of being worn like a hat. Macintosh's life cape is a waterproof garment, which is capable, by the introduction of air through a stop-cock into a vacancy formed by a double thickness of cloth, of being converted into a life-buoy. Air tight jackets, belts, pads, cushions, &c., have been devised in many forms.

Besides all the above contrivances, may be mentioned those, such as Captain Manby's, in which a rope is propelled by a cannon from the shore to a ship in distress.

LIGHT-BALLS, for military purposes, are hollow cases, either spherical, or in the form of cylinders terminated at each extremity by a hemisphere: they are filled with a combustible composition, and being thrown, by night, in a burning state from mortars, or in some cases from the hand, they serve to discover the working parties or troops of the enemy. The composition consists of pulverised saltpetre ($6\frac{1}{4}$ lbs.), pulverised rosin ($1\frac{7}{8}$ lbs.), ground sulphur ($2\frac{1}{2}$ lbs.), and linseed oil ($\frac{1}{2}$lb.) The balls are propelled from mortars varying from $4\frac{2}{5}$ to 10 inches calibre, and correspond to the size of the mortar employed. Spherical cases of pasteboard or canvas, filled with a composition which while burning emits a great quantity of smoke, are frequently discharged from mortars in order to conceal a movement of troops from the view of the enemy, or to suffocate the enemy: these are called *smoke-balls.*

LIGHTHOUSES. These important buildings are erected along the sea-shore, or upon rocks, from which lights are exhibited at night for the direction of mariners. Floating lights perform a similar office, being shown from the masts of vessels moored in certain positions, generally as beacons to enable ships to avoid shoals or sunken rocks in the æstuaries of great rivers.

The erection of lighthouses in this country has not proceeded upon any systematic plan, but in every instance they have been constructed simply because of the disastrous losses that had occurred for want of them. From this cause it arises that our lighthouse establishments in the several parts of the United Kingdom have until recently been conducted under entirely different systems, different as regards the constitution of the management, the rates or amount of the light-dues, and the principle on which they are levied. Under the operation of recent acts of parliament, all the public or general lighthouses around the coast of England are under the management of the Trinity House; those around Scotland under the Commissioners of Northern Lights; and those around Ireland under the Ballast Board of Dublin. There is a second class of lighthouses, consisting of local or harbour lights, which are managed by corporations and local trustees, under powers given for that purpose; but even these local lights are being brought more and more under general central authority. There are at the present time about 320 lighthouses round the several coasts of the United Kingdom. These lighthouses are maintained by dues levied on all vessels which leave the harbours of the United Kingdom, at so much per ton per vessel, according to the number of lighthouses which the vessels pass. These dues, which have amounted in some years to nearly 400,000*l.*, are in some instances very oppressive; but gradual improvements are being introduced in the whole system.

A principal object in the establishment of these buildings is to give intimation to vessels approaching the coast during the night as to the place in which they are. It is therefore of importance that the lights exhibited on the same line of coast should have some essential differences, so as to be readily distinguished by mariners. The different appearances thus required are given by having two lights placed either vertically or horizontally with respect to each other, or three lights, as at the Casket rocks, or by causing the lights to revolve or to appear only at certain intervals, and to remain in sight only for a given number of seconds at each appearance; or by the employment of lamps of different colours, as in some of the harbour-lights, which do not require to be seen at a great distance.

The mode of lighting now generally used in this country is that of placing an argand burner in the focus of a parabolic reflector. This instrument is made of silver strengthened with copper, and is about 3 or 4 inches in focal length, and 21 inches in diameter. The number and the arrangement of reflectors in each lighthouse depend upon the light being fixed or revolving, and upon other circumstances connected with the situation and importance of the lighthouse. The mode in use in the lighthouses of France consists in placing a large argand lamp, having four concentric wicks, and giving a very powerful light, in the centre of the upper part of the building, and placing around the lamp a series of glass lenses of a peculiar construction; thus using a refracting instead of a reflecting instrument to collect the light, and only one lamp instead of a greater number. The lens employed is about 30 inches square, plano-convex, and formed of separate rings or zones, whose common surfaces preserve nearly the same curvature as if they constituted portions of one complete lens, the interior and useless part of the glass being removed.

Of the fixed lights of England and Scotland, in 1844, 76 were *catoptric*, or reflecting lights; while 18 were *dioptric*, or lens lights. The reflecting lights had, on an average, about 15 burners each; and the one burner of each lens light was about equal in efficiency to 14 burners on the reflecting principle. The English floating lights had an average power of about 12 burners each. The Irish lights are powerful; they presented an average power of 21 burners to each fixed light. The average annual cost for keeping up the fixed public lights is about 450*l.* per lighthouse.

In France, the lighthouses and harbour-lights are all under a public board; and the expenses are paid out of the treasury, and met by levying a port charge of 10*d.* per ton upon shipping generally. In 1845 there were 52 general coast lighthouses, and 101 harbour-lights. In America, as in France, the lighthouses are maintained by the government.

We will here briefly describe the three most notable lighthouses of modern times; viz., the *Eddystone*, the *Bell-rock*, and the *Skerryvore*.

Eddystone.—The Eddystone is the name of a rock which lies about 12 miles south-west of Plymouth Sound, in a position peculiarly dangerous for ships entering the Sound. A lighthouse was built on this rock in 1696, but blown down by a storm in 1703. A second was built in 1706, and burned down in 1755. The present lighthouse was planned by Smeaton in 1756, and finished a few years afterwards. It is a circular tower of stone, sweeping up with a gentle curve from the base, and gradually diminishing to the top. The upper extremity is finished with a cornice, and surmounted by a gallery and lantern. The tower is furnished with a door and windows, and an interior staircase and ladders. The granite Eddystone rock was partly wrought to form a foundation; and the dressed stones (granite at bottom and limestone at top) were dovetailed to the rock in a manner calculated to give immense strength. These stones were generally from one to two tons weight each. The base of the lighthouse is about 27 feet in diameter, and the entire height is about 86 feet.

Bell Rock.—About twelve miles from Arbroath, on the Forfarshire coast, is a dangerous rock called the Bell or the Inchcape Rock. On this rock Mr. Stevenson built a beautiful lighthouse, which was finished in 1811. The foundation is 42 feet in diameter, and is built solid to a height of nearly 40 feet, every stone being dovetailed into those which surround it. The higher or hollow part of the building is divided into six rooms, used as a fuel room, an oil room, a kitchen, a bedroom, a library, and the light-room. There are two large bells belonging to the building, to be rung when the weather is too foggy to permit the lights to be seen from a distance.

Skerryvore.—In the Atlantic Ocean, between the Hebrides and Ireland, are many dangerous half-hidden rocks, which have occasioned numerous shipwrecks. On one of these rocks, called Skerryvore, a lighthouse has been built in recent years, under circumstances of immense difficulty. Mr. Alan Stevenson undertook the work in 1834, but it was not till 1844 that the lights were exhibited. The rock is 12 miles from a small island called Tirree; and Tirree is two or three days' sail from any part of the coast whence supplies could be obtained; hence the difficulties encountered by the engineers and workmen were most harassing. It was at all times difficult to approach the rock; and when there, the number of working days in a year was very small; the rock itself is excessively hard, and the difficulty great of transporting stones thither. But all difficulties gradually gave way to the skill and perseverance of the engineer, and the structure was at length completed. It is 138 feet high, curving inwards from a basis of of 42 feet. It contains 9 stories or apartments in height. More than 4000 tons of material were used in its construction. The lighting apparatus consists of eight annular lenses revolving round a lamp of four concentric wicks, and producing every minute a bright blaze visible to a distance of 18 miles.

Among modern contrivances for lighthouses is that of forming the body of the building of iron. Such was the lighthouse constructed by Mr. Alexander Gordon, in 1842, for Jamaica; and many others have since been made. These structures are formed of cast-iron plates or in some cases of sheet iron, riveted together and braced in various ways, and having provision made for the contraction and expansion of the metal. Mr. Bush for many years advocated the use of a peculiar kind of floating light or lighthouse on the Goodwin Sands, but after the expenditure of much time, money, and ingenuity, the project has failed. Another scheme due to Captain Bullock, has for its object the construction of a safety beacon on the same perilous locality; and many other contrivances have been experimentally tried for the same purpose; but we believe none of these well-meant schemes have shown indications of permanent success. One of the most remarkable of modern lighthouses or beacons is the *screw-pile* lighthouse of Mr. Mitchell. This lighthouse is constructed on spots where a sandy soil would render a fixed structure unavailable. It consists of a light timber edifice, supported on eight or more very long and powerful piles, which are separately screwed down firmly in the sand by a screw formed at their lower extremity. One such lighthouse was constructed on the Maplin Sand at the mouth of the Thames, another at Fleetwood, and another at Carrickfergus. More recently, Dr. Potts has devised a mode of forming a foundation for a lighthouse on sand, by the sinking of hollow cylinders, through the aid of an air-pump, which pumps out the air from within the cylinder, so that the cylinder is forced down by atmospheric pressure.

LIGNIN, or vegetable fibre, is the substance which remains after a plant has had its soluble matter dissolved out of it. Lignin, properly speaking, constitutes the skeleton of the trunk and branches of the tree. It varies in different kinds, as to its colour, hardness, texture, and specific gravity. The texture of lignin is always porous; these pores, when fresh, contain the juices of different substances; during the drying of lignin the water evaporates, and leaves the matters dry which it held dissolved. When dry, lignin is a non-conductor of electricity. When exhausted of air in its pores, it is much heavier than water. When kept entirely dry, or entirely immersed in water, it resists decay for centuries; but, when alternately wet and dry, it gradually decomposes. The wood inclosing Egyptian mummies is found in good preservation, although some of it must be about 3000 years old. When wood (or lignin) is heated in iron cylinders, a great variety of important substances are obtained, besides charcoal, such as pyroligneous acid, pyroxilic spirit, creasote, and tarry matter.

LIGNITE, consists of fossil wood carbonised to a certain degree, but retaining distinctly its woody texture. A greater degree of change constitutes *cannel* and *common coal*, in which the original structure of the constituent plants can only with difficulty be traced; a less change belongs to *peat*, so that lignite occupies a place between coal and peat. *Jet*, *Surturbrand*, *moor coal*, *Bovey coal*, *Cologne earth*, and *basaltic coal* are considered to be varieties of lignite. Lignite often occurs in beds of considerable thickness and extent, and supplies to particular districts a bad substitute for coal. In general, lignite is most plentiful in the tertiary strata, and coal among the older rocks of the secondary series. Lignite is found in various parts of England, France, Italy, and Switzerland.

LIGNUM VITÆ. [Guaiacum.]

LILLE. The manufactures of this town, which has been transferred from Flanders to France, are very important; they consist of all kinds of cotton goods; linen and linen thread, lace, blankets, and other woollen stuffs; paper, leather, beetroot sugar; steam machinery and ironmongery; gin, beer, and great quantities of oil, which is expressed in 300 windmills near the town; glass, soap, tape, hats, carpets, chemical products, &c. There are also iron and copper foundries, dye-houses, bleaching establishments, and sugar refineries. The trade in these various products and in colonial produce, wool, hides, hops, coal, tobacco, chicory, &c., is extensive. The town is lighted with gas, and has communication by railway and by canal with all parts of France and Belgium.

LIME. This substance, which is an oxide of Calcium, has been known from the remotest antiquity, and is most abundantly diffused in nature. It is never found pure, but always combined with other earths or with acids. It is easily obtained in a pure state, by applying heat to drive off the carbonic acid from carbonate of lime, leaving pure lime or *quick-lime*. Lime is white, opaque, and inodorous; its taste is acrid and alkaline. It cannot be burned in the strongest furnace. When exposed to the air it falls to powder. It readily combines with water, to form a *hydrate* and *lime-water*. A hydrate is formed when quick lime is slaked by the addition of water. Lime-water is prepared by dissolving the hydrate in water.

Lime is employed for a vast number of purposes, in common life, in agriculture, and in the arts and manufactures. Among its most important applications are the making of mortar, and the amelioration of certain soils. It is extensively used also in soap-making, leather-dressing, dyeing, and for various medicinal purposes.

LIME TREE. The lime tree is applied to many useful purposes. It is known in many foreign countries as the linden tree. The wood is of a pale yellow or white colour, close-grained, soft, white, smooth, and not liable to be attacked by insects. It is used by pianoforte makers for sounding boards, and by cabinet makers for a variety of purposes. It is turned into domestic utensils, and into small boxes for apothecaries. It is carved into toys, and is the material for some of the most exquisite carvings in our old English mansions. The blocks employed by Hollar for his wood engravings were of lime tree. The wood makes excellent charcoal for gunpowder. Baskets and cradles were formerly made from the twigs. Shoemakers and glovers use planks of lime tree upon which to cut the finer kinds of leather.

Lime-bark is used in making twine, ropes, baskets, mats, shoes, fishing nets, roof-coverings, and many other articles in various European countries; and in Carniola the peasants make a kind of coarse cloth from it. The leaves are used as food for cattle. The sap will yield sugar of very good quality. The fruit and flowers have been prepared into a kind of cocoa, pleasant in taste, but not fit for keeping. The flowers yield very delicate honey, especially in the Ukraine, where the bees who feed in the lime forests produce honey of great value.

LIMERICK. This Irish county has tracts of great fertility; especially one called the Golden Vein, which occupies the greater part of the eastern plain of Limerick. The soil is a rich, mellow, crumbling loam, and is equally suited to grazing or tillage: it is chiefly in pasture. A still richer soil is that of the 'Corcasses,' which extend for fifteen miles along the southern bank of the Shannon, from a little below Limerick to the embouchure of the Deel. They yield the greatest wheat-crops raised in Ireland; and their produce of potatoes is also large. Pasture and dairy farming are the staple occupations of the people. Great quantities of butter are made. Pigs of a very superior description are bred in great numbers by the dairy farmers.

There is a small manufacture of coarse woollens for home consumption, and the bleaching of linen is carried on, but on a contracted scale. There are paper-mills, and large and powerful mills for the grinding of corn.

The chief town of the county, *Limerick*, is the fourth town in importance in Ireland, and is the capital of the western part of the island as Dublin is of the east, Belfast of the north, and Cork of the south.

There are distilleries, breweries, tanneries, foundries, flour-mills, and ship-yards. Vessels of 1000 tons' burthen can approach within five miles of the city, and those of 400 tons can unload at the quays. By the inland navigation of the Upper Shannon, and the Grand Canal and Royal Canal, the city has communication with Dublin, as well as by one of the branches of the Great Southern and Western Railway. The number of ships registered at the port of Limerick is about 120. About a thousand vessels leave the port annually; and an equal number enter.

Limerick has a reputation for its lace, its gloves, and its fish-hooks; and the marble and slate of the neighbouring districts have considerable value.

LIMESTONE. In regard to the chemical composition of limestones, some, as statuary marble, are nearly pure carbonate of lime; others, as the dolomitic rocks of the Alps, contain a certain proportion of carbonate of magnesia; and some are penetrated by bituminous matter, as the black marbles of Yorkshire. Limestones also vary in quality, and become debased by admixture with sand, clay, oxide of iron, pyrites, &c.; so that there is in fact a real gradation from limestone to schist, to sandstone, to shale, to ironstone, &c. Limestones have a crystalline aggregation, as statuary marble, and generally the limestones mixed with primary systems of strata; or they are composed of small crystalline grains, as the magnesian limestone of Mansfield in Nottinghamshire; full of round concretionary parts, as the oolites of Portland, Bath, and Oxford; earthy, as chalk, and some magnesian limestones; or compact, as the lithographic stone of Solenhofen. The beds of calcareous rocks are of every thickness, from a mere lamina to some yards thick. The colours of limestone vary indefinitely; and the different kinds have very different degrees of value as building stone.

LINCOLNSHIRE. This county is famous for its fens. A general account of the great fen district of England, and of the changes which it has undergone, is given elsewhere. [BEDFORD LEVEL.] The artificial cuts or drains are very numerous; they are called by the several names of 'cuts,' 'drains,' 'leams,' 'droves,' 'becks,' 'eans,' and 'dykes.' The chief among them, in this county, are the Car Dyke, the South Forty-Foot, the North Forty-Foot, the East Fen Drain, the West Fen Drain, the Old and New Hammond Becks, and the Shire Drain. Of navigable canals, besides the Ancholme, Louth, Horncastle, Sleaford, Bourn, and other navigations, there are only two; viz, the Foss Dyke, and the Stainforth and Keadby Canal. When the works of the Great Northern Company are finished, Lincolnshire will be well supplied with railways.

The grazing land in this county cannot be surpassed in its capabilities for fattening cattle; and some of the drained fens and warp-lands along the rivers possess a high degree of fertility when cultivated. The lands which have been reclaimed from the sea by banking and draining are mostly laid in large farms, which require a considerable capital. In other parts of the county there are many small properties, cultivated by the owners, and kept with great neatness. Fish is much used as a manure. Ground bones are used very abundantly on the light sands. The grass-lands of Lincolnshire are some of the best feeding lands in the kingdom. Some of the finest pastures are fed off by horses which are fatted for the markets. Several parts of Lincolnshire have been improved by *warping.* The warping is effected by letting in the water of the rivers, which have a muddy current, by artificial channels and sluices, and retaining it there till low water. The river Humber carries off, in its course over various soils, all the finer particles which are too light to be immediately deposited. These consist of every kind of earth and portions of vegetable and animal matter, and are in such quantity that a layer one-tenth of an inch in thickness is often deposited between one tide and the next. Thus in a very short time a new soil is formed of any depth that may be desired, provided the land lies below the level of the river at high tides. Besides creating a soil, the warping fills up all inequalities, and a perfectly level surface is produced. The soil thus produced is of extreme fertility.

Lincolnshire is an agricultural county; but a few manufactures are carried on in the towns. At *Barton* a considerable trade in corn is carried on; and bricks, tiles, ropes, and sacking are extensively manufactured. BOSTON and GRIMSBY have been noticed in earlier articles. At *Bourn* wool-stapling and tanning are carried on, and the town has some trade in leather and wool. *Gainsborough* has a busy trade. By means of the Trent, which falls into the Humber about 20 miles below the town, vessels of 200 tons' burthen can came up to the wharfs. *Grantham* has a trade in corn, malt, and coals. *Lincoln* the county town has a large trade in flour, and there are some extensive breweries noted for their ale.

LINE. The French used to divide their inch into twelve *lines*, and the line into twelve *points*, which measures are out of date, since in all scientific investigations the metrical system is adopted. Sometimes, but rarely, the line has been divided into ten points, thus giving 1440 points to the foot. The French line is .0888 of an English inch, and is also two millimetres and a quarter. It is sometimes given in English books translated from the French; and on that account its meaning is worth bearing in mind.

LINEN MANUFACTURE. The woven goods in which flax is the chief material comprise *linens* as the principal; but also numerous others; such as *duck, check, drabbet, tick, huckaback, damask, diaper, drill, towelling, shirting, sheeting, sacking, sail-cloth, dowlas, canvas, &c.* Barnsley is the centre of the English flax manufactures, mostly conducted on the hand-loom system, but partly on the factory system. Dundee is the centre of the Scotch flax manufacture for coarse goods, and Dunfermline for fine, mostly conducted on the hand-loom system. *Belfast* is the centre of the Irish flax manufacture, one of the most important for the interests of that country.

The preparation of the flax for the spinners and weavers has been described under FLAX MANUFACTURE. We will here give a few statistics to illustrate the extent of the manufacture.

The flax factories in the United Kingdom in 1850 were as follows:—

	Factories.	Steam power.	Water power.
England and Wales	135	3,616	871
Scotland	189	5,004	1,421
Ireland	69	2,285	1,095
	393	10,905	3,387

From this we learn that the flax machinery was moved by an aggregate of 14,292 horse-power. These factories contained 965,031 spindles, and 1141 power looms. The persons employed in them numbered 68,434, of whom 47,617 were females. The children under 13 years of age were 1,581.

The exports of linen manufactures in 1850 comprised the following entries:—

Linen goods	122,397,457	yards.
Thread lace	464,164	"
Sewing thread	3,361,922	lbs.
Linen yarn	18,559,318	lbs.
Miscellaneous	£ 17,728	value.

LINSEED, the seed of *Linum usitatissimum*, or flax plant, contains a mealy albumen of so oleaginous a nature that it yields by pressure in great abundance the oil of linseed. The seed of the flax-plant is harvested, not merely with a view to the reproduction of the plant, but also because of the oil which it yields by compression. For both these purposes, of sowing and crushing, linseed is largely imported into the United Kingdom. Linseed is also much used as food for small birds. Some of the imported seed goes to Ireland, and is chiefly used for sowing. The best seed for this purpose is brought from Holland. The residuum of linseed from which the oil has been expressed is used, under the name of *oil-cake*, for fattening cattle. For the import of linseed or flaxseed, see FLAX.

LINSEED OIL may be procured by cold expression of the seeds, a process which makes the oil clearer; or the bruised seeds are roasted in the oil mills, in which case it is brownish yellow, and easily becomes rancid, probably from attracting oxygen. Linseed oil is pellucid, with a faint but peculiar odour and taste. By long boiling it becomes dark brown, tenacious, and thickened, but dries more easily, and in this state is used for printer's ink; by still longer boiling it becomes black, almost solid, and elastically tenacious, like caoutchouc, and in this state it serves for bird-lime.

Linseed-oil is used to form liniments, of which the most common is that with lime-water, as an application to burns. But it is much more extensively used in the arts, particularly for painting.

LINTING MACHINE. The lint used by surgeons has until lately always been made by hand; but linting or lint making machines have recently been invented. One such was patented by Mr. Taylor in 1850. A committee of the Army Medical Board was appointed a short time ago to report on the quality of machine-made lint; and their report being favourable, the substance is coming extensively into use in hospitals and in private practice.

In the linting machine, the cloth which is to be scraped into lint is wound on a roller, from which it unwinds as the operation proceeds. During its progress its surface comes within the action of a knife or scraper, which has a sort of chopping or vertical motion; this cuts to a small extent into the warp and weft threads; and the cloth being immediately afterwards drawn forcibly beneath the edge of the knife, a nap or pile is raised over the whole surface of the cloth. This constitutes lint.

LIQUATION, or ELIQUATION, was one of the processes (now almost disused) for separating silver from copper.

LIQUIDAMBAR. This is the name of some fine trees which occur in Java, the Levant, and North America. *Liquidambar styraciflua* is the species found in Mexico and the United States, in the latter of which it is called Sweet Gum, and forms a large and fine tree. The wood is of a hard texture and fine grain, and makes handsome furniture; but the tree is more noted for the fragrant liquid resin which exudes from incisions in the stem, though not very copiously. This is called *Liquidambar*, or Oil of Liquidambar, which has a pleasant balsamic odour and an aromatic bitter taste. This, becoming dry and opaque, forms what is called Soft or White Liquidambar, which resembles very thick turpentine, has a feebler odour than the liquid balsam, and contains less volatile oil.

LISBON. The trade of this interesting city, though much diminished since the loss of Brazil, is still considerable. It exports wine, fruits, and oil; and it imports corn, salt fish, salt butter, cheese, timber, iron, lead, tin, copper, coals, tar, and all sorts of foreign manufactures, with which it supplies the whole southern part of the kingdom. Lisbon has some manufactories of silks, paper, soap, and leather; its goldsmiths and jewellers are very expert; and there are also sugar refineries and potteries.

LITHARGE. [Red Lead.]

LI'THIUM, a metal, the oxide of which is one of the earths, and is called *lithia:* it occurs in a few minerals, combined with silica. When separated, the metal resembles sodium in whiteness; but it has not been much examined. None of the chemical compounds of lithium have yet been applied to much use in the arts.

LITHOGRAPHY. In printing from an engraving on a copper or steel plate, the ink is delivered from the incisions made therein with the graver or etching needle. An engraving on wood gives its results from the projecting surface of the block, or those parts which are not cut away by the graver. The lithographic process differs from both these modes, the impressions being obtained (by strict attention to chemical affinity) from a level surface.

There are various styles of lithography, but the principle of the art is uniformly the same.

The stone best calculated for lithographic purposes is a sort of calcareous slate, found in large quantities on the banks of the Danube in Bavaria. Stones much resembling the German have been found in some parts of Devonshire and Somersetshire, and also in Ireland; but they want some of the most essential qualities of those brought from Germany, which are therefore almost exclusively used. Even these vary much in quality, all the strata not being equally good. A good stone is porous yet brittle, of a pale yellowish drab, and sometimes of a gray neutral tint. The stones split into slabs varying from 1½ to 2½ inches in thickness, which are then cut or squared into the different sizes necessary for use, and the face or upper surface of each is made level. In this state the stones are sent from the quarry; but further preparation is yet necessary to fit them for the immediate use of the artist, and they are either grained or polished, according to the nature of the work they are intended to receive. Grained stones are used for drawings in the chalk manner, or for imitations of those produced with the black-lead pencil. Writings, imitations of etchings, pen and ink sketches, &c., require the face of the stone to be polished, which is effected by rubbing it with pumice-stone and water, or pumice-stone dust and water, applied with rags.

The two principal agents used for making designs, writings, &c., on stone, are called lithographic chalk and lithographic ink. They are composed of tallow, virgin-wax, soap, shell-lac, and enough lamp-black to impart a colour to the mass. These are incorporated by a peculiar process of burning in a closely covered saucepan over a fire, and the whole is ultimately cast into a mould, and receives the form calculated to fit it for use. The ingredients are the same in the chalk and the ink, but the proportions are varied. The chalk is used as it comes from the mould in a dry state; but the ink is dissolved by rubbing, like Indian ink, in water, and is used in a pen or camel-hair pencil. It is the presence of the soap in this greasy material which renders it soluble in water.

To render the lithographic process intelligible, let it be supposed that the artist completes a drawing with the chemical chalk just described, upon a grained stone. If, while in this state, a sponge filled with water were passed over the face of the stone, the drawing would wash out, the chalk with which it is made being, as we have seen, soluble in water, by reason of the soap which it contains. Before, therefore, it is capable of yielding impressions, a weak solution of nitrous acid is poured over it, which unites with and neutralises the alkali or soap contained in the chalk, and renders it insoluble in water. After this, the usual course is to float a solution of gum over the whole face of the stone; and when this is removed, if a sponge and water be applied to its surface, as before supposed, the drawing is found to be no longer removeable, because the chalk with which it is executed is now no longer soluble in water. In this state the work is ready for the printer, who obtains impressions by the following process.

Having thrown with the ends of his fingers a few drops of water on the stone, and spread them with a sponge, so as to wet, or rather damp, the whole surface equally, the printer finds that the water has been imbibed by the stone only on those parts not occupied by the drawing, which, being greasy, repels the water and remains dry. A roller properly covered with printing ink is now passed over the whole stone, which will not even be soiled where it is wet, from the antipathy of oil and water. But the parts occupied by the drawing, being, as we have seen, dry and greasy, have an affinity for the printing ink, which therefore passes from the roller, and attaches itself to the drawing. In this state it is said to be charged, or rolled in. Damped paper is then put over it, and the whole being passed through a press, the printing ink is transferred from the stone to the paper, and this constitutes the impression. By repeating in this manner the operations of damping the stone and rolling in the drawing, an almost unlimited number of impressions may be obtained.

The modes of lithography are, as we have said, various, but the illustration just given will explain the principle of them all. It consists in the mutual antipathy of oil and water, and the affinity which the stone has for both, *i. e.* in its power of imbibing either with equal avidity. Some of the coloured lithographs now produced are exquisite productions.

To insure complete success, great nicety is requisite in the preparation of all the agents employed in this art. Those who wish to study or practice the art in its full extent will do well to consult 'A Complete Course of Lithography,' by its discoverer, M. Senefelder, or 'A Manual of Lithography,' by M. Raucourt, both translated into English.

Plates of zinc have lately been much used as substitutes for the German stones, in chemical printing, and the practice is then called *zincography*: but, excepting the difference of the material on which the work is performed, it is precisely the same art as lithography.

LITMUS, or LACMUS, is a fine blue but fugitive colour prepared from the *Lecomora tartarea*, a lichen which grows in the Canary and Cape Verd Islands. In order to extract the colouring matter, the lichen is cleaned and reduced to powder; this is then mixed with urine and lime, and in a few days the blue colour is developed. The litmus is imported in small cubical cakes of dusky blue colour, which are light and easily reducible to powder.

Litmus is used as a chemical test for detecting the presence of acids, by which it is turned red, and the blue is restored by alkalis, so that when slightly reddened it may also be employed to detect alkalis. It will detect the presence of sulphuric acid, even when diluted with 100,000 times its weight of water.

LIVE STOCK. The animals necessary for the stocking and cultivation of a farm, and those which are kept on it for profit, or for the sake of their dung, are called the *live stock* of the farm, in contradistinction to the *dead stock*, which consists of the implements of husbandry and the produce stored up for use. To have the exact number of animals which will give the greatest profit is one of the most important problems which a farmer has to solve; and it also requires much experience and nice calculations to ascertain what stock is most profitable on different kinds of land and in various situations.

The following are the numbers of animals comprised among live stock, imported in the last two years:—

	1849.	1850.
Oxen and Bulls........	1,678	2,316
Cows	965	1,810
Calves................	1,002	1,345
Sheep	9,491	16,251
Lambs................	12	10
Swine and Hogs	199	675

LIVERPOOL. The advance of this most important commercial town has had few parallels in the world's history. In 1650 it is said there were only 15 ships belonging to the port. Towards the middle of the next century three docks were constructed for the convenience of the shipping employed in the African and West Indian trades. In 1764 more than half the African slave trade was carried on by the merchants of Liverpool. From the settlement of the cotton manufacture in Lancashire, Liverpool has become the port where the great bulk of the raw material of the manufacture is received, and whence the exports of manufactured goods are chiefly made to all parts of the world. The cotton imported into Liverpool is more than six-sevenths of the whole quantity imported into Great Britain. Still more recently, and especially since the employment of steam-vessels for the conveyance of merchandize, this port has enjoyed a very large proportion of the trade between England and Ireland, for the prosecution of which it is particularly well situated.

The magnificent docks of Liverpool, unequalled perhaps in the world, are noticed under DOCKS. The full number is now 21 docks, 2 half-tide docks, 8 graving docks and 4 basins. They are capable of containing 1500 sail. The annual income of the docks is about 300,000*l.*, and the charge about 280,000*l.*

The receipt of customs duties in 1850 was 3,366,284*l.*, against 3,472,202*l.* in 1849.

The growth of the trade of Liverpool has been very rapid. In 1816 there were 6,888 vessels entered the docks, of 774,243 tons burden, and paying in dock dues 92,500*l.*; whereas in 1850 there were 20,457 vessels entered Liverpool, of 3,500,000 tons burden, and paying 211,000*l.* dock dues.

Eight parts out of nine of all the American cotton brought to this country are shipped to Liverpool. There have often, in recent years, been 50,000 hogsheads of sugar, 20,000 barrels and bags of coffee, and 10,000 puncheons of rum, brought to Liverpool in one year. It has been estimated that 50,000,000 cwts. of goods have been shipped at the Liverpool docks in one year. As one among numberless illustrations, which might be given of the extent of Liverpool commerce, it has been stated that 27,000 cubic feet of logs of cedar for *pencils* have been in the docks at one time.

About two-fifths of the tonnage inwards and outwards are engaged in the trade with the United States of America. Liverpool keeps up a larger intercourse with Ireland than all the other English ports combined, and it has benefited more than any port in the kingdom (London alone excepted) from the application of steam power to navigation. Besides those which proceed to the United States and other foreign countries, steam ships of the first class proceed to and arrive from Dubiin daily; and it has communication more or less frequently with Drogheda, Belfast, Waterford, Newry, Londonderry, Glasgow, the Isle of Man, Whitehaven, Beaumaris, Bangor, Menai Bridge, and Carnarvon. Most of the Irish emigrants come to Liverpool to embark.

The inland trade of Liverpool is much assisted by means of canals, the most important of which in extent is the Leeds and Liverpool Canal, 128 miles long. The Mersey and Irwell navigation, the Duke of Bridgewater's Canal, and the Ellesmere Canal also connect Liverpool with the inland counties. Besides the various ramifications of the London and North Western Railway, there are now also the Liverpool and Bury Railway, and the Liverpool and Preston Railway.

One of the most interesting productions intended for the Great Exhibition, is a model of the commercial part of Liverpool, comprising the whole of the docks, and the great foci of trade and commerce in the town. The frontage of the town is almost five miles long, from north to south. The scale of the model is eight feet to the mile. There is also, associated in some respects with this model, a collection formed (or forming) of all the chief products imported into Liverpool; comprising a variety scarcely paralleled in any other British port. These two memorials of Liverpool greatness—the model and the collection of imports—will each occupy several hundred feet of space, and are intended to form a permanent exhibition at Liverpool after the grand but temporary display in London.

LIVONIA, one of the Baltic provinces of Russia, is a somewhat barren country. The chief occupations of the inhabitants are agriculture and the distillation of spirits. The country produces rye and barley, flax, hops, hemp, and linseed. The fruit, such as apples, plums, and cherries, is very indifferent. There are no minerals of importance nor manufactures, except in Riga. The exports are corn, hemp, flax, and linseed; the imports are salt, iron, lead, colonial produce, wine, manufactured goods, and articles of luxury.

LLAMA. This valuable South American animal was found by the Spaniards, when they conquered Peru, to be employed in bringing down ore from the mines among the mountains. Its ordinary load was 80 or 100 pounds, and its average rate of travelling with this burden was from 12 to 15 miles a day over rugged paths and through mountain passes; but, like the camel, if too heavily laden, it would lie down, and obstinately refuse to proceed; nor would it bear to be urged beyond its accustomed pace. Gregory de Bolivar estimated that in his day 300,000 were employed in bearing the produce of the mines of Potosia alone, and 4,000,000 annually killed for food.

As a beast of burden in its native mountains, whether of Peru or Chili, the Llama has yielded to the mule. But it is still most important on account of one of its qualities which attracted the attention of the ancient Peruvians; it is a wool-bearer, and that of no ordinary kind, the wool approximating in its character to silk. Large quantities of this material are imported into Europe for the manufacture of shawls and other delicate fabrics, and the improvement of this material has been made a subject of earnest consideration and trial. The *Alpaca* and the *Vicunu* seem to be species of Llama.

LOAM, is the name given to a soil compounded of various earths, of which the chief are silicious sand, clay, and carbonate of lime, or chalk. The other substances which are occasionally found in loams, such as iron, magnesia, and various salts, are seldom in such proportions as materially to alter their nature. Decayed vegetable and animal matter, in the form of humus, is often found in loams in considerable quantities, and the soil is fertile in proportion.

LOBSTER FISHERY. The lobster is found in great abundance on the rocky coasts of Great Britain, in clear water at no very great depth. Pennant mentions the great quantities supplied to the London markets, in his time, from the Orkneys and the eastern coast of Scotland; and states the number annually brought in well-boats from the neighbourhood of Montrose alone at sixty or seventy thousand. Lobsters being very voracious, the fishery for them is carried on sometimes by means of traps or pots made of twigs, baited with garbage, lowered into the sea, and marked by a buoy; sometimes by nets baited with the same materials; and in some countries, by torchlight, with the aid of a wooden instrument which acts like a forceps or a pair of tongs.

LOCKS AND KEYS. Great ingenuity is shewn in the numerous modes of shooting or working the bolt, in locks. In some locks the bolt is projected by the action of a spring; in others there are two or more bolts, one of which only is under the control of the key, the others being moved by handles; while in another class of locks two or more bolts are shot or projected by the action of the key alone. *Padlocks* are a kind of detached lock in which a curved bar of iron, pivoted to the lock at one end, may be passed through a staple, and then so secured by shooting the bolt into a cavity in its free end, which is inserted into the lock for the purpose, that it cannot be removed from the staples or links through which it has been passed.

By far the greater part of the almost innumerable ingenious contrivances for rendering locks inviolable may be classed under one of two systems of security. The first consists in the insertion in the lock of fixed obstacles, commonly called *wards*, which prevent the entrance of any key which is not formed with corresponding openings, so as to thread its way among them, and thus render the bolt inaccessible to any but the proper key. The second consists in the use of moveable impediments (which in their most general form are called *tumblers*) to the motion of the bolt itself, the security arising from the difficulty of bringing these moveable impediments, by the use of any but the proper key, to the actual and relative positions necessary to allow free motion to the bolt. In many locks both of the above means of security are used.

The key of an ordinary lock consists of a cylindrical shank with a loop-shaped handle at one end, and a piece called the *bit* projecting from it at a right angle at or near the other end. The bit end of the shank is hollow or solid, according as the lock may be opened from one side only, or from two. The projecting bit, after being introduced into the body of the lock through the key-hole, is turned round within the lock until it comes in contact with a part of the bolt which is so shaped that the bit of the key cannot pass it, to conplete its revolution, without shooting the bolt either backwards or forwards, as the case may be. When thus moved, the bolt is retained in its position by a spring, or some other means, until it is again moved by the reverse action of the key.

The varied and highly ingenious inventions of Chubb, Bramah, Mordan, and other lock-makers, depend on various combinations of the above two contrivances, the *ward* and the *tumbler*, aided by peculiarities in the form of the key.

As a means of security somewhat differing from any of the above, and affording certain advantages peculiar to itself, we may notice the *permutation* or *combination* principle, of which the simplest application is in a kind of padlock often termed a puzzle-lock, which opens without a key, but is regarded rather as an ingenious toy than as an available substitute for locks of the more usual construction.

Some locks have been made in which the action depends on the key being a powerful magnet. In others the difficulty of opening is increased by requiring a peculiar method of applying the key; but, in addition to the circumstance that the secret must be known to several persons, these contrivances have the disadvantage of being very inconvenient in use. In one invention a key with two bits, and requiring eight or nine distinct movements in the act of unlocking, is used with a double lock, capable of shooting two distinct bolts. Many contrivances have been effected for attaching an alarum to locks, by which the introduction of a false key should ring a bell or fire a pistol. But most of these contrivances are curiosities rather than conveniences. In the compound-locks for iron safes, which often throw out two or three bolts in every direction, that is to say, on each side, and towards the top and bottom of the door, these are usually but so many branches of four massive pieces of iron, capable of being simultaneously projected by a handle in the centre of the door, the actual lock being but small, and merely intended to move an apparatus by which the great bolts are themselves locked or held fast; so that the key need not bear

KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 28.

any proportion to the magnitude of the bolts by which the door is secured.

A most complete series of locks was constructed, some years ago, by the late Mr. Chubb, for the Westminster Bridewell. It consists of about eleven hundred locks, forming one series, with keys for the master, sub-master, and warders. At any time the governor has the power of stopping out the under keys, and in case of any surreptitious attempt being made to open a lock, and the detector being thrown, none of the under keys will regulate it, but the governor must be made acquainted with the circumstance, as he alone has the power, with his key, to replace the lock in its original state. These locks, although they have been in constant wear for sixteen years, are still in perfect condition.

Mr. Chubb, in an interesting work on this subject, remarks, 'The manufacture of locks and keys is carried on, principally, at Wolverhampton, and the adjacent towns in Staffordshire, as well as in Birmingham and in London, and gives employment to thousands of persons. Besides the home consumption, a large export trade is also carried on; and it is gratifying to know, that the use of the best locks, on which a great amount of labour is expended, is increasing, whilst greater attention has lately been paid to the style and character of the ornamental parts of both locks and keys."

Mr. Chubb has lately produced a remarkable specimen of lock-making. It is a gold finger-ring which instead of a stone contains a perfect padlock, on Chubb's patent principle, opening with its miniature key, all made of gold, and capable of locking and unlocking; the lock and key only weigh ten grains.

LOG AND LOG'LINE. This is the apparatus by which the velocity of a ship's motion through the water is measured. The log is a flat piece of wood, loaded with lead at one of its edges to make it float upright; and to this is attached a line about 150 fathoms long, divided into equal lengths by little pieces of knotted twine rove into it. These divisions begin about twenty or thirty yards from the log, where a piece of red rag is usually fastened, in order to show the place readily. From the lee quarter of the vessel the log is thrown into the sea, where it is supposed to remain stationary during the operation, and the line is veered out at least as fast as the ship sails. As soon as the red rag leaves the reel, a half-minute glass is turned, and, when the sand is all run down, the reel is stopped. Then, by measuring the quantity of line run out, the distance sailed by the vessel in half a minute is known, and by calculation its rate of going per hour. The usual way of dividing the line is to place the knots at distances of fifty feet from each other. Now, as 120 times half a minute make an hour, and 120 times fifty feet make almost a geographical mile, so many knots will run from the reel in one experiment as the vessel sails miles in the hour; from this comes the expression of a vessel's sailing so many knots an hour—meaning miles.

Mr. Berthon's log, patented in 1850, registers the speed of ships out at sea by the height of a column of water raised by the resistance. There are two tubes which project beyond the bottom of the vessel; those tubes have small apertures through which the water enters, the height of ascent being greater as the speed of the vessel increases. There are various minor contrivances to measure the speed by the indications obtained.

LOGWOOD, OR CAMPEACHY WOOD, imported from the West Indies for the purposes of the dyer, is the wood of a low tree called *Hæmatoxylon Campechianum*. The wood is hard enough to take a fine polish, and is very durable. Its colouring matter is dissolved both by water and alcohol, and it is principally derived from the presence of a peculiar body, to which Chevreul, who discovered it, gave the name of *hematin* or *hæmatoxyline*. Logwood is employed by the calico-painter to give a black or brown colour, the cloth being always first impregnated with alum mordant, and thus black is obtained. Iron mordant and logwood also yield a black, but it is not so good as with the alum mordant. Cloth with the alum mordant, dyed in a mixture of logwood and madder, has a fine brown colour fixed upon it. Logwood is also employed in the preparation of lake-colours. The logwood imported into Great Britain in 1850 amounted to 34,690 tons.

LOIRE. This important river, whose length is between 500 and 600 miles, constitutes the great outlet for the produce of central and western France. The Loire is connected with the Saône by the Canal du Centre, with the Seine by the Canals de Briare, d'Orléans, and du Loing, and with Brest harbour by the canal from Nantes to Brest; and it has many important commercial towns built on its banks.

The river also gives name to a department, which contains extensive forests of pine, fir, beech, and oak; on Mont Pilat, near St.-Étienne, an immense number of deals are made, saw-mills being established on every available stream of water. But much of the finest pine timber is made into charcoal, in consequence of the great difficulty of transport from the mountain-heights on which it grows. Great quantities of chestnuts are grown; these enter largely into the food of the people. The department contains one of the richest coal-beds in France, which, besides feeding the numerous factories and furnaces of St.-Étienne, and other places in the department, furnishes large quantities for exportation to Lyon and the towns on the Rhône. The quantity of coal annually furnished by the mines of Loire amounts to one-third of all the coal raised in France. Lead and iron mines are also worked; building stone, granite, potters' clay, &c., are found; mineral springs are numerous. The manufactures of the department are of the greatest variety and importance, and give rise to a very extensive commerce. The chief products are fire-arms, ironmongery, and machinery of all kinds, silks, ribands, crape, velvet, plush, laces, linen, cotton, glass, bricks, steel, iron, scythes, hardware, canvas, mill-castings, files and tools of all descriptions, cotton and linen yarn, lace, cutlery, earthenware, tiles, lime, &c. &c. Great numbers of coal barges and canal boats are built at Roanne and St.-Rambert. The great centre of manufacturing industry is St.-Étienne.

There are four other departments of France, whose names bear some resemblance to that of Loire; viz. *Loire-et-Cher*, *Loire Haute*, *Loire Inférieure*, and *Loiret*. They present varied aspects in respect to produce and manufactures; but are not so important in those respects as the department of the *Loire*.

LOMBARDY. The administration of the Austrian government in Lombardy has paid peculiar attention to the material improvements of roads, bridges, canals, dykes, and other public works. Among the most useful enterprises have been, constructing or repairing the dykes in the province of Mantua; completing the great canal called Naviglio; making roads in the mountainous districts of Bergamo, the great commercial road of the Splugen, and the road over the Stilfer Joch to Como and Lecco; and building the splendid bridge at Buffalora on the Ticino. Railways have also been constructed from Milan to Monza, 12 miles, Milan to Trevilio, 18½ miles, and Venice to Vicenza, through Padua; and others are in progress.

The Lombardo-Venetian kingdom is generally one of the most fertile countries of Europe; and the industry of the inhabitants, and the extensive system of irrigation, increase the natural fertility of the soil. Lombardy produces in abundance every thing that is necessary for the sustenance of its population —corn, wine, rice, fruits, cheese, and excellent meat. The chief articles of export are silk, rice, cheese, and hemp. The chief manufactures are silk, glass, paper, bronze works, and straw hats; but Lombardy is essentially an agricultural country, and receives most of the manufactured goods which it uses from the other parts of the Austrian monarchy. The bookselling and publishing trade, although subject to the censorship, is (in peaceable times) more flourishing at Milan than in all the rest of Italy put together.

A little further information concerning the industrial statistics of this beautiful country will be found under the names of some of the provinces and cities.

LONDON. To present a few industrial statistics of this, the greatest commercial city in the world, is of course all that can be attempted in a work like the present.

In the City of London there are 89 companies or guilds connected with trades or employments, eight of which are practically extinct; and one other, that of Parish Clerks, is not connected with the municipal institutions of the city. Most of the companies possess what is called a *livery*; that is, a part of their body, under the name of liverymen, if they be freemen of the corporation, enjoy privileges which other freemen do not possess—such as voting for mayor, sheriffs, chamberlain, &c. Most of the guilds have long ceased to be practically beneficial to the crafts to which they relate. Most of them are in possession of real property and money in the public funds, both for their own use and on various trusts. The Irish Society is a corporation connected in a peculiar manner with the corporation of London; its property is chiefly in the county of Londonderry, in Ireland.

That London is not commonly considered as a manufacturing town is owing to the more important aspects under which it presents itself, and not because of the absence of manufacturing industry. Manufactures of almost every kind are in fact carried on in the metropolis, and upon a scale of great magnitude. The largest breweries, distilleries, and sugar-refineries in the kingdom are in the metropolis. The manufacture of metals in almost every branch is carried on to a vast extent. Almost every kind of machinery, from the smallest wheels required by the watch-maker to the most powerful steam-engines, are made in London. The making of gold and silver articles, of optical and surgical and other instruments, tools of the best quality, and musical instruments, gives employment to numerous hands. Ship-building, with all its accessories, rope-making, mast-making, block-making, anchor-making, &c., has always been actively prosecuted. There are also numerous chemical works on a large scale, tanneries, soap-manufactories, potteries, and dyehouses. Male and female clothing of all descriptions is made, not merely for the use of the inhabitants of the metropolis, but for the supply of wealthy persons in various parts of the kingdom and even in the British colonies. There are not much fewer than 1500 separate trades or occupations carried on in the metropolis. The metropolis is also the great workshop of literature, science, and the arts. The number of books printed and published in all other parts of England is small in comparison with what is produced in London.

It is not possible to state with any pretensions to accuracy the amount of consumption in London of any except a very few articles of general use, because such commodities are becoming less and less under Excise and Customs regulations. The cattle sold in Smithfield amount to nearly 200,000 annually; sheep, 1,600,000; calves, 25,000; and pigs, 250,000. But, besides these, a large amount of slaughtered meat is now brought to the metropolis by railway and steamers. There are 5000 licensed publichouses, besides beer retailers, and exclusive of inns, hotels, and wine merchants. There are 1600 butchers' shops, 2400 bakers' shops, and 2800 grocers and tea dealers. The coffee shops are now very numerous. Concerning the recent arrivals of Coal and Corn in London, see those articles. See also Market-Gardens.

The relative proportion of the foreign and colonial trade enjoyed by the merchants of London, as compared with those of other ports, may be shown from the fact, that out of the gross receipt of customs at all the ports of the United Kingdom, usually about 22,000,000*l.* sterling, that of London about equals all the other ports combined. The shipping entries vary; but on the whole there is a constant progressive increase. In 1848 the amount was :—

	Vessels.	Tons.
From Foreign Countries .	7,686	1,267,875
From the Colonies	1,843	546,195
Coastwise.............	22,584	3,242,572
	32,113	5,056,642

The vessels which left London with cargoes we may presume to be about equal in number. The ships which entered the port of London from Foreign Countries alone, in 1850, amounted to 9,910, of 1,903,407 tons.

There are about 50 wharfs on the north and south banks of the Thames, within the limits of the metropolis, besides the canal wharfs and the docks for the shipping destined to foreign countries.

The facilities for accommodating shipping are noticed under Docks. The railways from the metropolis are mainly accommodated at six large stations: viz. Euston Square, King's Cross, Paddington, Waterloo Bridge, London Bridge, and Shoreditch; besides a smaller station in Fenchurch Street, and separate goods' stations at Camden Town, Vauxhall, and Bricklayer's Arms. The chief canal of London is the Regent's Canal, which curves round the northern part of the metropolis from Limehouse to Paddington (whence it communicates with the northern and western parts of the kingdom), and has several basins and wharfs: the remaining canals are all short, and comparatively unimportant.

There is no port in the kingdom which has profited more than London through the application of steam to navigation. A great part of the steam vessels that arrive and depart carry passengers only, and are therefore not required to make entry at the custom house, and with regard to such as carry goods no distinction is made at the custom house between them and sailing vessels; for which reasons no accurate account of the number of this class of ships that enter and leave the port can be given. Steam passage-boats are passing and repassing daily between London, and Chelsea, Kew and Richmond, and in summer some go up to Hampton Court; and between London and Greenwich, Woolwich, Gravesend, and other places, downwards; while, at less frequent intervals, steamers start from the Thames to nearly all the principal ports in the United Kingdom and throughout Europe.

That such a gigantic focus of industry will take up a worthy position in the Great Exhibition of All Nations, may well be expected and believed.

LONDONDERRY. In this county railways are in progress from Londonderry to Enniskillen, and from Londonderry to Coleraine. A remarkable feature of the last-named scheme is, that the railway is to cross Loch Foyle on an embankment 19 miles long, as a means of inclosing and reclaiming 18,000 acres of land. The best improved portions of the county are the district of Loch Neagh, the valley of the Roe, the valley of the Faughan, and the immediate vicinity of Londonderry on both sides of the Foyle. There is a very general scarcity of timber. The progress of agriculture in this county has been materially forwarded by the establishment of an agricultural school near Muff by the Company of Grocers of London, who here hold large estates under the crown. Oats and barley are the principal grain crops.

The manufacture and bleaching of linens is the staple trade of the county. The most extensive bleach-greens lie along the rivers Roe and Faughan, on the latter of which there is abundant water-power and numerous sites admirably calculated for this branch of manufacture. The weavers and flax-dressers are numerous. The export and import trade of the county is carried on at the ports of Londonderry city and Portrush, the latter being the seaport of Coleraine.

LOOM. [WEAVING.]

LOT. There are two departments of France which take their names from the river Lot. One, the department of Lot, is very fruitful. The hill-slopes along the rivers are generally laid out in vineyards, which yield annually 13 to 14 million gallons of wine, the best kinds being those of Cahors and Grand-Constant. About two-thirds of the whole produce is exported or distilled into brandy. The white mulberry is extensively cultivated for the production of silk. A few iron and coal mines are worked; lead, calamine, marble, millstone grit, granite, limestone, potters' and fullers' earth, &c., are found. Of manufacturing activity there is little; a little bar and cast iron, coarse cotton and woollen stuffs, brandy, and paper, are made. The corn-mills, which are about 1000 in number, are the only important manufacturing establishments in the department. The commerce is composed of the articles already indicated, and of hides, salt, oak-staves, groceries, small wares, broad cloth, &c.

The other department, that of Lot et Garonne, produces 14 to 15 million gallons of wine yearly, half of which goes for the home consumption; part of the surplus is distilled into brandy, and the remainder is exported to Bordeaux. Immense numbers of geese are reared, and form an important article of export. Iron mines are worked; good building stone, calcareous spar, gypsum, and marl are found. The chief manufactures are cork, sailcloth, linen, swanskins, pottery, linen and cotton yarn, iron, glass, paper, lime, ropes, leather, tobacco. The commerce is composed of the various industrial and agricultural articles enumerated, and of pitch and tar made from the pines of the Landes.

LOUISIANA. A few industrial statistics relating to this fruitful portion of America, will be found under UNITED STATES and NEW ORLEANS.

LOUTH, a maritime county of the province of Leinster in Ireland, is not rich in minerals. Iron and lead ore are the only minerals which have been observed, but nowhere in sufficient quantity to warrant mining operations. The soil of the southern division of the county is well calculated for every kind of grain crop. Farming in general is carried on in a superior manner. Green crops are grown by almost all the gentlemen farmers. The fences are usually of quickset, and the lands well drained. The linen manufacture is carried on with some activity at Ravensdale and Collon, where there are large bleach greens, but chiefly in Drogheda and its neighbourhood, where the trade is generally very brisk. The fisheries off the coast give occasional employment to several hundred persons.

Dundalk carries on a brisk trade, chiefly in the exportation of grain, cattle, and other agricultural produce, and in the importation of groceries and goods in boxes and bales for the supply of the counties of Louth, Monaghan, and Cavan. Steamers ply regularly to Liverpool twice a week. Drogheda is briefly noticed in respect to its commerce elsewhere.—[DROGHEDA.]

LÜBECK. The commerce of this celebrated city is of considerable importance. Lübeck has 80 ships of its own, and the arrivals are about 800 annually. The principal export and import trade is with Russia, Sweden, and Denmark; vessels of 9 feet draught can come up to Lübeck, where they enter a spacious basin lined with quays; larger ships discharge their cargoes by lighters at *Travemünde*, which is situated at the entrance of the Trave into the Baltic, and has a fine secure harbour. Steamers ply from Travemünde to St. Petersburg, Copenhagen, Hamburg, Amsterdam, and Stockholm. Small steamers convey passengers up the river to Lübeck. Lübeck was one of the most famous of the HANSE TOWNS.

LUCERNAL MICROSCOPE, is an optical instrument invented by Mr. Adams. It consists of a hollow pyramidal box, at the smaller extremity of which is a tube carrying the usual system of lenses for magnifying objects. At the larger end, which is towards the observer, there are two lenses in frames, their axes, as well as those of the small lenses at the opposite extremity, being coincident with the axis of the box; and between the exterior of the two lenses and the eye of the observer there is usually placed a plate of glass, rough-ground on one side, which serves as a screen to receive the rays of light proceeding from the object whose representation is to be viewed. The object is fixed in a small frame, as usual, and is placed in a groove made for the purpose immediately beyond the tube containing the system of lenses at the small end of the box. Instead of the plate of ground glass, a board painted white is frequently placed, to serve as a screen, at the distance of 6 or 8 feet from the instrument. Such a screen should have the form of a segment of a hollow sphere, the light being received on its concave surface. An Argand lamp, or an oxy-hydrogen light, is placed beyond the object. The light, after passing through a hemisphere of glass, is, when an opaque object is to be viewed, made to fall in a convergent state upon a small concave mirror, which is so inclined as to reflect the light back upon the object; and from the different points on the surface of the latter the pencils of rays proceed through the object-lenses and the box to the glass screen.

By the refraction of the light in passing through the lenses a highly magnified image of the object is formed; and several persons may then place themselves so as to see the image on the screen at the same time; or, by placing the eye at the small aperture in the produced axis of the instrument, one person may, with a pencil, draw on the glass, or on tracing-paper laid over it, the figure of the object, it being understood that the instrument is used by night or in a darkened room.

When the object to be viewed is transparent, the light is made to fall in a condensed state upon it, after having been transmitted through a convex lens, or two such; and from the object the rays proceed as before to the screen through the system of lenses which constitute the compound object-glass of the microscope, and through those at the opposite extremity of the box.

LUPULIN, is a substance extracted from hops, and containing from 8 to 12 per cent. of the vegetable matter to which hops owe their power, and to which the name of *lupulite* has been given. Lupulite is nearly colourless, but sometimes of an orange colour: in the former case it is opaque, but in the latter transparent; it has no smell till it is heated, and then it has the odour of hops; its taste is bitter.

LUTE, is a musical stringed instrument with frets, one of the numerous varieties of the ancient *Cithara*. Till towards the end of the 17th century its practice formed an essential part of a good education, but it has since been partially superseded by the guitar. The lute consists of three parts: the table, made of fir; the body or belly, of the same wood or cedar, constructed of nine convex ribs joined; and the neck, on which was fixed the finger-board, of hard wood, having nine frets made of catgut. To these is to be added the head or cross, in which the pegs or screws were placed. The lute had at first six strings, or rather eleven, for the five largest were doubled; but the number was gradually increased till it reached twenty-four.

LUTES, in chemistry, are substances employed in various operations for closing the joints of apparatus, and especially for connecting retorts and receivers so as to prevent the escape either of the vapour or gases generated during distillation or sublimation. The term lute is also applied to the external coating of clay and sand, or other substances applied to glass retorts, in order that they may support a high temperature without fusing or cracking. Common plastic clay answers sufficiently well in some cases, but in some small distillations, as of nitric acid, the Fat Lute is used, which is prepared by mixing dried and powdered pipe-clay into a paste with linseed oil; and the joint is further secured, both where this lute is used and in many other cases, by tying it over with moistened bladder. In luting common stills, in which oils or water are merely distilled, linseed meal and water made into a paste, form an effectual lute.

In luting, or rather coating, glass retorts, in order to enable them to sustain high temperatures, Stourbridge clay or Windsor loam mixed with tow have been used; but they require long drying, and are apt to crack. The simplest mode is that of brushing the retort over with a paste of pipe-clay and water, sifting sand upon it, drying it quickly in the ash-pit of the sand-heat, then covering it again with clay and sand, and repeating the alternate applications and drying till the coating is judged sufficiently thick.

LYNX FUR. The lynx skins imported for furriery purposes in 1847 amounted to 32,540 and in 1848 to 47,317.

LYON or LYONS. This most important French town is very advantageously situated on the line of railway from Paris to Marseille, now in course of construction, and on two navigable rivers the Rhône and the Saône, in the fork between which the greater part of the town is built.

Lyon is a flourishing manufacturing town. The staple articles of industrial produce are silk stuffs of all descriptions, which for solidity of texture, richness and permanence of dye, and beauty of design, are not equalled elsewhere. In this manufacture about 100,000 of the population are directly or indirectly concerned. Cashmere and silk shawls, ribands, cotton cloth, hosiery, hats, printed calico, jewellery, liqueurs, chemical products, gold and silver lace, crapes, tulle, glue, sheet lead, musical strings, ornamental paper, &c., are also made. There are, besides, numerous printing establishments, dye-houses, metal foundries, glass works, potteries, tan-yards, breweries, boat building yards, &c.

Lyon is also, from its advantageous position, a place of great commerce. The products imported into the town, for its own consumption, or for re-exportation, are wine, brandy, oil, hemp, flax, soap, rice, chestnuts, salt, raw cotton, coffee, indigo, sulphur, lead, teazels, madder and other dye-stuffs, &c. Timber, firewood, building stone, and asphalte are the chief articles brought down the Rhône to this city. Down the Saône are brought timber of all kinds, oak staves, fire wood, charcoal, tanning bark, iron and iron ore, gypsum, hay, straw, corn, building stone, bricks, tiles, &c. Steamers ply on the Saône to Châlon-sur-Saône, and on the Rhône to Avignon and Arles. The town has communication with the Rhine by the Canal du-Rhône-au-Rhin; and with Paris by the Saône and the canals that join it to the Seine. A railroad, 35 miles in length, unites Lyon to the great manufacturing town of St. Etienne and the extensive coal fields of the department of Loire.

LYRE. This musical instrument has been known under various names, from the earliest historical period. Some of the Greeks ascribe its invention to Mercury, some to Apollo; but it is possible they may have had it from the Egyptians, and the Egyptians from Asia. Of many instruments, figured or described in early writings, it is difficult to decide whether they should be termed lyres, lutes, harps, or guitars. The most ancient Grecian lyre had only three strings. That of Terpander had seven. Timotheus increased the number to eleven; and others were gradually added, till they reached sixteen, fifteen of which rendered the principal sounds in the Greek scale, and the sixteenth was the added or supernumerary sound.

M

MACCLESFIELD, is one of the silk manufacturing towns of the north. The various factories are situated on the Bollin. One of the cotton factories cost 30,000*l*., and some of the silk factories 14,000*l*. The silk trade of Macclesfield progressively advanced from 1808 to 1825, when it attained its greatest prosperity. It has since been less prosperous, but is still large. Every variety of silk article is produced here, from the narrowest riband to the different kinds of sarsnets, plain and figured gros de Naples, satin, silk, vestings, and velvets. It is likewise the chief place for the manufacture of silk handkerchiefs of every description.

MACE. [NUTMEG.]

MACERATION is the steeping of substances in cold liquids, either merely to soften the parts of the substance operated on, or to dissolve the aromatic parts of a substance when *digestion* would not merely dissolve but dissipate them.

MACHINE; MACHINERY. The advantage which any machine affords for overcoming resistance consists in the reaction by which it supports a certain portion of the weight producing that resistance, so that the motive power has only to counteract the remainder. This may be immediately observed in those simple machines called the *mechanical powers*. For example, in the lever, the wheel and axle, and the pulley, any convenient portion of the resistance may be made to rest on the point of support, or the point of suspension. Again, in the inclined plane, the wedge, and the screw, the motive power, the resistance and the reaction of the support, being, in the case of equilibrium, represented by the three sides of a triangle, the ratio of the first to either of the others may be varied at pleasure by the construction of the machine.

The powers employed to give motion, through machinery, to any object, are produced by the muscular strength of men or animals; the actions of weights, springs, wind, water, steam, or fired gunpowder; and these powers may generally be considered as pressures exerted during certain portions of time. Even that power which is produced by a sudden impulse, as when a rammer descending by its weight falls on the head of a pile, is only a pressure existing during an indefinitely short interval of time. The point in any machine to which the moving power is applied is called the impelled point, and that against which the resistance acts is called the working point.

In the classification proposed by Dr. Lyon Playfair, and adopted by the Commissioners at the Great Industrial Exhibition, *machinery* forms one of the four great divisions into which the specimens exhibited are to be disposed; and this division is subdivided into six classes; viz. 1. Machines for direct use, including carriages, and railway and naval mechanism; 2. Manufacturing machines and tools; 3. Mechanical, civil engineering, architectural and building contrivances; 4. Naval architecture, military engineering and structure, ordnance, armour, and accoutrements; 5. Agricultural and horticultural machines and implements; 6. Philosophical, musical, horological, acoustical, and miscellaneous instruments. This classification is doubtless convenient for the immediate object in view; but it gives to the word 'machinery' a much wider application than is ordinarily adopted.

Our exports of machinery and mill-work in 1850 amounted in value to 1,043,764*l.*

MACKEREL FISHERY. [FISHERIES.]

MADDER. This useful dye-drug is procured from one of the many species of the plant *Rubia*, a name derived from *ruber* (red), in allusion to the red colour yielded by many of the species. Amongst the numerous species several are employed in medicine and in the arts; in the latter for the sake of the colouring matter which is contained in the roots. *Rubia tinctorum*, Madder, has been long known, and was employed in medicine even in the time of Hippocrates, but is valued chiefly as a dye. It is a native of Europe and Asia Minor, but is now extensively cultivated in Holland and France; the culture has likewise been attempted, and successfully, in this country; but the English madder could not be sold so cheap as the foreign; it is therefore still largely imported, chiefly from Holland, France, Italy, Turkey; though cochineal, since it has become cheaper, is much used for the same purposes. It is employed by dyers and calico-printers as a red and scarlet dye. It has also the singular property of turning red the bones and secretions of fowls and other animals fed on it. *Rubia cordifolia*, the *Munjeet* of India, a native of Nepaul, &c., possesses similar properties, and is imported into England from Calcutta.

About 254,722 cwts. of madder and madder root were imported in 1849, and 261,841 in 1850.

MADEIRA. This beautiful and fruitful island produces many tropical plants near the sea-shore. Above this region, to a height of from 750 to 2,500 or 2,800 feet, the fruits and grain of Europe, especially wheat and maize, are raised; and in this region are also the extensive vineyards, which till recently furnished the most important article of exportation. Then follows a tract covered with high trees, which rises to 3,200 feet and higher, where many plants and trees are found which do not occur in Europe; and above this level is a region of grass, fern, and heath. The commerce of Madeira is considerable. The exports consist chiefly of Madeira and Malvasia de Madera wines. Minor articles of export are, fruits, dragon's blood, honey, wax, orchil, and tobacco, besides provisions for the vessels bound to more remote places. The imports consist of manufactured goods, corn, fish (herrings and cod), oil, salt-beef, salt, and some tropical productions. The imports into Great Britain from Madeira consist mainly of wine and nutmegs. The wine imported thence in 1847 amounted to 154,701 gallons.

MADRAS. A few commercial statistics of this city and presidency will be found under EAST INDIA COMPANY.

MADRID, has no commercial or industrial features to call for notice here, further than such as are described under CASTILE and SPAIN.

MAGAZINE, is a strong building, constructed generally of brick or stone within a fortified place, or in the neighbourhood of a military or naval station, in order to contain in security gunpowder or other warlike stores. The buildings in which gunpowder is contained are constructed with every precaution necessary to insure dryness. They are generally in places remote from other buildings; they are furnished with metallic conductors, in order to avert danger from lightning; and, for security against the attempts of ill-disposed persons, they are surrounded by a wall and ditch. The great magazines which have been constructed in this country consist of several parallel vaults, separated from each other by brick partition-walls, in which are doorways for affording lateral communication. Each vault is about 90 feet long, 19 feet wide internally, and from the floor to the crown of the arch 19 feet high. The side walls are from 8 to 10 feet thick, and are strengthened by buttresses built at intervals against them. The thickness of the brickwork forming the vaulted roof is 7 or 8 feet at the crown, and about 3 feet at the hances.

MAGDEBURG. The industry and commerce of this portion of the Prussian dominions receive a few illustrations under PRUSSIA.

MAGIC LANTERN. The object of this remarkable optical instrument is to obtain an enlarged representation of figures on a screen in a darkened room, by means of the pencils of light issuing from a lamp or candle and passing through a convex lens.

The instrument consists of a lantern generally of tin, and of a cubical form, in the interior of which is the light; and at a perforation in one of the sides is applied a tube, projecting horizontally from it, which carries two glass lenses. A groove in front of the lantern and parallel to that front receives a rectangular frame containing the glass plates on which are painted, with transparent colours, the objects of which an enlarged view is to be obtained. A remarkable improvement in the manner of employing the magic lantern was first exhibited in London in the year 1802. The lantern itself is similar to but larger than that which serves for more general purposes, and the images are represented on a transparent screen, which is stretched in a vertical position across a theatre or an apartment; and, this being made quite dark, the spectators occupy the space in front of the screen, while the apparatus is disposed on the opposite side. All light is excluded both before and behind the screen, except that which, in proceeding from the lantern, produces the image to be observed; and, the screen being itself invisible, the spectators can scarcely divest themselves of the idea that they are looking into a dark cavern, in which the objects appear to be gradually advancing towards or receding from them. The allusions produced have caused the name of *Phantasmagoria* to be applied to the apparatus.

The magic lantern and the phantasmagoria are used only for purposes of amusement; whereas the CAMERA OBSCURA has been made available in photography.

MAGNESIA. This name, derived from a province in Asia Minor, has been applied to several useful substances which contains the metal *magnesium* as a basis. Oxide of Magnesium, termed also, from the mode of procuring it, *Calcined Magnesia*, is an alkaline earth, possessing the usual qualities of alkalies in their habitudes with acids, and likewise very valuable properties as a medicine. Sulphate of Magnesia, or *Epsom Salts*, in the ordinary form, as met with in the shops, are small acicular crystals. [EPSOM SALTS]. *Magnesia Alum*, *Magnesia Pharmacolite*, and *Magnesite*, are three naturally formed minerals, in which magnesia is a chief element. *Magnesian limestone* is a valuable building stone. *Magnesium*, the base of all these substances, is of a white colour, like silver; its lustre is metallic and brilliant; it is very malleable, and fuses at a red heat. When heated to redness in the air or in oxygen gas, it burns brilliantly, and, combining with oxygen becomes magnesia. *Chloride of Magnesium* forms a transparent colourless mass: it is inodorous, intensely bitter, very deliquescent, and soluble both in water and alcohol. This salt is one of the saline ingredients of sea-water. Carbonate of magnesia constitutes the *Common Magnesia* of the druggists.

MAGNETIC POWER. The combination of Magnetic power with galvanic power, in several recent mechanical contrivances, are briefly noticed under ELECTRO-MOTION and TELEGRAPH.

MAGNOLIA. This genus of American and Asiatic plants includes many species which are applied to useful purposes. Of the *Swamp Magnolia*, the bark has a bitter and aromatic odour resembling sassafras. On this account it has been used in America as a substitute for other aromatic bitter barks, as Cascarilla, Canella, &c., and, it is said with great success. Although not much used in Europe, very favourable reports of its efficacy in chronic rheumatism, ague, and remittent fever have been given. Of the *Cucumber-tree*, another species, a tincture is made of the fruit, and is used in cases of rheumatism. Other species are applied to useful purposes, chiefly in North America.

MAHOGANY. There are many species of trees belonging to the genus *Sweetenia*, which include among them the mahogany. One of the species yields the *African Mahogany*, brought from Sierra Leone; the timber is hard, but is liable to warp; it is employed where a hard cheap timber of large scantling is needed; the negroes employ an infusion of the bark in medicine. Another species yields the beautiful East Indian *Satin-wood*, which is of a deep yellow colour, close grained, heavy, and durable. The most useful and well-known species, however, is the *Campeachy Mahogany*; the timber of which is so familiar to us as to need no description. It appears to have been first imported into this country about the year 1724. From the elevated parts of the country the wood is closer grained and darker coloured than that grown near the coast; the former is termed *Spanish* and the latter *Honduras* mahogany. Spanish mahogany is imported in logs about ten feet long, and from twenty to twenty-six inches square; whereas Honduras mahogany can be procured in logs of larger size. When the grain of mahogany is more than usually beautiful, it will obtain a price for fancy cabinet-work far beyond the usual market standard. On one occasion Messrs. Broadwood, the eminent piano forte manufacturers, gave 3,000*l.* for three logs of mahogany, which were each about 15 feet long by 38 inches square; it was of exquisite beauty and closeness, and was cut up into thin veneers for the more costly pianofortes.

Since the abolition of the duty on mahogany, the import has largely increased. In 1848 the import was 32,000 tons. The attention of ship-builders is being attracted towards the fitness of mahogany for building vessels.

MAILS. A few words concerning the Post Office Mails, as a remarkable commercial feature of our age, will be found under Post Office.

MAINE. The productions and industry of Maine claim a little of our attention under United States.

MAINE-ET-LOIRE. In this department of France about 11,000,000 gallons of white and red wine are made annually, some of which is of good quality. Since 1838 a good deal of effervescing wine, resembling the true champagne, and rivalling it in quality, has been manufactured. The department is famous for its melons. A considerable quantity of cider is also made. Iron and coal mines are worked; and marble, granite, building and lime-stone, slate, and potters' clay are quarried. The slate quarries of the department, especially those of Angers, are vast and frightful excavations, worked right from the surface of the ground. They give employment to about 3000 men, who raise about 80,000,000 slates annually. The number of factories and workshops of different kinds in the department is about 200, in which sail-cloth, linen, cotton handkerchiefs, flannels, paper, oil, cotton and woollen yarn, &c. are made. There are also numerous tanyards, sugar-refineries, distilleries, bleach-mills, and dye-houses.

MAIZE, or *Indian Corn*, is a plant commonly cultivated in the warmer parts of the world, where it answers a purpose similar to that of wheat in more northern countries. It is the *Zea Mays* of botanists, of vigorous growth, with stems of not more than two feet high in some varieties, and reaching the height of eight or even ten feet in others. Each grain has a long thread-like style, which projects beyond the enveloping sheaths; and as there are some hundreds of them upon each spike, the whole form a long tassel, which looks as if made of silk. A plant generally bears two full ears, the grains of which vary greatly in number: some of the largest ears in America contain at least 800 grains.

This plant in its wild state is met with in Paraguay, in Chili, and in North America. The bread made from maize is not so palatable to some as wheat bread, but, by mixing it in certain proportions with wheat, it makes a very pleasant food. In the United States of North America, Indian corn forms almost the only bread eaten by many of the people; and in the slave states it is the only bread that the negroes eat. It is not, however, in the shape of baked bread that maize is most generally used in Europe, but in boiled messes and soups, as peas are with us.

A light, moist, and warm soil suits this plant best. It thrives well on land broken up from grass. The time for sowing maize in the south of France is the month of April; farther north, it is sown later. When the maize is fully ripe, the ears are twisted off by hand and laid in a dry place; they are turned occasionally, that the sheath may not become musty, and are then stored in a dry place. The leaves are gathered for fodder a short time before the ears are pulled. In America and in Italy mattresses are stuffed with the dry sheath, which makes a cool and elastic bed. Horses, pigs, and poultry are fond of maize; it gives the flesh of the last two a peculiarly fine flavour. One of the most important uses of maize in Europe is to sow it thick, to be cut green as food for cows, oxen, and sheep. In a proper climate there is no plant which gives so great a mass of green food as maize. The produce is most abundant and nutritive.

Since the repeal of the Corn Laws, maize has been imported in considerable quantity into this country. The importations for the last three years were as follows:—

1848	1,575,521 qrs.
1849	2,224,459 „
1850	1,286,264 „

About 230,000 cwts. of maize-flour were imported in 1848; but the quantities in the next two years were much smaller.

MALAGA. From the earliest agss, under all the nations who have possessed it, this Spanish sea-port has been renowned for its commerce. Its imports are colonial produce, broad cloths, cottons, laces, spices, hardware, and cutlery. Its exports amount to about 1,000,000*l.* sterling annually. They consist of wine, grapes, muscadel raisins, almonds, figs, lemons, olive oil, brandy, anchovies, and lead. The harbour is spacious enough to accommodate a large fleet; it is protected on the east by a massy stone mole, five furlongs in length, and terminated by a handsome light-house.

MALIC ACID was discovered in 1785 by Scheele. It received its name from having been first obtained from the juice of apples, in which it exists in considerable quantity; but it also exists in many other fruits. Malic acid is colourless, inodorous, very sour to the taste, and acts strongly on vegetable blues; in a moist air it is deliquescent; it is very soluble both in water and in alcohol. Nitric acid converts it into oxalic acid. Its saline compounds are called malates, some of which exist in nature. They are not an important class of salts.

MALLEABILITY is that property of certain metals which admits of their being extended by the blows of a hammer or by pressure. In this quality gold exceeds all other metals: thus the gold-leaf sold in books is so extremely thin, that less than 5 grains cover about 270 square inches, and the thickness of each leaf does not exceed $\frac{1}{200000}$th part of an inch. Metals which are malleable are also ductile, that is, they may be drawn into wire. Iron which has been made hot by hammering loses its malleability, and cannot be again hammered till it has been annealed.

MALLOW. The common or *Marsh mallow* belongs to the *Malva* genus of plants. It grows in waste places and road sides; and the whole plant, but especially the root and the leaves, yield by boiling a mucilage which is very useful in medicine.

MALMSEY. This luscious and high-flavoured wine is made in the island of Madeira from grapes of a peculiar kind, which are suffered to attain the last stage of ripeness before they are gathered. Malmsey wine has much body, and will retain its good qualities for a long time. When newly made, Malmsey Madeira is of the same golden hue as the ordinary wine of the island, but its colour is materially deepened by age. Malmsey wine is also made in the island of Teneriffe, but the quality is greatly inferior to that of Madeira.

MALT AND MALTING. Malt is grain, usually barley, which has become sweet and more soluble in water, from the conversion of its starch into sugar by artificial germination to a certain extent, after which the process is stopped by the application of heat. The making of malt, called *Malting*, is conducted as follows—The barley is steeped in cold water for a period which (as regulated by law) must not be less than 40 hours; but beyond that period the steeping may be continued as long as it is thought proper. Here it imbibes moisture, and increases in bulk; at the same time a quantity of carbonic acid is emitted, and a part of the substance of the barley is dissolved by the steep-water. 100 bushels of grain, after being steeped, swell to the bulk of 120 bushels; and the quantity of matter which the steep-water holds in solution varies from $\frac{1}{50}$th to $\frac{1}{100}$th of the weight of barley. It consists chiefly of an extractive matter of a yellow colour and disagreeable bitter taste. After the grain has remained a sufficient time in the steep, the water is drained off, and the barley thrown out of the cistern upon the malt-floor, where it is collected into a heap called the *couch*, about 16 inches deep. In this situation it is allowed to remain about 26 hours. It is then turned by means of wooden shovels, and is diminished a little in depth. This turning is repeated twice a day or oftener, and the grain is spread thinner and thinner, till at last its depth does not exceed a few inches.

When placed in a couch, it begins gradually to absorb oxygen from the atmosphere, and to convert it into carbonic acid, at first very slowly, but afterwards more rapidly. The temperature, at first the same with that of the external air, begins slowly to increase; and in about 96 hours the grain is at an average about 10° hotter than the surrounding atmosphere. At this time the grain, which had become dry on the surface, becomes again so moist that it will wet the hand, and exhales at the same time an agreeable odour, not unlike that of apples. At the time of this moistening, which is called *sweating*, the roots of the grains begin to appear, at first like a small white prominence at the bottom of each seed, which soon divides itself into three rootlets, and increases in length with very great rapidity, unless checked by turning the malt. About a day after the sprouting of the roots, the rudiments of the future stem, called *acrospire*, may be seen to lengthen. It rises from the same extremity of the seed with the root, and, advancing within the husk, at last issues from the opposite end; but the process of malting is stopped before it has made such progres.

As the acrospire shoots along the grain, the appearance of the kernel, or mealy part of the corn, undergoes a considerable change. The glutinous and mucilaginous matter is taken up and removed, the colour becomes white, and the texture so loose that it crumbles to powder between the fingers. The object of malting is to produce this change: when it is accomplished, which takes place when the acrospire has come near to the end of the seed, the process is stopped by drying the malt upon a kiln. The temperature at first does not exceed 90°; but it is raised very slowly up to 140° or higher, according to circumstances. The malt is then cleared, to separate the rootlets, which are considered injurious. In familiar language, malting may be considered as a change of the *starch* of grain into *sugar*, preparatory to a further change into *spirit*.

The subsequent processes of BREWING and DISTILLATION are described in previous articles.

The quantity of malt charged with excise duty in the last three years was as follows:—

1848..............	37,545,912 bushels.
1849..............	38,935,460 „
1850..............	40,745,050 „

MALTA. The Maltese harbour is about 3,400 yards in length, with an entrance 450 yards wide, defended by a strong fort. The harbour varies in width from 700 to 450 yards, and is surrounded by all the requisite buildings for a naval arsenal: it is one of the finest harbours and naval stations in the Mediterranean. Of the surface of Malta about two-thirds are cultivated, and the remaining third is bare rock. There is much good native earth in the valleys, which has been converted into productive fields; but a great portion of the land has been brought to its present state of culture by the industrious native, who with great labour and expense cuts away the hard surface of the rock, and frequently finds a quantity of earth lying inert in the crevices and interstices beneath. The produce of Malta is cotton (which is its staple), wheat, barley, pulse, potatoes, barilla, cumminseed, and sulla, or the French honeysuckle, which is used as fodder. As there is no meadow-land, much barley is cut when green for draught animals; and the straw (which is very fine) is a good substitute for hay. The natives of Malta are hardy and industrious. The great bulk of the people who are not employed in field-labour are stonecutters.

The British produce and manufactures exported to Malta in 1849 amounted in value to 387,744*l.*

MANCHE, LA. In this department of France, apple and pear trees are extensively cultivated for making cider and perry, the favourite beverages of the country. Of cider above 22,000,000 gallons are made annually; some of it, especially that made near Avranches, is of excellent quality. Hemp and flax are grown in considerable quantity on the eastern slopes of Cotentin. Fruits of various kinds are sedulously cultivated in the arrondissement of Avranches. Excellent butter is made, and large quantities of it are exported from Isigny. The department is rich in minerals. Iron, lead, and coal mines are worked; granite and building stone are quarried; marble, slate, potters' clay, and limestone are found. Manufacturing industry is actively exerted in the making of iron, the working of zinc and copper, the fabrication of plate glass, serge, calico, drugget, cutlery, woollen stuffs, lace, tape, hair-cloth, porcelain, oil, hardware, cotton yarn, paper, leather, soda made from kelp, basket-work, &c. Ship-building is actively carried on at Cherbourg and other towns on the coast. The articles enumerated, and the products of the soil, support an active commerce and coasting trade. The chief exports are fresh and salt fish, corn, cattle, horses, poultry, wax, honey, salt butter, feathers, salt, salt provisions, soda, &c.

The great engineering works at CHERBOURG are noticed elsewhere.

MANCHESTER. This most important town, the centre of the largest cotton-manufacturing operations in the world, is situated in a district which contains some excellent coal strata, a circumstance to which the place is in no small degree indebted for its prosperity. It has the credit of having given an impulse to our means of internal communication, and has reaped an ample reward. The achievements of Brindley were prompted by the desire which the Duke of Bridgewater had of sending his coal from Worsley to Manchester at a small expense; and Manchester now possesses the means of water-communication with almost every part of the country. In the railroad enterprises Manchester has held a prominent station. It furnished its full share of the capital employed in the formation of the Manchester and Liverpool Railway; and it is now the centre of a system of railways radiating in six different directions. There are two magnificent viaducts across the town, for connecting the Liverpool line with the Yorkshire and the London lines.

The commercial spirit dates back to a very early period. At first the woollen was the only branch of trade, but since the middle of the last century the cotton business has nearly superseded the former fabric. The series of brilliant inventions and discoveries, applied, improved, or originated in the district of Manchester, which comprise the steam-engine, the spinning-jenny, the mule jenny, the fly-frame, the tube-frame, the mule, &c., have proved most effective instruments in aiding the development of the cotton manufactures. Several hundred millions of pounds of cotton are brought into Manchester from Liverpool every year; and the cotton factories are by far the most important buildings in the town: there are more than two hundred of them within the precincts of the town and parish. Some of them are only spinning factories; others are both spinning and weaving. Bleach-works, dye-works, and print-works, all connected with the cotton manufacture, exist on a large scale in and near Manchester.

The processes of throwing and weaving silk were extensively carried on at Macclesfield several years before they reached Manchester. The silk-mill of Mr. Vernon

Royle, erected in 1819--20, was the first brought into operation in the latter town. Since then the trade has rapidly increased. Printing is another branch of the silk business, chiefly, if not exclusively, carried on at Manchester. Dyeing of silk is also extensively pursued, and in fact the town is becoming the centre of transactions in the silk trade. Besides the manufactures in cottons, silks, and woollens Manchester carries on large manufactures in hats, umbrellas, and small wares. Machinery of the finest kind is also made there to a large extent.

The warehouses of Manchester are on a vast scale; they contain not only the woven products of the town's factories, but the produce of most of the other cotton towns is brought to Manchester, as a central exchange for the manufacturer and the dealer. It was calculated in 1837, that 700,000 tons of goods were carried by canal alone from Manchester to the south, yearly; besides that which passed north, east, and west, and besides the railway goods' traffic. In 1851 the amount is vastly greater, especially in respect to railways.

Manchester, as a centre of the calico-printing trade, presents a fair field for the exercise of taste in designing; and a School of Design is gradually producing important results in the town. The report of the Schools of Design for 1850 states:—'The Manchester school is in a flourishing condition. The greatest number of pupils on the books at any former period was 217, reduced to 90 when the present master undertook the re-establishment of the school. There are now about 350, the average attendance being the full amount which the premises can accommodate, although additional space has lately been taken into occupation. The students are also of a better class than at any former period. There is a large proportion of adults, and about 50 of the advanced students are actively engaged in the production of designs, principally as pattern draughtsmen.'

The report proceeds:—'The school is undoubtedly gaining in the estimation of the manufacturers. In fact, the practical effects of the school upon the manufactures of the town are making themselves manifest in a way which may waken the interest of the most indifferent, by showing that good art possesses a money value. In the case of those manufacturers who produce goods to compete with the French manufactures in the American markets, attention to design has at all times been indispensable; and previously to the establishment of the schools they were under the necessity of employing foreigners, not only to sketch their designs, but also to draw out their patterns, at great expense, and under the disadvantage of much uncertainty. Those manufacturers who have had the intelligence to understand the manner in which the schools would become available, are now able to produce with certainty better patterns, at far less cost, by means of their own apprentices pursuing their studies in the school; the apprentices at the same time obtaining higher wages than were ever paid to artisans of the same class before. Many of these young men, as they acquire experience and knowledge of their business, are exhibiting much talent, as designers, in the strict sense of the term.'

Mr. Annersley, the principal of this school, has lately given notice that the sum of 110*l*. has been placed in his hands by a calico-printer of Manchester, for the purpose of being divided into prizes for the best designs suited for printing on calico or delaine, as follows;—20*l*, for the best set of six three-colour patterns; 10*l*. for the second ditto; 5*l*. for the third ditto; and similar prizes for the best, second, and third best four and five colour patterns, which make up the sum thus offered.

The prize patterns are sent to the Great Exhibition, where about 14,000 square feet of counter space is occupied by Manchester contributions.

MANDIOC. The names of *Mandioc*, *Cassava*, and *Jatropha Manihot*, are given to an American plant, and to a wholesome food prepared from it. Bread is made from a kind of meal procured from the root or tuber which is somewhat parsnip shaped. The tuber is dug up, washed clean, peeled, and ground or grated. In Brazil where mandioc bread is made more largely than in any other country, many persons are employed together in peeling the tubers, which are then applied to and pressed against the face of a wheel made to revolve with great rapidity; and in this way the tubers are ground, the pulp falling into a trough beneath. The pulp is then placed in bags, which are exposed to a pressure sufficient to force out the juice which is of an unwholesome character. The pulp is then poured out upon a hot iron hearth, where it becomes baked into thin cakes. Though deemed somewhat harsh flavoured by persons accustomed to corn bread, these mandioc cakes are highly relished in Brazil. It is only the *bitter cassava* which requires to have the juice expelled; that of the *sweet cassava* is wholesome. When fermented with molasses, the juice yields an ardent spirit.

Tapioca, which is capable of being made into excellent puddings, and into light food for invalids, is a kind of starch prepared from the farina of cassava tubers. A considerable quantity of tapioca is brought annually from Brazil to Europe.

MANDOLINE, is a musical instrument of the lute kind, but smaller, having four strings, which are tuned in the same manner as those of the violin. The mandoline is still met with occasionally in Italy, but has fallen into disuse in most other parts of Europe.

MANGANESE. This metal was first discovered by Scheele and Gahn, about 1775. Its natural compounds are very numerous, and the metal is easily separated from them. Manganese has a grayish white colour, and resembles white cast iron in appearance; it is hard, brittle, and has a fasciculated crystalline structure; its specific gravity is 7.05; it is inodorous and tasteless, but when breathed upon, emits a smell somewhat resembling that of hydrogen gas. By exposure to the air, manganese readily tarnishes by oxidisement, and even in a very short time attracts sufficient oxygen to lose its metallic lustre, and falls to a reddish brown powder; hence the necessity for preserving it immersed in naptha. Even at common temperatures it slowly decomposes water; and at a red heat the decomposition is rapidly effected, and in both cases hydrogen gas is evolved, and oxide of manganese formed.

The ores of manganese are chiefly oxides, and are very numerous. There are no fewer than five oxides of the metals, of which the protoxide gives an amethystine colour to glass. *Manganic acid* has not hitherto been obtained in a separate state; but manganate of potash is easily prepared. It is of a green colour, and has long been known by the name of *mineral chameleon*, on account of the change of colour which the solution undergoes during the process. *Hypermanganic acid* has a fine red colour, and is rapidly decomposed by organic matter, as paper or linen. It bleaches coloured matter. Manganese combines with chloride and with sulphur. It also combines with several other metals, as gold, silver, copper, tin, and iron; with the last-mentioned, combination takes place readily, and the iron is rendered harder, whiter, and more brittle by it; and it is stated that iron which contains manganese is best adapted for making steel. A small quantity of iron causes manganese to obey the magnet, and renders it less oxidable. The oxides of manganese, and especially the binoxide, as containing most oxygen, are largely employed in the preparation of chlorine, for the manufacture of bleaching powder, or chloride of lime. It is employed in glass-making to correct the yellow colour which oxide of iron is apt to impart to the glass; it is used also in making the black enamel of pottery. Sulphuret of manganese has also been used within a few years to give a brown colour in calico-printing. The binoxide, the sulphate, and the hydrochlorate of manganese, are all employed in medicine.

MANGEL WURZEL. [Beet.]

MANGLE. [Calendering.]

MANGROVE. The Mangrove trees are found on tropical shores, where they form extensive forests. The wood of the *Red Mangrove* is heavy, of a deep red, and takes a fine polish. The bark is used in dyeing red, and is used in the West Indies as a fever medicine. The *gymnorhiza* species of Mangrove produces yellow, hard, durable wood; it has a sulphureous smell and burns with a vivid light. It is chiefly used by the natives for fire-wood, and for making posts for constructing their houses. The pith of the wood, boiled in palm wine or with fish, is used as food.

MANIFOLD WRITER. [Copying Machine.]

MANIPULATION, in chemistry, embraces every part of the subject which is of a mechanical nature, such as the operations of weighing, measuring, the application of heat and electricity, the various modes of effecting solution, precipitation, distillation, and sublimation, and in fact every step in chemical research includes manipulation. The whole subject is treated in Faraday's 'Chemical Manipulation.'

MANNA, is the concrete juice of the *Ornus Europæa*, a species of ash which is a native of the south of Europe, growing abundantly in Sicily, Apulia, &c. The juice exudes spontaneously in warm dry weather, and concretes upon the bark of the tree; the finest manna is however procured by making longitudinal incisions of about three inches long. The manna flows at first in the form of a thick juice, which gradually concretes. The finest kind is called *Calabrian* or *flake manna;* it is in pieces of a pale yellowish white colour, is light, rather dry, and brittle, and it bears frequently the impression of the branch on which it concretes. It has a slight peculiar odour, and a sweetish taste, mixed with a slight degree of bitterness, and altogether leaves a disagreeable impression. Although it has a composition not unlike sugar it is not fermentable.

Besides the genuine manna above described, other sweetish secretions are exuded by some other plants which are usually considered to be kinds of manna. These appear to be all produced in warm and dry parts of the world, and are the produce of various species of plants. Manna belongs to the same series of vegetable bodies as sugar, and like that compound is widely distributed in the vegetable kingdom. It is a mild and useful medicine.

MANTUA. The territory of Mantua, one of the provinces of Austrian Italy, is noted for its fertility. It contains numerous fine meadows well adapted for the grazing of cattle, and irrigated by numerous streams and canals; vines and mulberry trees also abound. Landed property is very valuable in this district, which labours however under two disadvantages, namely, the danger of the inundations of the Po, to prevent which the dykes and sluices are kept in constant repair at a great expense, and the unwholesomeness of the air in summer. Neither in the province generally, nor within the city of Mantua, are much manufactures or commerce carried on; Mantua depends on its fine Arts rather than on its productive industry.

MANURE. Every substance which has been used to improve the natural soil, or to restore to it the fertility which is diminished by the crops annually carried away, has been included in the name of manure. There are some substances which evidently belong to both classes of manure. Of these *lime*, either in its caustic state of quick lime, or its milder form of a carbonate or chalk, is the principal. Lime, being an earth less porous than sand, and more so than clay, has an improving effect on soils in which either sand or clay prevails; but it has also a chemical effect as an alkaline earth.

Perhaps the most important class of manures are the excrements of animals. From the most ancient times of which there are any records, the dunging of a field has been an important part of cultivation. The preparing of the dung of animals, so as to render it more efficacious, is a later improvement, which however has not yet attained the perfection of which it is capable. A mixture of the dung of all the different animals kept on a farm, with all the straw that can be afforded, will give a manure of an average strength, which may be used upon all kinds of land. The great use of *liquid* manure on light soils is to impregnate them with soluble matter, which, being diffused through their substance, supplies nourishment to the roots of plants, wherever they may shoot out. It may be applied to the land at any time before the seed is sown, and soon after, when the blade springs up or the seed begins to form. The great effect of liquid manure has set farmers on finding some artificial substitute for it. Such substitutes are obtained by mixing all kinds of refuse animal matter (such as the refuse from oil mills and other manufactories) with water, and inducing putrefaction. This becomes a branch of trade in those countries where nothing will grow without manure. The increase of manure by the formation of *composts* is well known in many parts of Britain, and by their means the land has in many districts been rendered much more productive.

Bones and Guano are important substances for manuring. The various substances which are generally enumerated as occasionally used for manure, are chiefly the refuse of manufactures, consisting of earths, salts, and organic substances. Soapers' waste is chiefly lime with a small portion of alkali. The scrapings of leather, horn, bones, and the refuse of the shambles, the hair or wool of animals, and rags made of these, may be all classed together. They must be distinguished as acting in a twofold manner: they absorb and retain moisture, at the same time that they afford nourishment by their gradual decomposition. One substance has been highly extolled as a manure. This is called *urate*, being a compound of urine and plaster of Paris. It is formed by mixing sand and burnt gypsum with urine, and forming a hard compound, which is afterwards reduced to powder. The ashes of vegetable substances which have been burnt in the open air contain a great portion of potash, with some fine earths. The refuse ashes from bleachers' and soap-boilers' premises have still some portion of alkali in them, and as they contain lime and other earths in a very divided state, their effect on the soil is very perceptible.

Mr. Blachfield took out a patent in 1849, for an artificial manure, composed of the following substances:—1100 cwt. of river sand saturated with sulphuric acid, 400 cwt. of superphosphate of lime, 300 cwt. of sulphate of ammonia, 100 cwt. of sulphate of soda, 100 cwt. of sulphate of potash.

MAP-MAKING. The mechanical execution of a map is simply an example of engraving on steel, copper, stone, wood, or zinc; but there are a few expressions relating to the projection or planning of a map which it is useful to know.

The methods adopted in the construction of maps are as various as the taste and judgment of the geographers themselves, but they may all be referred to two principles, viz. *Projection* and *Development*. By *Projection* is is meant the representation of the surface of a sphere on a plane, according to the laws of perspective. By *Development* is to be understood the unfolding or spreading out of the spherical surface on a plane. This however first supposes the sphere to be converted into a cone or a cylinder—these being the forms, portions of which most resemble portions of a sphere, and which, at the same time, are susceptible of the required development.

The *Gnomonic* or *Central Projection* supposes the eye to be placed in the centre of the sphere, and that the various objects to be delineated are transferred from a sphere to a plane, which is a tangent to its surface. The Maps of the Stars, prepared by the Society for the Diffusion of Useful Knowledge, are on this projection. In the *Orthographic Projection*, the eye is supposed to be at an infinite distance, so that the visual rays leave the sphere in parallel lines; the representation will decrease in accuracy with the increase of distance from the centre; the parts near the circumference being much foreshortened and distorted. In the *Stereographic Projection*, the eye is supposed to be placed at the surface of the sphere, and to view the concave of the opposite hemisphere through the plane of that circle, in the pole of which the eye is placed. It is especially calculated for maps of the world, as usually made in two hemispheres, from the circumstance of the representation being less distorted, and also on account of the meridians and parallels intersecting each other at right angles, as they do on the globe. In the *Globular Projection*, the eye is supposed to be placed at a distance from the sphere equal to the sine of 45°; that is, if the diameter of the sphere be equal to 200, the distance of the eye from the nearest point of the circumference would be $70\frac{7}{10}$. Some modification was subsequently deemed desirable, in order that the meridians might intersect the equator at equal distances. This condition is nearly fulfilled when the distance of the eye is $59\frac{1}{2}$, the diameter being 200. This projection is also much used in maps of the world. In the *Conical Projection*, the sphere is supposed to be circumscribed by a cone, which touches the sphere at the circle intended to represent the middle parallel of the map; the points on the sphere being projected on the cone, the latter is then conceived to be unrolled or developed on a plane surface. In the *Cylindrical Projection*, the sphere is supposed to be circumscribed by a cylinder instead of a cone. The peculiarity of this method is, that the meridians, as well as the latitude circles, are projected in parallel straight lines. In *Mercator's Projection*, so largely used by mariners, the degrees of latitude on the chart are made to increase towards the poles, in the same ratio as they decrease on the globe; by which means the course which a ship steers by the mariner's compass becomes on the chart a straight line; the various regions of the map, however distorted, preserve their true relative bearing, and the distances between them can be accurately measured.

MAPLE. The useful purposes to which the Maple-tree is applied are noticed under Acer.

MARBLE. A limestone which will admit of being worked equally in all directions, and is capable of taking a good polish, deserves the title of marble; when it is granular and of a white colour, it may be useful in statuary.

The varieties of marble are exceedingly numerous. Taking them in respect to colour, we find the following among others:—*Black Marbles.* Most of these contain bitumen, and are fœtid when bruised. They include the Namur marble, the marble of Ashford in Derbyshire, Dent in Yorkshire, near Crickhowell, Tenby, Kilkenny, &c.; the marble anciently called Marmor Luculleum, and now Nero Antico. *White Marbles* comprise the marble of Paros; the Carrara marble, of finer grain, much used in modern sculpture; the Skye marble, that of Inverary, Assynt, Blair-Athol, &c. *Ash* and *Gray Marbles* include a beautiful marble, of compact oolitic texture, at Orleton, near the Clee Hills in Shropshire. *Brown* and *Red Marbles* comprise the Rosso Antico; a marble on the estate of the Duke of Devonshire, near Buxton. The mottled brown marble of Betham Fell, near Milnthorp, is of good quality. Among *Yellow Marbles* are the Giallo Antico; Siena marble. That used in ancient Rome is said to have been from Numidia. *Blue Marbles.* Of these there is one example near St. Pons in Languedoc. *Green Marbles* present as an example the Marmor Lacedæmonicum of Pliny, dug near Verona. *Black Marbles* variegated with other colours; *White Marbles* variegated with other colours; *Ash* and *Gray Marbles* variegated with other colours; and similar variegated varieties of *Brown*, *Red*, *Yellow* and *Green Marbles*, are abundant. The British Islands contain numerous examples of marbles containing shells and corals. Some of the Plymouth, Ashburton, and other Devonian limestones are extremely beautiful, from the abundance of fine corals exquisitely preserved in them; the crinoidal marbles of Flintshire, Derbyshire, and Garsdale in Yorkshire, are elegant examples of the carboniferous limestone; the shell marbles of Buckingham, Whichwood Forest, Stamford, Yeovil, may be noticed, from the oolitic rocks. That of Petworth and Purbeck, from the Wealden strata, has been extensively used by the architects of the middle ages.

The mechanical working of Marble does not differ much from that of stone. [SCULPTURE; STONE MASONRY.] Beautiful specimens of English and Irish marble have been sent to the great Exhibition.

MARBLING. There are many processes in the Arts by which an attempt is made to imitate the veins and markings of marble. Marble itself may be stained or dyed of any required colour. Litmus or indigo for blue; logwood for brown; alkanet root for crimson; alkanet and wax for flesh colour; sal ammoniac, verdigris, and white vitriol, for gold colour; sap green or verdigris for green; dragon's blood or cochineal for red; gamboge, turmeric, or saffron for yellow—these are the colouring matters employed, used when hot.

The marbling of books or papers is effected by applying to them a coloured preparation of the required tint. The pigments employed are Prussian blue, indigo, rose pink, or any of the well known colours, chiefly mineral. These are ground up with a little ox-gall and small beer to a proper consistence. Linseed and water are boiled in a copper pan to a mucilaginous consistence, and are poured into a trough to cool. The colours are then successively sprinkled on the surface of the mucilage in the trough with a brush, and are waved or drawn about with a quill or stick, according to taste. When the design is thus formed, the book, tied tightly together between cutting boards of the same size, is lightly pressed with its edge on the surface of the liquid pattern, and then withdrawn and dried. It will be found to have taken up a thin layer of colour. This illustrates one only among many ways of marbling paper. Ordinary book edges are simply sprinkled with colours, from a brush dipped into it.

The marbling of wood is simply an attempt to imitate the tints and markings of marble by ordinary painters' colours.

MARGARIC ACID, is prepared from soap made with olive-oil and potash. It crystallises in pearly needles; it is insoluble in water. It has an acid reaction; and its salts, except those of the alkalis, are very sparingly soluble in water. Its saline compounds are termed *margarates.* The *Margarate of Potash* presents the varied forms of brilliant scales, a solution, and a jelly, according to its mode of preparation. A substance nearly allied to this acid, and called *Margarin*, is a peculiar fatty matter contained in vegetable oils, and also in animal fats, as mutton suet and hog's lard. This substance is very soluble in cold æther, which distinguishes it from stearin. *Margaron* is a solid white fatty matter which crystallises in pearly scales, and is obtained by distilling margaric acid with excess of lime.—The whole of these substances obtain their characteristic designation from the Greek name for a *pearl.*

MARJORAM, is an aromatic potherb used in cookery, especially among the French. It is a native of Barbary and the Himalaya mountains. In gardens it is little better than an annual.

MARKET GARDENS. The market gardens near London, which chiefly supply Covent Garden market, have a soil which is a moist alluvial loom deposited from repeated overflowings of the Thames, which are now prevented by banks or dykes. The gardener's year properly begins in autumn, when the land is dug, or rather trenched, and well manured. Various vegetables which will be required in winter are now sown, and especially those which are to produce plants to be set out in spring; spinach, onions, radishes, and winter salads are sown, and, when the weather is severe, are protected by a slight covering of straw or mats. In February, the cauliflowers which have been raised in frames or under hand-glasses are planted out. The cabbage plants are pricked out. The radishes, onions, and salads go to market as soon as they are of sufficient size, and sugar-loaf cabbages succeed them. As the cauliflowers are taken off, they are succeeded by endive and celery, and the same is the case with the cabbages. Thus there is a constant succession of vegetables, without one moment's respite to the ground.

The principle on which the gardens are cultivated is that of forcing vegetation by means of an abundant supply of dung, constant tillage, and occasional watering. The whole surface is converted into a species of hotbed; and crop succeeds crop with a rapidity which is truly astonishing. Those vegetables which arrive at a marketable state in the least time are always the most profitable, and those also for which there is a constant demand at all times of the year. With an abundant supply of manure, the market-gardeners have no fear of exhausting the soil; and dissimilar vegetables may grow together on the same ground. Raspberries, gooseberries, and currants are planted in the rows between fruit trees; which rows being thirty or forty feet apart, leave ample room for vegetables. The market gardeners near London do not raise many peas or beans, except such as are forced and require glass frames to protect them. The chief supply of peas in the season comes from a greater distance, and is the produce of whole fields sown for that purpose by the farmers within a moderate distance of London. An acre of the richest garden ground near London is said to yield produce valued at 220*l*. in a year.

An abundant supply of manure is indispensable in a market garden, and this can generally be obtained in large towns at a trifling expense. The neighbourhood of a town is therefore a necessary circumstance towards the production of the crop, as well as its sale. The profits of a garden near London, of the extent of ten or twelve acres, are as great as that of a farm of ten times the extent cultivated in the best manner, without the help of purchased manure.

The *Morning Chronicle* has lately given some interesting statistical details respecting the supply of London from the market gardens. The *Green Markets* are the Covent Garden, the Borough, Spitalfields, Farringdon, Portman and Hungerford Markets. Of these Covent Garden is not only the largest, but is said to be the largest in the world. It is divided into six sections, for fruit stands, flower stands, potato stands, casual cart stands, yearly cart stands, and yearly pitching stands, all of which pay a rental according to the kind of commodity sold, and the conveniences required for the sale. The following is given as one recent year's amount of sales at Covent Garden market, all of home-grown produce:—

Apples	360,000	bushels.
Pears	230,000	„
Cherries	90,000	„
Plums	93,000	„
Gooseberries	140,000	„
Currants	90,000	sieves.
Strawberries	638,000	pottles.
Raspberries	30,000	sieves.
Filberts	1,000	tons.
Walnuts	25,000	bushels.
Cabbages	16,000	loads.
Turnips	10,000	„
Carrots	5,000	„
Onions	500,000	bushels.
Brocoli, Cauliflowers	1,000	loads.
Peas	270,000	bushels.
Beans	100,000	„
Celery	18 million	heads.
Asparagus	60	„
Endive	150,000	scores.
French Beans	140,000	bushels.
Potatoes	83,000	tons.
Watercresses	23,000	cwt.

All the other vegetable markets of London united, present but a small aggregate, compared with this of Covent Garden.

MARL is an earthy substance found at various depths under the soil, and extensively used for the improvement of land. It consists of calcareous and argillaceous earth in various proportions, and as the former or the latter prevails, so it is beneficially employed on clays or sands. There are several distinct sorts of marl—*clay marl*, *shell marl*, *slate marl*, and *stone marl*. The effect of marl is the same as that of clay and chalk upon sandy soils; on heavy soils its effect is proportioned to the quantity of calcareous earth which it contains. The peculiar advantage of marl is its readily crumbling to powder by the effect of air and moisture. An excellent use of marl is in forming composts with dung and peat earth. It is laid in layers with the dung and peat, and if the heap is well soaked with urine or the washings of stable-yards, it will in a short time become a most valuable manure for all kinds of soils.

MARMALADE. Marmalade is properly a conserve made of quinces and sugar, and is named from the Portuguese name for a quince. Marmalades are, however, now made of orange, citrons, apricot, hips, apples, pears, plums, and other fruits. It is by using the cheaper varieties of these fruits, that Marmalade is now sold at such a low price. Marmalade is made either by pounding the pulped fruit in a mortar with white sugar; or by mixing them together by heat, passing them through a hair sieve while hot, and then putting them into pots or glasses. The fruit pulps are obtained by rubbing the fruit through a fine hair sieve either at once, or after it has been softened by boiling.

MARNE. There are two French departments thus named, which present a fair amount of productive and commercial industry.

In *Marne* the vine for the production of the famous Champagne wines is the chief object of the landholder's care all through the department, more especially in the arondissement of Reims and Épernay, wherein the white wines of Sillery, Aï, Mareuil, Pierry, Épernay, and Dizy; and the pink wines of Verzenay, Verzy, Bouzy, Taissy, Cumières, Aï, Hautvilliers, Mareuil, Dizy, and Pierry, all of the first class. The Champagne vintage is noticed under Wine Manufacture. Tho quantity of wine of all kinds made in the department annually amounts to 15 or 16 million gallons. In this department, chalk, flint, millstone of the best quality, building-stone, potters' and brick clay, and turf, are the chief mineral productions. The chief manufactures are woollen stuffs of all kinds, and cotton hosiery, which centre chiefly at Reims. There are also several tan-yards, dye-houses, paper mills, glass works, potteries, rope-walks, oil mills, soaperies, and establishments for the making of Spanish white. The most important article of commerce is Champagne wine, the great marts for which are Reims and Epernay. Other articles of trade are corn, flour, brandy, the articles previously named, together with timber, hides, and firewood, of which great quantities are sent for the supply of Paris.

Haute Marne, the other of these two departments, is also a wine country. The vine is extensively cultivated in favourable situations, and about 13,000,000 gallons of wine annually made, two-thirds of which are consumed on the spot, and the rest is exported to Switzerland and to the departments of Vosges and Haut-Rhin. The department is rich in iron ore; several mines are worked; the metal is smelted and manufactured into bars, utensils, and tools in numerous furnaces and foundries, in which wood charcoal is the fuel exclusively used. Building stone, marble, alabaster, gypsum, &c., are quarried. Marl, brick earth, fuller's earth, and turf are dug. Besides ironmongery and cutlery, the industrial products include brandy, vinegar, cotton and woollen yarn, drugget, woollen stockings, leather gloves, cast-iron tubes, paper, leather, beer, &c. The commerce in the products before named, and in timber, planks, fire-wood, oak staves, oil, honey, &c., is considerable.

MAROCCO. In this large country of Northern Africa are cultivated wheat, barley, rice, Indian corn, and holcus sorghum, or dhurra. Other objects of cultivation are cotton, tobacco, sesamum, hemp, saffron, henna, and different kinds of peas and beans. The plantations of date trees, olive trees, and almond trees are very extensive. The fruit-trees of southern Europe are also common, especially the fig and the pomegranate. Forest trees are numerous on the northern slope of the Atlas. The Marocco sheep produce a wool not inferior to any for softness, fineness, and whiteness. Goat-skins constitute one of the most important articles of export. The mineral wealth of Marocco is very imperfectly known, but is supposed to include gold, silver, copper, lead, iron, rock salt, and fuller's earth.

As the inhabitants dress chiefly in wool, the manufacture of woollen cloth is general, but the material is usually coarse. In some places however there are manufactories on a large scale, which supply articles of export. A few silk goods are also woven. The inhabitants of Fez are distinguished as goldsmiths, jewellers, and cutters of precious stones; many of them are also occupied in making Marocco leather, and different kinds of earthenware. Tanning and leather dressing are carried on extensively; and carpet weaving is also much practised.

The Moghribins carry on a very active commerce with Soudan or the interior of Africa, and with Egypt and Arabia, by caravans, and with several parts of Europe by sea. From Timbuctoo, as a central point, the merchants traverse the adjacent countries, exchanging their goods for those of Soudan. The caravans which go to Mecca are chiefly composed of pilgrims, and are much more numerous than the trading caravans. They depart only once in the year, and follow two routes.

European vessels visit the harbours of Tetuan, Rabatt, Saffi, and Mogadore, and export the produce of the empire to Italy, France, Spain, England, and Holland, bringing in return the produce of European and other countries.

MARSEILLE. This influential French city is the chief port of the Mediterranean; and the steam-packet station for Italy, the Peninsula, and the East. It is likewise one of the stations for the Anglo-Indian Overland Mail; although in this respect Trieste may possibly interfere with it at some future day. A railway is in course of construction direct from Paris, through Dijon, Lyon, and Avignon, to Marseille.

Marseille depends entirely upon its commerce, which is extensive; and, since the conquest of Algeria by the French, has been rapidly on the increase. Within the last few years an artificial basin has been made in the roadstead near Marseille by the construction of a dyke between the small fortified islands of Ratonneau and Pomègue, in which vessels of the line may anchor with perfect safety, and on the shores of which ship-building is extensively carried on. The number of vessels which enter the port of Marseille annually is estimated at 5000 or 6000; the custom-house and other dues collected exceed 1,100,000*l.* annually; and the municipal revenue is about 110,000*l.* The French trade with the Levant is entirely carried on from Marseille. The chief imports are of raw cotton, sugar, dye-woods, and divers articles from the Levant; exports, of wines, brandy, corn, dried fruits, oil, soap, hosiery, damask, and other linens, woollens, silks, leather, hides, &c. The local manufactures consist of soap, morocco and other leather, glass, porcelain, hats, gunpowder, alum, sulphur, vitriol, and cutlery. The refining of sugar and salt, calico printing, the distillation of brandy, essences, and liqueurs, cork-cutting, and the preparation of anchovies, dried fruits, olives and wine for exportation are carried on.

MARTELLO TOWER, is the name given to a circular building of masonry, generally two stories high. The lower story is divided into chambers for the reception of stores, and the upper serves as a casemate for troops. The roofs are vaulted, and that of the upper story is shell-proof. On the terreplein of the roof are placed pieces of artillery, which rest on platforms of timber traversing on pivots, so that the guns are capable of being fired in any direction. The whole work is generally surrounded by a ditch and glacis.

There are several of these Martello towers on the south coast, near Hastings; but not being wanted for military purposes, they are occupied by the Revenue Coast Guard.

MARTIN SKINS. The skin or fur of the martin is used to a considerable extent in this country for furriery and other purposes. The number imported in 1847 was 259,032, and in 1848 it was 219,195.

MARYLAND. A few industrial statistics of Maryland are given under UNITED STATES.

MASONRY. [STONE MASONRY.]

MASSACHUSETTS. [UNITED STATES.]

MASTICH, is a resin which is extracted from the trunk and branches of the *Pistacia lentiscus* by incision. This tree grows in the Levant, and particularly in the island of Chios. Mastich is composed of two resins, one of which is soluble in dilute alcohol, and the other is not; this last constitutes from $\frac{1}{5}$th to $\frac{1}{12}$th of the whole weight of the mastich, and possesses very nearly the characters of copal, it being soluble in absolute alcohol, æther, and oil of turpentine; these liquids also dissolve mastich without leaving any residue. Mastich is principally employed as an ingredient in varnish, and as a temporary stopping for carious teeth.

MATCH, is a material employed in firing military mines or in discharging pieces of ordnance. Before the invention of fire-locks, hand-guns or small arms were fired by matches, which the soldiers carried with them when on service; and matchlock fire-arms are still used in some parts of Asia. What is called *slow-match* is only a piece of slightly twisted hemp which has been well soaked in a strong solution of saltpetre with boiling water. The materials employed in the formation of *quick-match* consist of a wick of cotton steeped in a mixture of saltpetre and mealed gunpowder with spirit of wine and rain water.

MATCHES; CONGREVES; LUCIFERS. The manufacture of these humble and marvellously cheap articles marks a curious stage in the progress of civilization, where luxuries become conveniencies, and then become necessaries. The friction of two pieces of dry wood we now regard as a barbarous mode of procuring light; yet it is a scientific one, where the materials for a quicker process are wanting. The flint and steel had a long reign in this country; the tinder box formed an item in Wolverhampton manufactures; and the sulphur-tipped matches, arranged in bunches spread out in fan-like manner formed the stock in trade of many an itinerant dealer. As mechanical ingenuity supplied the flint and steel and tinder box to supersede the rubbing sticks, so has chemical ingenuity made a wide step in advance, by showing how to tip the little splints or matches with a composition which will kindle by slight friction.

Whether called *Congreves*, *Lucifers*, or *Instantaneous Lights*, these small but valuable articles are now made in almost inconceivable quantities. Hand cutting has long been unable to produce the splints in sufficient quantity; nothing less than steam power can do this. At one among many saw mills in London, these matches are made in the following way. The wood employed is American yellow pine. It is first sawn into blocks about 12 inches long, 5 or 6 wide, and 3 thick. Several of these blocks are placed in a machine where a number of revolving cutters, worked with great rapidity, slice the blocks up into layers, and cut the layers into splints. One machine will cut up two million splints in a day. The splints, as liberated from the machine, slide down into another room, where women and girls tie them up in boxes, the boxes in parcels, and the parcels in bundles. These splints are sold by the *hogshead* to the lucifer match makers, each hogshead containing perhaps two million splints. At one saw mill alone, it is estimated that the timber of four hundred large pine trees is cut up yearly for lucifer matches!

The chemical composition which gives to the matches their easy-igniting power, can now be bought at a very low price; and as children are chiefly employed in the manufacture, the matches can be sold extremely cheap. Whether the colour be red, yellow, brown, blue, or green, the composition possesses the requisite quality in respect to ignition by friction; and chemists are now acquainted with many such. There are many processes and compositions adopted. In one, the matches are dipped into a mixture of phosphorus, oil of turpentine, and flowers of sulphur; and afterwards into a mixture of gum arabic, chlorate of potash, and soot. In a second method the composition consists of chlorate of potash, phosphorus, gum arabic, and gelatine; the matches being dipped into melted sulphur before being dipped in this composition. In a third method, the composition consists of gum arabic, vermilion, phosphorus, and saltpetre. What are called *chlorate matches* are dipped into a mixture of chlorate of potash, flowers of sulphur, powdered lump sugar, gum arabic, and vermilion; these matches were originally lighted by dipping their ends into sulphuric acid; and it was in endeavouring to avoid the necessity of using this dangerous acid that the manufacturers hit upon the composition requisite for *lucifers*, which in turn gave way to the equally efficient and less noisy *congreves*. The lucifers here spoken of were dipped into a mixture of sulphuret of antimony and chlorate of potash, made into a paste with a solution of gum.

The dipping, drying, packing in boxes, pasting, &c., are of course very simple operations; but they are far from being safe, for among the fires of London during the last few years, a considerable number have occurred at the premises of lucifer match makers.

MATERIALS, STRENGTH OF. The strength of any material object, as a rod, bar, beam, chain, or rope, is that power by which the substance resists an effort to destroy the cohesion of its parts. If a rod or bar be suspended vertically, and a weight fixed to the lower end, that weight would tear asunder the bar, fibre from fibre, or particle from particle, if increased beyond a certain limit. Supposing the bar to be one inch square, the following weights would suffice to tear it asunder, according to the material of which it is made:—

English oak . .	8,000 to 12,000 lbs.
Fir	11,000 to 13,488 lbs.
Beech	11,500
Mahogany . . .	8,000
Teak	15,000
Cast-steel . . .	134,256
Iron-wire . . .	93,964
Swedish bar-iron .	72,064
Cast-iron . . .	18,656 to 19,488 lbs.
Wrought-copper .	33,792
Platinum-wire . .	52,987
Silver do. . .	38,257
Gold do. .	30,888
Zinc do. .	22,551
Tin do. .	7,129
Lead do. .	3,146

Rope, line, and cables range from 5000 to 12,000, according to the material and the mode of twisting.

According to the experiments of Mr. Barlow it appears that a bar of malleable iron is extended one ten-thousandth part of its length by a direct strain equal to one ton for each square inch in the area of the transverse section: when stretched with ten tons per inch its elasticity was injured, or the bar did not return to its original state.

In relation to the power of bearing a *crushing* pressure, various materials have been found to take rank as follows:—Iron, granite, limestone, oak, Portland stone, white deal, elm, red brick, and chalk.

Since the strengths of beams attached at one end or supported on props, the other dimensions being the same, vary as the squares of the vertical depths, it follows that the most advantageous position, when the areas of the transverse sections are equal, is that in which the broadest surface is in a vertical position. In this manner girders and joists in edifices are invariably placed.

When a beam or bar is attached at one end to a wall, or when it turns upon its middle point like the great lever of a steam-engine, if it be required that the beam should be equally strong in its whole length, it should be made to taper towards its extremities. If a weight be applied at any point in the length of a beam which is supported on two props, the strain produced by it will be the greatest when it is placed in the middle.

Such machines as capstans and windlasses, also axles which revolve with their wheels, are, when in action, subject to be twisted; so that their fibres tend to become curved in oblique directions: the strain thus produced is called that of *torsion*, and the strength of a solid cylinder to resist this kind of strain is found to be proportional to the cube of the diameter. Since the strain of torsion depends on the diameter of the cylinder, it is evident that a hollow cylinder must be stronger than a solid one containing the same amount of material.

We may remark that in testing the stability of the Palace of Industry in Hyde Park, a number of ingenious contrivances have been employed, to determine the strength of the materials to render the service required of them; especially in respect to the columns and girders.

MATRASS, is a glass chemical vessel, employed for the purpose of digesting, boiling, and distillation.

MAURITIUS. This British colony, formerly called the Isle of France, was once covered with woods, and even now a considerable part of the native forest is allowed to remain for ornament round the plantations. Many tropical and a few European plants are cultivated. The culture of the sugar-cane has spread rapidly since the English obtained possession of the island. The quantity of sugar it supplied to England, in 1828, was 40,320,000 lbs.; in 1847, 133,679,952 lbs.; but in 1848 the entire crop of the island yielded only 99,234,352 lbs. This diminution is no doubt in some measure, if not entirely, owing to the fact that a fatal disease has lately made its appearance among the cane plants of the island; and to such an extent that, in 1848, 10,000 plants of a different species of cane were introduced from Ceylon, but it is said with little success, as the insect (a species of coccus) which preyed upon the old plants seeks its food on all plants of the same genus as the sugar-cane. In consequence of this disaster, and perhaps also of the effect of the act of 1846 on the sugar trade of the island, much attention is now given to extend the cultivation of the mulberry for the production of silk, which cultivation had been previously introduced with great success in those parts of the island that were least adapted for the growth of the sugar cane. Coffee and pepper are also cultivated to some extent. The trade of the island is carried on not only with England, but with the countries around the Indian Ocean. There is packet communication monthly between Mauritius and Ceylon.

In the three months ending Oct. 10, 1850, the imports into Mauritius in British vessels amounted in value to 296,951*l.*, and in Foreign vessels to 22,301*l.*; being larger amounts than in the corresponding period of 1848 and 1849. The exports in the same three months were 121,287*l.*: being somewhat smaller than in the corresponding three months of 1848 and 1849. The yield of sugar in Mauritius in 1850 has been estimated at about 55,000 tons, or 120 million pounds.

MAYO. The geological structure of Mayo resembles, in its general features, that of Galway, exhibiting an arrangement of primary and secondary rocks skirting a limestone basin. As usual, the cultivated district and the field of limestone are co-extensive. Indications of coal are said to have been observed in Slieve Carnon, and deposits of manganese occur near Westport, but at present there are no mining operations carried on in this county beyond the quarrying of slates. Marble susceptible of a good polish has been quarried in several parts of the barony of Murrisk. Generally speaking, cultivation occurs only in detached patches. In 1847 out of the 1,363,882 acres which Mayo contains, there were only 122,567 under crops. The coast fishery, which might be rendered very productive, gives employment to about 4,000 fishermen. Turbot, sole, cod, ling, hake, haddock, plaice, oysters, lobsters, and herrings, are caught.

The manufacture of linens is carried on to a considerable extent by the country people: the cloth is generally sold in the rough state by the small manufacturers, and bleached in other counties. There is also throughout the county the usual home manufacture of friezes and coarse woollens.

The 'Castlebar Telegraph,' in a recent article concerning the products which will be forwarded to the Exhibition from Mayo, states that 'It is an undoubted fact that no equal extent of country in Ireland — ay, in Great Britain — can excel Mayo in her minerals of copper, lead, tin, iron, metal, marble, coal. We have also seen silver and gold extracted by a chemical process, by Dr. Atkinson of this town, upon whose authority we state that the country around us, for miles, abounds in minerals sufficient to enrich thousands of our population if they but possessed the knowledge of acquiring it. Recently, we are informed, a rich coal mine was discovered on the estate of Lord Kilmaine, in the neighbourhood of Castlebar.'

MEADOWS are properly low grounds on the banks of rivers, which, being kept moist by their situation, and also occasionally flooded by the rise of the waters, are best adapted for the growth of grass, and are generally mown for hay. Some meadows of great extent, belonging to a community or district, in which every inhabitant has a right to send his cattle to graze, under certain regulations, are never mown. The herbage of low wet meadows is generally coarser and less nutritious than that of those which lie higher; hence upland hay, as it is called, is preferred for the better sort of cattle. Upland meadows are very valuable wherever there is a demand for good hay. Of late years the practice of *soiling* has been extensively adopted; that is, all the grass is mown and carried every day in a green state, to cows or horses tied up in a stable. When a natural meadow has been neglected, and the grass is of an inferior quality, and mixed with rank weeds and moss, it requires much care to restore it to its original fertility.

MEATH. This county has very few mountain wastes, and the proportion of the bog is small. The land is flat rich pasture-land. The soil is for the most part a loam of the richest character, and in many places of such depth that the turning up of a fresh portion of the soil by ploughing deeper than usual is considered as an efficient substitute for manuring. The farms are on the average larger than in most other parts of Ireland; the grazing farms average about 150 acres; and tillage farms 20 to 50. The mode of farming, though very slovenly and defective, bears some resemblance to that of England. The whole quantity of land devoted to green crops is small, in consequence of the abundance of the natural pastures, which are of unequalled richness, and have led the farmers to give their chief attention to grazing. The quantity of cattle fattened in the pastures of the county is considerable, and the breeds fattened are numerous. The grazing is carried on on a large scale. Many persons fatten from 300 to 500 cows in a season, besides bullocks and sheep. Oxen are frequently employed in the plough. There are large flocks of sheep kept by the more extensive farmers.

The only home manufactures are a little coarse linen, sometimes, though rarely, a little coarse frieze coating, and the knitting of coarse worsted stockings, which last branch of industry is pretty commonly done by girls, widows, and old women. Spinning and weaving, from the cheapness of manufactured goods, have almost entirely ceased.

There is another Meath, called *West Meath*, or *Westmeath*, the soil of which comprises heavy loam, light loam, hilly sheepwalks, and a great deal of bog. The chief crops raised by the farmer are oats and potatoes; a very little wheat, some barley, flax, rape, and clover are grown. Dairy farming is practised to some extent in this county. The manufactures of the county are not important; they consist chiefly of the most necessary articles, such as coarse linens, woollens, and cottons.

The Shannon is navigable for steam-boats conveying goods and passengers. The Royal Canal crosses this county from east to north-west. The principal roads are good. The Midland Great Western Railway passes through the county.

MECHANICAL POWERS. This name is given to certain simple machines or engines, either of which is occasionally used by itself in moving bodies or raising weights, or any of which are combined together in the formation of the complex constructions which are employed in manufactures and the arts.

The several machines to which the name of mechanical powers is applied are the LEVER, the WHEEL AND AXLE, the INCLINED PLANE, the WEDGE, the SCREW, and the FUNICULAR MACHINE.

The object proposed in every machine is to transmit a force from the point at which it is immediately applied to that at which some resistance is to be overcome or some operation to be performed; and, in the transmission, the intensity of the motive power is to be increased so that effects may be produced which could not be accomplished by that power alone. The increase of the power is obtained by causing part of the resistance which is to be overcome to rest on the machine or on the fixed points which serve for its support, so that only the part which remains is opposed to the motive force. Thus a heavy body may be raised to a certain height from the ground by means of an inclined plane, on which part of the weight is destroyed by the reaction of the plane.

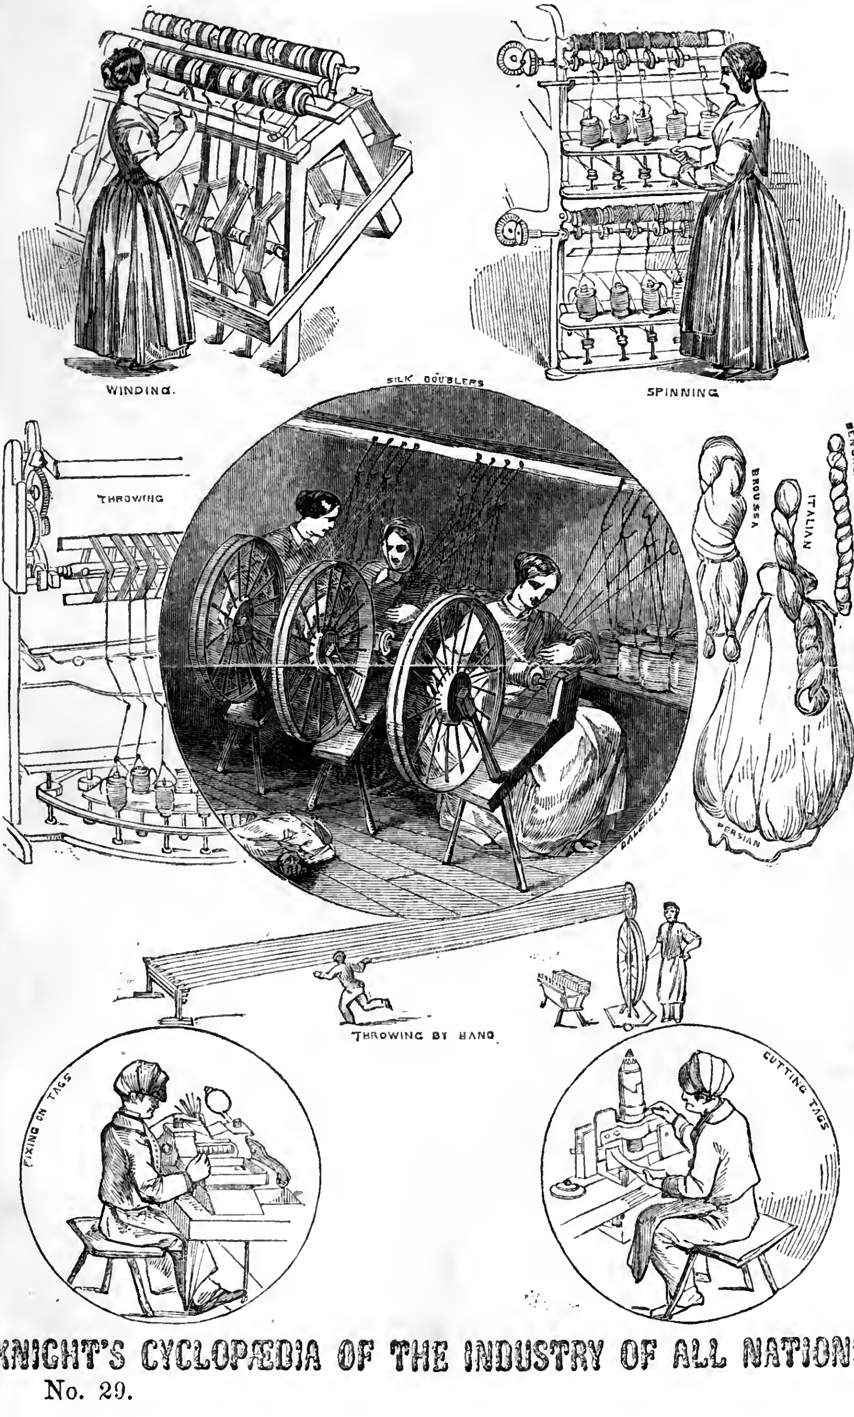
This manner of overcoming a resistance will serve to illustrate the fact that in every application of a mechanical contrivance to overcome a resistance, as much advantage is lost in respect of time or space as is gained in respect of power. For it is evident that, in order to raise the object vertically through a space equal to the height of the plane, it would be necessary to move it over a space equal to the length of the plane: that is, through a space which bears the same ratio to the vertical height as the weight of the object bears to the power required to move it up the plane.

All the familiar tools, implements, instruments, machines, and engines, exhibit the operation of some one or more of the mechanical powers.

MECHLIN. The industry of this ancient town is briefly adverted to under BELGIUM.

MECKLENBURG. In this member of the German confederation, agriculture forms the chief employment of the inhabitants; wheat, rye, barley, and oats are raised in large quantities for exportation. The forests produce some excellent timber. The breeds of horses, cattle, and sheep, are good, and the geese of Mecklenburg are celebrated for their size and flavour. Fish abonnd on the coast and in the lakes. The manufactures, though at present inconsiderable are extending. *Rostock*, is the principal trading port of Mecklenburg, and possesses about 150 ships. The chief exports are corn and wool: imports, colonial produce, wine and bay salt. There are manufactories of linen, soap, &c. In *Schwerin* there are manufactures of vinegar, cloth, pottery, and tobacco. *Wismar* has a harbour considered to be the safest in the Baltic. Wismar possesses from 60 to 70 vessels, and the entries into the harbour average 300 ships annually. The exports consist chiefly of corn; the imports are mostly Swedish productions. Fishing, agriculture, and the manufacture of tobacco and linen employ a large portion of the population. *Ratzeburg* is bounded on the west by the lake of Ratzeburg, by means of which timber, corn, pulse, flax, and cattle are sent to Lübeck for exportation. The inhabitants also carry on considerable fisheries.

MECONIC ACID, is a substance found only in opium, in which it exists in combination with the alkali Morphia. It is a crystal-



KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 29.

line substance, which acts on litmus paper, and has a sour taste; it is soluble in four times its weight of water, and also in alcohol. The salts which contain this acid are called *meconates*. The chief among them are combinations of the acid with Ammonia, Potash, Soda, Lime, Magnesia, Barytes, and Iron: the whole of these crystallise. It forms many curious compounds with other substances, but they are not yet of much value in the arts.

MEDAL: MEDALLION. Some account of the mode of executing these works will be found under CLICHÉ MEDALLIONS, and INTAGLIO. See also MINT.

MEERSCHAUM PIPES. Whether smoking be a good or an evil practice, it leads at the present day to a wide system of commercial enterprise. The *meerschaum* pipe is one among many manufactures connected with it. Meerschaum means in German *sea foam;* and the equivalent French name of *écume de mer* is applied to the same substance. It is a silicated magnesian mineral, found in Greece, Turkey, and a few other countries. It is used by the Tartars for washing linen, somewhat in the same manner as pearl ash or fullers' earth. The mineral is principally used however as a material for tobacco pipes, which, when made, are soaked in melted tallow, then in white wax, and finally polished with shave-grass. If genuine, a meerschaum pipe acquires a beautiful brown colour after being smoked for some time, the oil of the tobacco being absorbed by the clay; and this is a point to which connoisseurs in smoking attach much importance.

Dr. E. D. Clarke gives some interesting details on this subject. In the Crimea the meerschaum clay is called *keff-kil*, and forms a stratum about two feet thick, beneath a much thicker stratum of marl. 'The first rude form is given to the pipes upon the spot where the mineral is found; here they are pressed within a mould, and laid in the sun to harden; afterwards they are baked in an oven, boiled in milk, and rubbed with soft leather. In this state they go to Constantinople, where there is a peculiar bazaar or khan for the sale of them; they are then bought up by merchants, and sent by caravans to Pesth in Hungary. Still the form of the pipe is large and rude. At Pesth a manufacturer begins to fit them for the German markets. They are there soaked for twenty-four hours in water, and then turned in a lathe. In this process many of them, proving porous, are rejected. Sometimes only two or three out of ten are deemed worthy of further labour. From Pesth they are conveyed to Vienna, and frequently mounted in silver. After this they are carried to the fairs of Leipsic, Frankfort, Mannheim and other towns upon the Rhine, where the best sell from three to five and even seven pounds sterling. When the oil of tobacco, after long smoking, has given them a fine porcelain yellow, or which is more prized, a dark tortoise-shell hue, they have been known to sell for forty or fifty pounds of our money.'

Dr. Clarke's description refers to a period many years back; but it will serve to illustrate the subject.

MEISSEN. It is in this town in Saxony, about 18 miles from Dresden, that the celebrated *Dresden China* is made. There is a large factory supported by the government, where all the processes of the porcelain manufacture are conducted on a very complete scale. Some specimens of a highly curious character are displayed at the Great Exhibition.

MELON. In regions where most cooling vegetables disappear on the approach of great summer heat and drought, the melon, together with the water-melon, become essential substitutes. The antiquity of the cultivation of melons being so remote, and their dispersion over large portions of Asia and Africa so extensive, their indigenous locality cannot be traced at the present day. So far as moisture is concerned, the melon will bear a tropical heat; and, generally speaking, it will not succeed perfectly in the open air beyond the 43rd parallel of latitude. Its range of atmospheric temperature may be estimated at between 70° and 80°. Light is so essential, that unless the plants are kept near the glass, no tolerable degree of flavour will be acquired. A free admission of the air is also to be recommended, so far as it is consistent with the maintenance of a high temperature.

MELTING. The temperatures at which solids melt are also their freezing points; the freezing of water and the melting of ice, for instance, both occur at 32° F. In addition to the list given under FREEZING, are the following melting points:—

Tallow	92° to 127° F.
Phosphorus	108°
Stearin, from hog's lard	109°
Spermaceti	112°
Margaric acid	134°
Potassium	136°
Yellow wax	142° to 149°
White wax	156°
Sodium	190°
Sulphur	218° to 234°
Tin	442°
Cadmium, about	442°
Bismuth	497°

Lead	612° F.
Zinc	773°
Antimony	809°
Silver	1873°
Copper	1996°
Gold	2016°
Iron, Cast	2786°

MEMBRANE. The thin membranes which exist so largely in animals are applied to many useful purposes. The bladders used for covering vessels, the thin substance called goldbeaters' skin, the strings of catgut used for musical instruments—all are examples of this kind. They are briefly noticed under appropriate headings in this work.

MENAI BRIDGES. The Menai Strait is the locality of two of the finest engineering works of our country; viz., the *Suspension Bridge* of Telford, and the *Tubular Bridge* of Stephenson.

This narrow channel, about 17 miles in length, which separates the island of Anglesey from the mainland of Wales, intervenes on the great mail-route from England, by way of Holyhead, to the eastern coast of Ireland. Telford's bridge was commenced Aug. 10, 1819, and the mail-coaches drove over it for the first time Jan. 30, 1826. The distance between the supporting pyramids or points of suspension is 560 feet, and the height of the carriage way above high water in the Strait is 100 feet. The roadway of the bridge is divided into two carriage ways, each 12 feet wide, with a footpath 4 feet wide between them. The main chains are 16 in number, with a deflection of 37 feet, their ends being secured in a mass of masonry built over stone arches between each of the supporting piers. The weight of the chains, plates, screw-pins, wedges, and transverse ties is 398 tons; that of the suspending rods and platforms is 246 tons; making a total suspended weight of 644 tons. It is estimated that the bridge will bear 732 tons more than its own weight.

Notwithstanding the excellence of this bridge, it was deemed inadequate to bear the trains of the Chester and Holyhead Railway; and hence arose Mr. Stephenson's grand project for the *Tubular Bridge*. This unequalled structure, called the Britannia Bridge, consists of two tubes of iron placed side by side, through which the up and down trains of the Chester and Holyhead Railway respectively pass. The entire length of each tube is 1516 feet, and the height above high water 102 feet. Each tube consists of four pieces, the ends of which rest upon and are joined together on a central pier built on the Britannia Rock in the middle of the Menai Strait, on two towers on the shores of Anglesey and Caernarvonshire respectively, and on two abutments farther inland on each coast. There are therefore eight tubes in all. The clear length of each tube reaching from the side-towers to the central tower is 460 feet, so that the entire length of tube across the Strait is 920 feet, leaving 596 feet for the entire length of the side tubes. The top of each tube forms a regular arch of slight curvature; the bottom is quite straight and horizontal. The interior height is 26 feet in the centre, and 18 feet 9 inches at the ends. The internal width is 14 feet from side to side. The tubes are formed of plates of wrought iron strongly riveted together. The weight of each tube is about 5000 tons, or 10,000 tons for the whole of the double tube of iron.

The lifting of these tubes was the grandest mechanical operation, perhaps, that the world ever saw. The hydraulic presses with which the lift was effected are displayed at the Great Exhibition; they ought to be preserved, as a memento of this great engineering work. It may be interesting to add a record of the *dates* which marked the progress of the work. On June 30, 1845, the bill sanctioning the construction of the Britannia Bridge was passed by Parliament. In July the preliminary experiments to determine the form of structure commenced; April 13, 1846, the first workmen were engaged on the bridge; April 21, first stone of the Britannia tower was laid; June 13, 1847, the first vessels arrived with iron at the Strait; August 10, the first rivet was inserted; February 22, 1849, the Caernarvon and Anglesey towers were completed; April, 1849, the pontoons were brought to bear; May 4, first tube was completed and platform cut away; June 20, first tube floated; June 22, last stone in Britannia tower laid; November 9, first tube deposited in permanent bed; December 4, second tube floated; February 7, 1850, second tube deposited on permanent bed; March 3, Caernarvon small tube lowered; March 5, first engine passed through tube, and last rivet inserted; March 18, single line of tube opened for public traffic: June 10, third tube of second line floated; July 11, third tube deposited; July 25, last tube floated; October 21, second line of tube opened for public traffic.

Holyhead, at which the railway terminates, is a market-town with a good harbour, and is situated on the northern coast of Holyhead Island. Holyhead harbour is formed by a pier faced with hewn limestone 900 feet in length, at the head of which the water is 14 feet deep at low tides; but the government and the company are about to incur a large expenditure in forming a magnificent harbour.

The direct distance across from Holyhead to Kingstown Harbour in the Bay of Dublin is 64 miles.

MENTHA, is the name of many useful species of plants. *Mentha piperita* is the common *peppermint*, which, when dried, yields a peculiar aromatic odour, and a pleasant camphor-like taste; the dried herb is used for the preparation of a distilled water and of a volatile oil; and from the oil, of which there are three varieties, the essence of peppermint is prepared. *Mentha pulegium* is the *pennyroyal*, which, besides being medicinal in its natural state, is made to yield a distilled water, a spirit, and a volatile oil. Analogous products are also obtained from a third species, the *Mentha viridis* or *spearmint*.

MERCATOR'S PROJECTION. The nature of this useful variety of chart is briefly noticed under MAP-MAKING.

MERCURY, or QUICKSILVER. This metal, which possesses the remarkable property of being fluid at usual temperatures, has been known from the remotest ages. Although it is met with in very large quantity, yet the mines occur in comparatively few places; those of Almaden in Spain, and Idria in Carniola, are the most important. There are however mines of this metal in Hungary, Transylvania, and the district of Zweibrücken in Germany. Mercury has been obtained for a very long time in China and Japan, and although the amount of the produce is unknown, there is every reason to think it is considerable; it is also found at Huancavelica in Peru. The average yearly produce is estimated at about 2000 tons, of which about two-thirds come from Almaden. The quantity brought to England in 1848 was 1,562,663 lbs. and in 1849 it rose to 2,682,592 lbs; in 1850 it was very much smaller, owing to monopoly arrangements.

Mercury is always obtained from cinnabar, which is a bisulphuret of the metal; it is found in the red sandstone associated with coal at Almaden; sometimes, as in the district of Zweibrücken, the cinnabar occurs in the subordinate porphyries; and at Idria in the subordinate bituminous schist, but rarely in limestone itself.

Various processes are adopted for the purpose of separating the mercury from the ore, all of which depend upon the volatility of the metal, its conversion into vapour in distilling vessels or retorts, and its condensation by cold. In order to separate the sulphur from the metal, either iron or lime may be employed; the first forms sulphuret of iron, and the latter of calcium, with the sulphur, and the metal is thus set free, volatilised, and condensed. The retorts employed are made of cast or sheet iron or earthenware.

Mercury is fluid at ordinary temperatures, is of a silvery white colour, and possesses a high degree of lustre; it is inodorous, tasteless, unacted upon or very slightly by exposure to air at common temperatures, and not at all by water at any temperature. The specific gravity of mercury is about 13·568. It boils at 670°. At 40° below zero, mercury becomes solid, crystallises in octahedrons, and gives a dull sound like lead; at the moment of congelation it contracts considerably; when in this state it is malleable, and may be cut with a knife. It is only on some few rare occasions that our Arctic explorers have encountered a cold so intense as to freeze mercury; in such case a *spirit* thermometer is the only one available, for spirit has never yet been frozen or solidified.

The number of valuable compounds which mercury forms with other substances is very considerable. The *binoxide* is a dark red crystal used in medicine. The protochloride constitutes *calomel*, and the bichloride *corrosive sublimate*. The bi-sulphuret yields *cinnabar* or *vermillion;* and another combination of mercury and sulphur forms *Ethiop's mineral.* The sulphate of mercury is *Turbeth mineral.* The fulminate of mercury forms *detonating powder*. All the alloys of mercury, or combinations of mercury with other metals, are called *amalgams*, and are noticed elsewhere. [AMALGAM.]

The uses of mercury in the arts are most varied and abundant. A few among them will be found briefly noticed under BAROMETER, BUTTON MANUFACTURE, GILDING, PENDULUM, PHOTOGRAPHY, SILVERING, THERMOMETER. All these relate to mercury in its liquid or metallic form; the chemical compounds of mercury with other substances have a still more extensive range of usefulness. The *medical* use of mercury lies beyond the scope of this volume.

MERTHYR TYDVIL. This town, one of the most important in South Wales, is the centre of the great iron smelting operations of that country. The stores of iron and coal in the immediate neighbourhood are most abundant; and the smelting is carried on upon a larger scale than at any other spot in the kingdom. In the immediate vicinity of Merthyr are the Dowlais works of Sir John Guest, the Cyfarthfa works of Messrs. Crawshay, the Plymouth works of Messrs. Hill, the Pen-y-darren works of Messrs. Thompson, and two or three of smaller rank. At no great distance from Merthyr are the large iron-works of Hirwain, Aberdare, Pentwain, Varteg, Blaenavon, Bryn-Mawr, Nant-y-Glo, Ebbw Vale, Beaufort, Sirhowy, Rhimney, and many more. At the Dowlais works (the largest in the world) there are 18 blast furnaces, 77 puddling furnaces, 66 balling furnaces, besides a number of refining furnaces. About 1000 tons of coals per day are used at the works; and in busy times from 5000 to 6000 persons are employed. The quantities of iron and coal sent down the Taff Valley, by railway and canal, from the Merthyr district to Cardiff, are immense.

MESSINA. The produce and industry of Messina receive a little illustration under SICILY.

MESTA. The Mesta is a very peculiar kind of right of pasturage in Spain. Spain has vast tracts of unclaimed pasture-land on which the wealthy owners of flocks claim prescriptive right to pasture their sheep at the proper seasons.

The number of migratory sheep at the beginning of the present century amounted to about five millions. In the month of April the flocks leave the plains of Andalucia and Estremadura for the cooler pastures of Leon, the two Castilles, and Aragon, whence they begin to return southwards in October; for the lands depastured during the winter months a low price is paid, regulated by usage, and on which no advance is allowed. The sheep are divided into flocks of 10,000, each managed by a conductor, who has under him 50 shepherds and as many dogs. They pass unmolested, and feed over the pastures and commons that lie on their road; they are not allowed to traverse cultivated lands, but the proprietors of such lands are obliged to leave a clear space, 85 yards wide on each side of the road, for the passage of the flocks. At night they are penned in with nettings made of the esparto rush. The different routes and the length of each day's journey in these migrations are fixed by immemorial usage. Lambing takes place during the winter sojourn in the south. The sheep-shearing commences in May on the northward journey, and is effected in vast buildings by the roadside, called *Esquileos*, capable of containing 50,000, and some of them 60,000 sheep; the principal of these buildings are in the environs of Segovia.

The wool of the sheep belonging to the *Mesta* is celebrated for its fineness, length of fibre, and silky softness: this excellence is said to be owing to the habits of the sheep, whereby they are led to live in almost always the same temperature. The meat of these sheep is however of inferior quality.

The mesta is very unpopular in Spain, for the following among other reasons—the number of persons (40,000 or 50,000) whom it takes from the cultivation of the soil; the immense extent of valuable land kept out of cultivation; the continual trespass on the cultivated lands near the route taken by the flocks in their migration; the scarcity of food for the stationary sheep in the line of march; the loss in an agricultural point of view (in respect to manure) of the sheep never being penned on arable land; and the despotic behaviour of the shepherds, who are protected in their improper privileges and conduct by the tribunal of the mesta. All attempts to abolish the mesta have, however, failed.

METALS; METALLURGY. The metals form a numerous and highly important class of simple or elementary bodies. They amount in number to upwards of forty. They are, given alphabetically, as follows:—*Aluminum*, *antimony*, *arsenic*, *barium*, *bismuth*, *cadmium*, *calcium*, *cerium*, *chromium*, *cobalt*, *columbium*, *copper*, *gulcinium*, *gold*, *iridium*, *iron*, *latanium*, *lead*, *lithium*, *magnesium*, *manganese*, *mercury*, *molybden*, *nickel*, *osmium*, *palladium*, *platina*, *potassium*, *rhodium*, *silver*, *sodium*, *strontium*, *tellurium*, *thorium*, *tin*, *titanium*, *tungsten*, *uranium*, *vanadium*, *yttrium*, *zinc*, *zirconium*. Some chemists rank *selenium* and *silicium* also among the metals, and a few newly discovered metals are now undergoing examination.

With the exception of mercury all metals are solid at the usual temperature of the air, and the colour of most of them is grayish-white. The lustre of metals is great and peculiar, and is well known by the name of the metallic lustre; they differ however very considerably in the degree in which they possess this property. When reduced to a state of minute division, the metallic lustre is lost but the colour remains. The metals are generally reckoned perfectly opaque, even when reduced to thin leaves; but it is found that gold-leaf which is $\frac{1}{200000}$ part of an inch thick, suffers light to pass through it, and it has a green colour; it is therefore extremely probable that all metals, if they could be rendered equally thin, would also be translucent. There are some metals, such as lead, tin, copper, and iron, which, when rubbed, emit a peculiar and disagreeable smell; and others, such as arsenic and antimony, which emit an odour when heated. All the metals are heavier than water, except sodium and potassium. Platinum is the heaviest. About one half of them are ductile or malleable, and the other half brittle. Gold is the most ductile and the most malleable, iron is the most tenacious, and titanium the hardest, in their native state. The elasticity and sonorousness of metals are generally associated with their degree of hardness. There are not however any metals which are by themselves either very elastic or sonorous; but there are alloys which possess these properties in a high degree, as for example those of copper and tin.

Metals are sometimes lamellar, sometimes granular, and frequently crystalline: indeed, some of them, and more especially copper, occur crystallised in the form of the cube and its varieties. Bismuth is a metal which may be artificially crystallised in cubes with great facility.

No particular effect has been attributed to the agency of light upon metals. The metals are good conductors of heat; some of them rank in the following order in this respect—gold, silver, platina, copper, iron, zinc, tin, lead. Their capacity for heat ranges them in a different order, bismuth and lead taking the lead. Immediately that heat pervades the metals, and before it fuses them, it expands them in all directions. This dilatation is different in different metals; it varies also in the same metal with every degree of the thermometric scale; but from the freezing to the boiling point of water it may however be regarded as nearly constant. The fusing point of metals varies extremely. [Freezing; Melting.]

Some metals are volatilised at moderate degrees of heat: among these are mercury, cadmium, arsenic, tellurium, zinc, potassium, and sodium; but there are others which may be exposed to the most intense heat of a wind furnace without being at all vaporised.

The relative conducting powers of the principal metals for electricity are as follow:—copper, gold, silver, zinc, platina, iron, tin, lead, mercury, potassium. Each of the following metals is positive with relation to those which follow it:—zinc, lead, tin, iron, antimony, bismuth, copper, mercury, silver, gold, tellurium, palladium, platina. There are two metals only which are capable of being rendered permanently magnetic, namely, iron and nickel; the former of these only is met with possessing this property in nature; it is an oxide of iron, and commonly called the *loadstone*. Most of the metals combine with each other and form compounds differing very materially in properties from their constituent metals. [Alloys.] All metals unite with oxygen, but with different degrees of facility and affinity; most of them combine with more than one proportion of oxygen and some of them with several proportions. A few of these compounds form acids, but most of them oxides. Hydrogen, chlorine, bromine, sulphur, iodine, and phosphorus, all combine with some or other of the metals. Some metals, as potassium, sodium, and manganese, decompose water even at common temperatures, combining with its oxygen and evolving the hydrogen; others, as iron and zinc, require to be strongly heated, or the presence of an acid, to effect this decomposition.

Although most metals are dissolved by acids, yet platina and gold are exceptions to it, these and some others requiring chlorine, and generally in the nascent state called *aqua regia*.

Metallurgy, or the separation of metals from their ores and from other compounds, varies in its processes according to the metal; for which see Copper, Gold, Iron, Lead, &c. The working of metals into useful forms constitutes the basis of such numberless mechanical arts that we cannot here even enumerate them; the principal among them will be found under their proper headings.

In relation to commerce, the metals form a very important section of our Exports and Imports. Among our Imports for 1849 and 1850 we find the following:—

	1849.	1850.
Copper and copper ore,	47,433 tons	45,930
Wrought copper .	51,808 cwts.	97,706
Iron in bars . . .	29,396 tons	34,066
Steel	1,012 tons	49
Lead	7,216 tons	11,977
Zinc	15,915 tons	18,626
Tin	35,827 cwts.	33,332
Mercury	23,952 cwts.	3,170
Watches	86,305*l.*	97,245*l.*

Our Exports of metals in the same two years included the following:—

	1849.	1850.
Iron, pig, bar, and wire . . .	567,417 tons	615,150
Iron, cast . . . ,	16,549 tons	21,201
Iron, wrought . .	117,431 tons	136,514
Steel, unwrought .	8,097 tons	10,587
Brass	23,811 cwts.	25,899
Copper	409,603 cwts.	422,309
Lead	17,027 tons	22,083
Tin, unwrought .	35,292 cwts.	31,663
Tin plates . . .	709,788*l.*	928,181*l.*
Machinery . . .	700,631*l.*	1,043,764*l.*
Cutlery and hardware . . .	2,201,315*l.*	2,639,728*l.*

In respect to Exhibitions of Manufactures, such as that which so largely attracts public attention in 1851, the metals form by far the most bulky of the specimens.

METEORIC STONES. [Stones, Meteoric.]

METERS. The increased use of gas for lighting streets and buildings has led to the invention of a number of *gas-meters*. In the early stage of the system, gas was charged for at so much per light, according to the number of holes in the ring of the burner; but it has become gradually admitted that a more equitable principle would be to charge for the quantity actually consumed. This is done by measure; and a gas-meter determines the number of cubic feet consumed. The meter is placed at some spot between the main and the burner, so that all the gas must pass through the meter before reaching the burner. The meter is a hollow box, and in most cases contains water in some of the interior compartments; but whether so or not, the progress of the gas through the meter moves a system of wheel-work, by which index hands shew the amount which has passed.

METRONOME. This ingenious instrument was introduced about the year 1814, by John Maelzel (civil engineer and mechanician to the Emperor of Austria), for the purpose of determining the movement, *i.e.* the quickness or slowness, of musical compositions. Of Maelzel's Metronome there are two kinds. The one is a pendulum kept in motion by a spring and wheelwork, and which ticks the vibrations:—the other is also a pendulum, but without any machinery, and acting only so long as the force of the impulse given shall last. The former, therefore, it will be obvious, is complicated and expensive; the latter is simple and cheap.

Much opposition was made to the use of this excellent instrument, when first introduced; but it is gradually coming into extensive use.

Mr. Greaves of Sheffield has lately registered a very simple and cheap metronome. In size and form it resembles a small watch, and can be carried in the waistcoat pocket. It consists of a case containing a tape 40 inches long, which can be drawn out to any required length, and be there retained by a stop. The extreme end of the tape being held by the finger and thumb, the case forms the bob of a pendulum, which may be swung to and fro. Instead of holding it between the finger and thumb, a small spring affords the means of attaching it to a pianoforte or a music stand. As all pendulums oscillate a certain number of times in a minute according to the length, the tape is drawn out more or less according as the oscillations are to be slow or quick; and this depends upon the tune of the piece of music. The tape has marks to indicate any number of oscillations per minute from 60 to 160; and it is also marked with those Italian words which serve to point out the quickness or slowness of a piece of music: such as *presto, spiritoso, vivace, allegro, poco allegro, moderato, allegretto, andante, andantino, larghetto, lento, largo, grave, adagio.*

MEURTHE. In this department of France a very large quantity of wine is made; in ordinary years the produce is 20 to 21 million gallons. The surplus over the home consumption is sold into Alsace and the department of Vosges. In the arrondissement of Sarrebourg, where the climate, owing to the proximity of the Vosges mountains, is colder than in the rest of the department, the vine is not cultivated at all. Rape is extensively grown, both for green food and for making oil. Hay is abundantly produced along all the river bottoms. Potatoes, potherbs of all kinds, and fruits are largely cultivated. Iron ore is found, but too poor to be worth digging for. Building stone, marble, and limestone are quarried; lithographic stone, red and gray granite, grindstone grit, glass sand, potter's clay, &c., are found. A mine of salt-rock at Vic, and several salt-springs, are the most valuable mineral treasures of the department.

The industrial activity of the department has been greatly developed within the last few years, and is exerted on a great variety of products, among which are—woollen cloth, calico, canvas, embroidered muslins and cambrics, playing cards, room paper, cut and plate glass, tobacco pipes, oil, mineral acids, cotton twist, gloves, beet-root sugar, candles, basket and wood work, &c. There are also some iron and bell foundries, numerous glass-works, tanyards, paper mills, dye houses, and potteries. Of the articles just enumerated and of its agricultural produce the commerce of the department is composed.

MEUSE. This is another of the French departments, deriving its name from an important and busy river. The lower part of the basin of the Meuse includes a good deal of fertile flat land, with not a few marshes and peat bogs; the upper part of it is in general fertile, and presents some pretty and some bold scenery. The basin of the Meuse communicates with those of the Rhine, the Seine, and the Schelde, by means of canals.

In the department, hemp, flax, and oleaginous seeds are cultivated. Cattle, swine, and goats are numerous; horses are small. Gooseberries and strawberries are grown in very large quantities in the neighbourhood of Bar-le-Duc and Ligny, whence they are largely exported in the preserved state. Gruyère and cream cheese are made in the arondissement of Commercy. About 20 to 24 million gallons of wine are made annually, two-thirds of which are consumed on the spot, and the remainder is exported to Belgium.

Several iron mines are worked; good building stone, marl, potters' clay, and slates are found. Fossils of great variety, and some of large dimensions, are met with. The chief manufactures are—iron, made in about forty forges and furnaces, cotton cloth and twist, hosiery, oil, glass, paper, pottery, beer, leather, inferior brandy, &c. The commerce of the department is fed by the articles already enumerated, and by timber, oak staves, clover seed, butter, fat pork, hides, wool, confectionary, &c.

MEXICO. Humboldt asserts that within these states almost all the vegetable productions may be grown which are found between the equator and the polar circle. Any enumeration of them here would therefore be unnecessary. The agriculture of the tablelands does not supply any article for exportation. Cotton is grown along the shores of the Pacific, and in the valley of the Rio Nasas, in a deep depression of the northern table land; and coffee on the eastern coast, west of the town of Vera Cruz; sugar is cultivated in many places, and a considerable quantity is exported; cocoa is collected in the low country along the river Huasacualco; and indigo along the southern coast, but only for home consumption. Tobacco, which in many parts succeeds very well, is only permitted to be grown in certain places.

The domestic animals, brought over from Europe by the Spaniards, have multiplied greatly in Mexico, owing to the wide tracts which are not or cannot be cultivated, and which afford pasture-ground for nine or ten months of the year. Cattle is abundant, both on the table-lands and the lower tracts. Jerked beef and horns are exported. Sheep are numerous on the table-lands, especially on the northern, which are much drier; and wool is an article of exportation. Horses abound generally. Horses and mules are exported in great numbers to the United States. On the great plains bordering on the Red River and the Arkansas the American buffalo abounds. Game is abundant, especially deer and hares. The cochineal insect is reared with great care on the table-land of Mixtecapan, whence by far the greatest part is brought to the markets of the world.

Mexico is noted for its mines of gold and silver. The gold mines occur chiefly on the western side of the Sierra Madre, north of 24° N. lat.: the silver mines are richest on the mountains which rise on the table-lands, and in those which border their margin. Besides the precious metals, Mexico has abundance of copper, iron, and lead, which are worked. The iron mines, however, have only been opened since the year 1825. A quicksilver mine is worked at S. Onofre, on the northern declivity of the Sierra Madre. The carbonate of soda, which is necessary for the smelting of the silver ore, is collected in several lakes, where it is found crystallised on the surface in great abundance.

Before the Mexican Revolution in 1810, there were many flourishing manufactures in Mexico, the annual produce of which amounted to from eight to ten millions of Spanish dollars, or about two millions of English money. The most considerable were those of cotton and wool in the towns of Puebla, Cholula, Tlascala, Queretaro, Lagos, Guadalaxara, and Tezcuco. The manufactures of soap, leather, and saddlery were also considerable. The manufacturers owed their prosperity to the high price at which, under a system of monopoly, European goods were sold in that country. After the harbours were thrown open to a free trade (in 1820) the manufactures began to decline, and are now much diminished.

The commercial intercourse between the coast and the table-lands is difficult on account of the steep ascent to the table-lands from the coast. Even in those parts where there is no obstacle to the use of carriages, the goods are commonly carried by mules, on account of the great number of these animals, and the low price at which they are bought.

The maritime commerce is considerable; but it is carried on chiefly in foreign vessels, Mexico possessing few vessels of her own. In the beginning of the present century the exports, according to Humboldt, amounted to 22,000,000 of Spanish dollars, and the imports to 15,000,000 of dollars. Between 1820 and 1830, however, the exports considerably diminished, on account of the comparatively small produce of the mines, the precious metals constituting the principal article of exportation. The coinage of gold and silver in Mexico in 1845 amounted to 15,141,816 dollars. The amount of gold coined in Mexico in the 18 months ending June, 1849, was 1,351,416 dollars, and of silver, 27,003,989 dollars; which, with nine or ten million dollars' worth left uncoined, present a total of about 38,000,000 dollars' worth raised in 18 months. It is understood that, but for the high price of quicksilver for smelting or amalgamating, the produce would have been larger.

The total Mexican exports are estimated at about 20,000,000 dollars, of which 18,000,000 are in precious metals. The British and Irish produce exported to Mexico in 1848 was valued at 945,937*l*. Our imports from Mexico consist chiefly of cochineal and logwood.

The aboriginal architecture of Mexico resembles that of Egypt, not only in the vast scale and massiveness of its monuments, but in the application of the pyramid, or of forms composed of it. Pyramids not inferior to those of Egypt, and some of even still larger dimensions in their plan or base, exist in the Mexican territories; and examples of the second class occur in pyramid towers, consisting of a series of truncated pyramids placed one above another, each successive one being smaller than the one on which it immediately rests, so that it stands upon a platform or terrace. At Teotihuacan, about eight leagues to the north-east of the city of Mexico, are an immense number of pyramids, several hundred small ones ranged in files or lines, and two larger ones consecrated to the sun and moon. Besides monuments which are chiefly works of magnificence, others exist which attest the high degree of civilization attained by the aboriginal nations of Mexico, such as Cyclopean roads and bridges. The former of these were constructed of huge blocks of stone, and frequently carried on a continued level, so as to be viaducts across valleys.

MEZZOTINTO is a peculiar mode of engraving designs of any description upon plates of copper or steel. In this style of engraving, which essentially differs from every other, the surface of the plate is first indented or hacked all over by the action of an instrument something like a chisel, with a toothed or serrated edge, called a *cradle*, or mezzotinto *grounder*. This tool, being rocked to and fro in many directions, indents or barbs the plate uniformly over its face, and produces what is called the mezzotinto grain or ground. The barb or nap thus produced retains the printing-ink; and if in this state of preparation an impression were taken from the plate upon paper, it would be uniformly of a deep black colour.

The mezzotinto ground having been laid, the business of the artist properly commences. Having traced or drawn, with a pencil or other instrument, his outline upon the paper (unless, indeed, as is sometimes the case, this should have been etched by the ordinary process previous to the mezzotinto ground having been laid), he proceeds to cut away the nap or ground, in conformity with the design, from all those parts which are not intended to be perfectly black in the impression. The instruments required for this purpose are *scrapers* and *burnishers*. With the former he scrapes away more and more of the ground in proportion to the brightness of the light, and the burnishers are used to produce perfect whiteness where it is required, as the high lights on the forehead or tip of the nose, or white linen in a portrait, &c. As the work proceeds it may be blackened with ink, applied with a printer's ball or otherwise, to ascertain the effect; after which the scraping may be again proceeded with, the artist taking care always to commence where the strongest lights are intended to appear.

The great facility with which mezzotintos are executed, as compared with line engravings, will be obvious, seeing that it is much easier to scrape or burnish away parts of a dark ground corresponding with any design sketched upon it than it is to form shades upon a white ground by an infinite number of strokes, hatches, or points, made with the graver or etching needle. Herein consists the leading difference between this and all other modes of engraving; for, while the process in each of these is invariably from light to dark, in mezzotinto it is from dark to light; and even the very deepest shades are produced, as we have seen, before the design is commenced. The characteristic or distinguishing excellence of mezzotinto engraving would seem to consist in the rich profundity of its shadows, and its chief defect seems to be a corresponding poverty in the lights. Lithography has of late years, in a great degree, superseded mezzotint.

MICA is a mineral which usually occurs in thin plates, semi-transparent, and of a peculiar lustre. It consists chiefly of silica and alumina, with small proportions of potash, lithia, and other substances. It is very useful for many optical purposes, since it is easily separable into very thin plates, and is in that state almost transparent.

Mica gives the name of *mica schist* to one of the earliest groups of stratified rocks known to geologists, and very extensively distributed throughout the mountain regions of the globe, often in contact with granite, but more frequently superposed on gneiss. It is frequently interstratified with gneiss, primary limestone, quartz rock, chloritic schist, and clay slate. It differs from gneiss by the absence of felspar. In respect of the magnitude, relative abundance, and crystalline aspect of the ingredients of mica schist, there is every possible variation, so that some specimens approach obscurely to granite, others to well defined gneiss, and others to clay slate.

MICHIGAN. A few industrial statistics of this American state will be found under UNITED STATES.

MICROMER. These ingenious contrivances for measuring small spaces or angles with great accuracy or convenience, present many varieties.

Wire Micrometer.—This frequently consists of two fine wires or spider's threads, of which one is fixed and the other moveable, in the eye-tube of a telescope at the place where the image is formed. The moveable wire is in a sliding plate which, by a screw, is moved parallel to the other, and perpendicularly to the axis of the telescope, till the object appears to be comprehended between the wires; and a graduated scale is provided for the measurement of the angle. Each division is equal to the extent of space moved by the wire during one revolution of the screw, and the head of the screw is graduated, in order to subdivide the scale. The instrument was invented by Mr. Gascoigne in the seventeenth century, but it appears to have been afterwards neglected, and was re-invented by M. Auzout. The micrometer microscope, for reading off the divisions of graduated circles, is an instrument of this kind.

The *Position Wire Micrometer* has lately come very much into use for observations of double stars, and is the wire micrometer proper for equatorials. In this construction there are two wires parallel to each other, each moveable by its own screw: the whole apparatus can also be turned round in the plane of the wires, so as to place the wires in any direction, the angle round which it is turned being read off by two verniers upon a small circle called the position circle. The mode of measuring double stars by this instrument is a very refined problem in practical astronomy.

The *Divided Object-Glass Micrometer.* If an object-glass be cut across so as to form two semicircles, and the semilenses be separated by sliding one beyond the other, each portion will form its proper image, and these will retreat from each other as the semilenses are moved. The semilenses are mounted on slides, and the quantity of separation read off upon a scale.

The *Divided Eye-Glass Micrometer.* This consists of a convex lens bisected in the direction of a diameter, and placed either at the end of a telescope nearest the eye, or between some of the other lenses of the eye-piece; it acts as a micrometer by separating the two halves of the lens, as in the former case.

The *Reticule Micrometer* is employed where less accurate measurement is required. The reticule, or diaphragm, as it is sometimes called, is any fixed arrangement of wires or bars which can be applied to a telescope for the purpose of measurement. Suppose, for example, a cross like an X to be cut out of brass plate, and inserted in the principal focus of a telescope. A star, in passing through the field of the instrument, is occulted at its passage behind each of the bars, and the time noted. The *interval* will show, by an easy calculation, how far it passes from the vertex; and the *mean* of the times, the moment when it passes the axis of the diaphragm. This reticule is very convenient for mapping, if placed in the meridian, or for cometary observation, if the telescope is mounted as an equatorial, however rudely.

The *Circular Micrometer.* A metal ring is set in the centre of a perforated glass plate, and the outer and inner edge of the ring is turned true. The plate is fixed in the focus of a telescope, and the observer notes the time when a star disappears at the outer ring, reappears on the inner ring, disappears again, and finally reappears. These data afford the means for measuring small angles.

It need hardly be stated that manufacture of such apparatus as the above must take a high rank in philosophical instrument making.

MICROSCOPE. As the *micrometer* enables the man of science to measure very small spaces, so does the *microscope* afford the means for seeing smaller objects than would otherwise be visible. The scientific principles of the microscope are beyond the present work; it is only as a work of *construction* that it is treated here.

By the term *Simple Microscope* is meant one in which the object is viewed directly through a lens or combination of lenses. When, however, the magnifying power of the glass is considerable, it requires to be placed at the proper distance from the object with great precision: it cannot therefore be held with sufficient accuracy and steadiness by the unassisted hand, but must be mounted in a frame having a rack or screw to move it towards or from another frame or stage which holds the object. The lens is then called a *microscope;* and it is furnished, according to circumstances, with lenses and mirrors to collect and reflect the light upon the object, and with other conveniences.

The *Compound Microscope* has two lenses which have totally different functions; the first receives the rays from the object, and, bringing them to new foci, forms an image, which the second lens treats as an original object, and magnifies it just as the single microscope magnified the object itself. Each of these purposes is further carried out by an increase in the number of lenses. By means of successive improvements, the Compound Microscope now holds a very high rank among philosophical implements; while the transcendant beauties of form, colour, and organization which it reveals to us in the minute works of nature, render it subservient to the most delightful and instructive pursuits.

The *Solar Microscope* consists of a conical tube fixed by its base to a frame of wood, which is screwed to a closed window-shutter, at an aperture purposely made in the shutter: the tube projects into the room, which, when the observations are to be made, is rendered quite dark, and is sometimes lined with black cloth. The magnifying power is produced by a system of lenses contained in the tube, as in other microscopes. On the exterior of the window is a frame carrying a rectangular piece of looking-glass, which, by turning on a hinge, is capable of being fixed at any angle with the wall of the building, while, by means of a ring and a rack and pinion, it can be made to turn on the horizontal axis of the instrument, so as to permit the rays of the sun, whatever be the position of the latter, to be reflected into the tube. These rays are made to converge on the object; and from thence, after refraction through the system of object-glasses, they proceed to a screen, on which they depict the magnified image. The solar microscope is now nearly superseded by the *Oxyhydrogen Microscope*. [LUCERNAL MICROSCOPE.]

MIDDLESEX. The interest in this small county is so absorbed by that of the gigantic metropolis which it contains, that we need not enter upon its industrial and commercial features here. It would be but a very slight deviation from accuracy to say, that the whole county is occupied either by persons whose daily avocations are centred in London, or by persons who supply the various markets of the metropolis with produce. There are malting, brewing, distilling, and other processes carried on upon a considerable scale in the extra-metropolitan parts of Middlesex, but chiefly looking to London as a centre.

MILAN is a gay thriving city: its markets are abundantly supplied with every luxury. Numerous coffee-houses, splendid hotels, abundance of handsome carriages, several theatres (among which is La Scala, one of the largest in Europe), well supplied with actors and singers,—all attest the habits of a luxurious capital. It is also a famous seat of learning and of the fine arts. But whatever may be its attractions in these directions, Milan can hardly be called a commercial city. Its manufactures consist chiefly of silks, printed cottons, plate-glass, jewellery, artificial flowers, soap, and leather.

MILE. The connection between measures of length and commercial matters renders it useful to have at hand a comparison of the different lengths of a mile, in different parts of Europe. The English statute mile is 8 furlongs, each of 220 yards, or 40 poles of 5½ yards or 16½ feet each. It is also 80 surveying chains of 22 yards each. It is therefore 1760 yards, or 5280 feet. The square mile is 6400 square chains, or 640 acres.

	Yards.	Stat. miles.
Ancient Roman mile....	1614	.917
Modern Roman mile....	1628	.925
English statute mile	1760	1.000

MILK. This remarkable and valuable liquid consists, in addition to the watery portion, serum, &c., of globular particles, having a diameter of about one ten-thousandth of an inch. They are composed of a fatty matter (butter) and a coagulable substance, which in many points resembles albumen, termed *caseine*, or the matter of cheese. Milk is a compound fluid, chiefly consisting of oil, sugar, and protein.

Milk may be brought to a dry state, and powdered, in which condition it keeps for a length of time; and by dissolving it in tepid water an artificial milk may be formed, capable of being used at sea, particularly for children during long voyages. Of the valuable use of milk in dairy husbandry, see BUTTER; CHEESE; DAIRY. Milk is also used as an antidote in cases of poisoning by some metallic salts, such as corrosive sublimate, perchloride of tin, sulphate of copper, &c.

There is too much reason to believe that the milk sold in busy towns is far from pure; water is often added to increase the quantity, and strange compounds (according to chemical tests) are added to imitate the quality. Until dealers learn to be commercially honest, there is no cure but the vigilant observation of the buyers; for it is doubtful whether legislation could meet the evil.

MILLET, is cultivated largely in the southern parts of Europe—in Spain, Italy, the south of France, Switzerland, and southern Germany; but it is grown most extensively in the East Indies, China, Arabia, Syria, Egypt, and

Nubia. It has also been introduced into the West Indies, where it is called *Guinea Corn.* In the East millet is used as food for man; but in Europe, though it is sometimes made into loaves and cakes, and frequently into puddings, it is mostly used for feeding poultry and domestic animals. The leaves and panicles are given, both green and dried, as fodder to cattle.

MILLS; MILL WORK. The name of mill is employed rather indefinitely in machinery. A cotton factory is called a mill; a windmill is a mill; a coffee-grinder is a mill; and many agricultural implements are called mills. Without extending the application too widely, we will notice a few of the mills connected with agricultural pursuits.

All the machines for grinding corn and seeds are mills, whatever may be their particular application. At the Smithfield Cattle Show, and similar agricultural exhibitions, such mills are numerous. One prevalent form is that of an iron machine supported on four legs, having a winch handle on one side, a fly wheel on another, a hopper at the top, and a crushing apparatus in the centre. The grain or seed is put into the hopper, the winch handle is turned, the grain becomes crushed to powder, and falls out at the bottom of the apparatus. Sometimes the mill is made chiefly of wood, but with iron wheel and crushing apparatus. Lloyd's wheat mill, in addition to the usual mill apparatus, has a chest which acts as a flour dressing machine. Some mills are adapted for crushing beans rather than seeds.

Crosskill's patent mill has a somewhat higher class of action, since it is adapted either for hand, horse, or steam power. In addition to the grinding of corn and seed, it will hull rice, coffee, and olives; crush bones and metallic ores; and grind colours, drugs, charcoal and various other substances.

The crushing apparatus in mills is of two kinds, either one stone working round in contact with another; or two metallic surfaces between which the substance is forced, but between which it cannot pass except in a fine state.

MILLSTONES. The millstones employed in grinding corn require to be made of a peculiar kind of stone. The greater proportion of our millstones are procured from a particular spot in Western Germany. At about ten miles from Coblenz is a small town called Andernach, the chief trade of which is in millstones procured from the neighbouring quarries of Nieder-Mendig. There are several quarries, averaging about 50 feet in depth, each quarry shaped like an inverted cone, down the sides of which the quarry men descend by a spiral path. The quarry men have to cut away through a superincumbent layer of soft porous stone, till they come to a layer of hard, blackish, heavy stone, regularly porous, and yielding sparks when struck with iron. This is the mill-stone, and requires good and well prepared tools to work it; it is supposed to be a compact lava from some extinct volcano; and as there are fissures or gaps at intervals, these facilitate the separation of the stone into blocks suitable for millstones. All round the bottom of the conical cavities, the stone has been excavated in galleries or horizontal passages. The stones are brought to shape by means of hammers and chisels. A deep socket is cut through the middle of such stones as are intended for *runners*, or upper stones. The furrows on the surfaces of the stones are produced by means of a double edged hammer, about 14 lbs. weight.

The hard volcanic stratum from whence the millstones are cut, extends five miles in length by three in breadth; so that the supply may for all practical purposes be deemed inexhaustible. It is known that millstones have been procured from this spot during a period of 2,000 years. Four or five families usually unite in the labour of sinking a shaft and working the stone; all assisting in the labour according to their strength and ability. The workers divide themselves into four groups —the miners, the lifters, the cutters, and the loaders. When the millstones are properly shaped, they are sent down the Rhine upon the immense timber rafts which navigate that river. When the rafts arrive at Holland, they are broken up for the sale of the timber; and the millstones are distributed in various quarters according to the demand.

MINARET in Turkish and Eastern architecture, is a very slender and lofty turret, having one or more projecting balconies around it, that divide it externally into two or more stories. They are used in Mohammedan countries for the purpose of calling the people to prayers, and therefore serve the purpose of belfries; but they are also frequently added merely for ornament.

MINERALS. Various methods of arrangement of minerals have been proposed by different authors. According to Werner, minerals were divided into the four classes of earthy minerals, saline minerals, inflammables, and metals: Karsten classed them under the heads of earths, salts, combustibles, and metals: Haüy divided minerals into acidiferous earthy substances, earthy substances, non-metallic combustible bodies, metallic bodies, substances not sufficiently known to admit of classification, rocks and volcanic products; Phillips's classes are, earthy minerals, alkaline-earthy minerals, acids, acidiferous earthy minerals, acidiferous alkaline minerals, native metals, metalliferous minerals, and combustible minerals; Berzelius made a chemical classification. Various modes of classifying minerals have depended on the relative *structure, fracture, hardness, specific gravity, transparency* and *lustre* of the minerals. The study of this subject in a systematic form constitutes the science of *Mineralogy.*

MINIATURE PAINTING. Miniature painting, properly so named, is in water-colours, though it is not at all similar in its process to that employed in water-colour drawings in general. Instead of being applied in washes, or by different tints laid over each other, the colours are entirely dotted, stippled, or hatched upon the surface; though sometimes only the face and other flesh parts are so executed, as requiring greater finish and delicacy, while the drapery and background are either partially or wholly executed according to the usual mode of water-colour drawing. The material employed for painting upon is generally ivory (the surface of which is first prepared for receiving the colours), or vellum; sometimes Bristol-board, or other drawing-paper of that sort. Ivory however is preferred, as not only more durable, but bearing out the colours with greater brilliancy.

MINING. The use of the metals, and consequently some process for the extraction and separation of them, may be traced to the most remote antiquity. In respect to our own country, mines were worked in Britain by the Romans; but during the Saxon period they were much neglected; and subsequently to this period they were chiefly worked by Jews. In the reign of Elizabeth the art of mining had fallen into so much decay that an importation of foreign skill was found necessary to revive them; and the Germans, long and justly celebrated as skilful miners, received every encouragement to settle in this country and turn their attention to them. In the 17th century the use of gunpowder in mines was introduced; and early in the next century the rich copper mines of Cornwall were first worked. The invention of the steam-engine was early rendered applicable to mining in this country, and contributed to the present perfect state of the art. After the invention by Savery and Newcomen, the steam engine became a most useful auxiliary in the hands of the miner; and the improvements of Watt were still more beneficial. The Cornish steam engines are now among the most powerful in the world. The use of iron pumps instead of wooden in the shafts, and the laying down of tramroads in the galleries of a mine, were two other great improvements. Great improvements, too, have been made in the mechanical treatment of the ores after they have been extracted.

There are four principal classes into which mineral deposits may be divided; *veins, beds, masses,* and *fragmentary deposits. Veins* are generally long, narrow, and irregular fissures, traversing the rocky crust of the globe, which they penetrate to an unknown depth, and at a high angle of inclination. They are for the most part filled with sparry and stony substances called the 'veinstone,' or the 'gangue,' of the vein, but contain here and there irregular masses or 'bunches' of the metallic ores, often of immense size and value, and which it is the principal business of the miner to discover and extract. Most of the metals are of common occurrence in veins. *Beds* are layers of mineral substances interposed between the strata of solid rock, which, except in their containing valuable matter, they very much resemble. Several of the metals, especially lead, are occasionally found in beds; coal, clay-ironstone, and rock-salt, exclusively so. *Masses* or *Pipe-Veins*, are irregular branching cavities descending either vertically or obliquely into the rock, and filled up with metalliferous matter. They usually contain copper, lead, or oxides of iron. *Fragmentary Deposits* occur associated with many of the loose superficial beds of sand and gravel which occur in the valleys of mineral districts, consisting of the detritus of the neighbouring mountains, which has been washed down from thence at remote geological epochs. Tin and gold are the chief metals found in this form. Each kind of metallic ore is found to prevail in some one geological formation rather than others.

Most metals are found in the state of *Ores*, that is, chemically combined with certain mineralizing substances. The most important of these mineralizing bodies are oxygen and sulphur; the next in rank are chlorine, and the sulphuric, carbonic, and phosphoric acids. These elements require to be separated by the processes of metallurgy; but there are also other mechanical impurities scarcely less important, which require to be partially separated in the mine, and which therefore fall entirely within the province of the miner. It frequently happens too that ores of a worthless character are mixed up with the more valuable ones; thus copper and lead are very generally accompanied by iron pyrites and blende, both of which must be regarded as impurities, and therefore separated as far as possible previous to any process in the furnace.

Veins or beds are seldom visible at the surface of the ground, being generally concealed by the soil. As the deposits usually present no trace of their existence at the surface, certain general indications must be had recourse to for their discovery; the number of indications which guide the miner is considerable, and increases as science and experience advances. When a new vein or mineral deposit has been by any process discovered, the most usual step, after obtaining the consent of the proprietor, is the formation of a company; for companies are generally found to work mines better than individuals. The company agree with the proprietor as to the extent of ground within which operations may be carried on, the proportion of the gross mineral produce or its equivalent in money which the owner is to receive free of all expense in raising and making it marketable, and other matters.

In commencing the mining operations, the usual system is, to dig down from the surface until the vein or bed is reached. A spot is selected as the site of a shaft, which is frequently sunk in an inclined direction upon the course of the vein, or if intended to be perpendicular, it is commenced upon that side towards which the vein inclines or underlies, and at such a distance from its 'back' or outcrop, as to come down upon it at a given depth, say 10, 20, or 30 fathoms. On cutting the vein, the shaft is for a time suspended, and two horizontal passages, often termed 'galleries,' but by the miner 'levels,' are excavated or 'driven' upon the vein in both directions. These passages are usually about six feet in height and three or four in breadth, and rather smaller above than below. They are the principal means of exploring the contents of veins. If the shaft is deep, 'cross-cuts' and other levels are made at different heights, so as to explore the vein at different parts. After cutting the vein, there are two modes of proceeding—continuing the shaft perpendicularly through the vein, or obliquely upon the vein; the choice between these two plans depends on a number of practical circumstances. Supposing the shaft to proceed perpendicularly after cutting the vein, on reaching the depth of ten fathoms or thereabouts below the point of intersection another cross-cut will be driven to it. In this manner the shaft proceeds indefinitely, cross-cuts being driven at every ten fathoms or whatever distance is most convenient, and levels extended from each upon the course of the vein, the nature and value of which are thus thoroughly explored.

The mining operations are soon affected by the impurity of the air. It is chiefly in the ends of the levels that the evil of imperfect ventilation begins to be felt, the air here gradually becoming close and unfit for respiration, as the levels advance further from the shaft, especially when from the hardness of the ground frequent blasting is necessary. As soon as this is found to be the case, a remedy of a very simple nature is applied, which consists in sinking a small pit, termed a 'winze,' upon the vein, from the upper level to the extremity of the one below it. This communication having been effected, the two levels became perfectly ventilated, each having a double communication with the atmosphere by which both an ascending and descending current is produced. The winzes are generally made at intervals of 20 or 30 fathoms apart, and from each level to those above and below it: they serve not only for ventilating the galleries, but also assist the exploring and working of the vein.

The various operations may proceed indefinitely, according to the richness of the vein The shaft will continue to be sunk, cross-cuts driven to the vein at every ten fathoms or thereabouts, levels extended in both directions from them, and the ground between them subdivided by winzes. The excavations will now have assumed a regular form, and become what is properly termed a *mine*. In mining operations, where the vein is not very hard, the ore may be broken down with the 'pick' only, but it is generally necessary to blast it with powder, by which process large quantities are detached from the vein by every shot. The ore having been detached is carried in tram-waggons to the shaft, and thence raised to the surface. When the levels have been extended to a considerable distance from the shaft, the ventilation will again become defective, notwithstanding their communication by winzes. The expense of the transport of ore and masses of rock and rubbish to the shaft also becomes considerable; and if the prospects of the mine continue such as to warrant the expense, a new shaft must now be sunk on one or both sides of the former. This new shaft will be so placed as to intersect the vein much deeper than the former, and this point will be so arranged as to correspond either with one of the deepest levels, or some proposed level deeper still. By accurate measurements, mining engineers are able to work a second shaft from many different depths at one time. At the Consolidated Mines in Cornwall, a perpendicular shaft, 204 fathoms in depth, was worked from fifteen different points at once. Mining shafts are generally about eight feet by six in area.

As veins are generally found to run nearly parallel, and often at no great distance from each other, and as the neighbourhood of a productive vein is a favourable indication of the contents of others in its vicinity, transverse levels or 'cross-cuts' are frequently driven from mines at various depths, with a view to discover side-veins or to make trial of branches which diverge from the main lode. Metalliferous veins are often traversed by other veins crossing them at nearly right angles, which seldom contain ore, except perhaps near the points of intersection: they are termed 'cross-courses,' or 'cross-veins.'

Where a vein has been worked by driving a level towards it from a valley or other convenient point on the surface, the drainage to the point of intersection is, of course complete; and hence in mountainous countries, where deep ravines occur, levels may be made for draining at a much smaller expense than where engines are required to pump the water up from a great depth.

The tools and processes employed by the miner in the excavation of the rock or the vein are simple. As his work is chiefly of two kinds, simly *excavating* the ground when soft, and *blasting* it when hard, his tools are suited to each process, the 'pick' and 'gad' being used for the former; the 'borer' or 'jumper,' and the hammer used to propel it, for the latter, with several minor accessories for firing the shots, when the hole has been completed to its proper depth. The *pick* resembles a common pickaxe, but is smaller and more convenient, the iron head being sharp and pointed at one end, and very short and hammer-shaped at the other. The wedge or 'gad' is sometimes used in conjunction with the pick; it is made of wrought iron, and often with curved sides. The 'borer' or jumper' is an iron rod or circular bar, usually about two feet in length, steeled, and formed into a flat sharp edge at the end; it is driven into the rock by one man with a heavy hammer, while the other continually turns it round so as to expose the cutting edge to fresh surfaces of the rock. The pulverised matter is drawn out from time to time by a tool called a 'scraper;' and in the hole so formed are placed the powder and fuse for blasting.

When the influx of water in a mine becomes at all considerable, recourse must be had to the power either of a water-wheel or a steam-engine to discharge it to the surface. If a water-wheel is used instead of horse-power, pumps are in that case fixed in the shaft, proportioned in size to the quantity of water to be drawn, 10 or 12 inches in diameter being a very common size where there is only a moderate influx. The pumps used in mines do not act like common household pumps; they are arranged in 'lifts' or columns, of considerable height, often indeed from 20 to 30 fathoms, the water being discharged into cisterns placed at the foot of each. The pumps are now commonly made of iron. The whole column of pumps in a shaft is commonly worked by a single pump-rod, which goes down the middle of it and communicates with each column by a rod attached to its side. The steam-engine has long been the great auxiliary of the English miner, both for drawing up the minerals and for discharging the water.

The mode of support used in mines is of three kinds—by leaving pillars of the vein, for which purpose the poorer masses are of course selected; by timbering; and by walling either with brick or stone. Timbering is a very common and convenient plan, and consists of timber frame-work and boards. Shafts and levels are sometimes also supported by walling.

The ventilation of mines is most generally and most effectually accomplished rather by a judicious arrangement of the works and frequent communication with the surface than by mechanical means, although it sometimes becomes necessary to resort to the latter. The general mode of working and ventilating coal-mines is noticed under COAL.

The ore raised to the surface is enormous in some mines. At the Consolidated Mines in Cornwall it has sometimes amounted to 200 tons a day, of which three-fourths is earth or rubbish. To remove this rubbish is the object of *dressing*, for which purpose the lumps are taken to the 'dressing floors,' near the mouths of the principal shafts and levels, and are there broken with hammers. The ore is then picked out by boys and women, and further subjected to various processes of crushing, stamping, and washing. When the metallic portions are as far separated as it is possible for them to be by these processes, they are roasted in furnaces, to drive off the oxygen and all other chemical substances that may be combined with them.

During the year 1850, a number of new English mines were opened, and many old mines were brought more prominently than before into notice. As a field of investment and speculation, English mines, after a long period of depression, have lately revived; and there are not wanting indications that something of the recklessness of railway speculation will soon be observable in mining transactions. There are public manias of this kind which seem to supervene at intervals of a few years. There were dividends, to the amount of 213,570*l*., paid in 42 Devon and Cornwall mines in 1850; being larger in amount than in the four preceding years. The Devon Great Consols Mine, near Tavistock, is at the present time the richest in the United Kingdom; no other mine yields so large a return for the capital sunk in working it; and the value of the shares, in respect to premium on the original price, excels any thing that the railway ferment has presented to us, either in England or elsewhere. Most of the best mines in Devon and Cornwall yield both tin and copper, the copper being generally found below the tin.

Various details relating to English mining will be found under COPPER; CORNWALL; DERBYSHIRE; IRON; LEAD; &c.

MINT; COINING. The mode of coining English money in early times, was rude and inartificial; the sole expedient employed being to fix one die firmly in a wooden block, and to hold the other in the hand as a puncheon; then, by striking the latter forcibly and repeatedly with a hammer, the impression required was at length worked up. Scarcely any improvement was made in this method until about the middle of the 16th century, when the power of the screw was applied to coinage at the French mint.

When bullion or ingots of gold or silver are sent to the mint to be coined, the weight and quality are ascertained with scrupulous exactness, in order that an equivalent in coin may be returned for it. They are melted in pots, with such proportion of alloy as shall give the requisite standard of quality. The melted and alloyed metal is cast into bars, and these bars are rolled into plates of the proper thickness, whether for sovereigns, half sovereigns, shillings, or any other coins. The plates or sheets are cut up into circular pieces by a cutting-out press, each scrupulously accurate as to weight and size.

Then come the processes for impressing a device on each surface of the coin. The coining press consists of a screw, to which the upper die is connected; this is worked by a fly, and forces that die which is attached to it with considerable force upon the other die, which is firmly fixed below. The circular form of the piece admits of some addition to the impression, to preserve the outer edge. This was first attempted by placing a graining so as to form a regular circle on the outside of the legend, quite to the edge of the coin. Afterwards a legend was imprinted upon the edge of the larger pieces; such an impression is given to the edge of the coin by passing it between two plates, so that when the coin has been carried by the moveable plate to the end of that which is fixed, it has become marked upon the whole of the edge. As it is difficult to impress a legend upon the rim of the smaller coins, a graining has been devised for the protection of their outer edge; this, which is called *milling*, has at different times been rectangular and diagonal to the thickness of the piece, according to the views entertained as to the best mode of preventing coin-clipping.

From the money, when finished, two pieces are taken for every 15 lb. weight of gold, and two at least for every 60 lbs. weight of silver. These selected pieces (which are presumed to be an average of the whole) are subjected to rigorous assayings—one called the *private assay* within the mint; and the other the *trial of the pix*, at which some of the great officers of the government are always present.

At the London Mint the melting pots will each hold 400 lbs. of gold. The ingots into which the gold is cast are 10 inches long, 7 broad, × 0·6 thick. The press-room has eight stamping presses, which will together strike nearly 20,000 coins in an hour. In standard coins, the pure gold is alloyed with a little silver, and the pure silver with a little copper. A sovereign weighs 123·274 grains, of which 113·001 grains are pure gold; a shilling weighs 87·27 grains, of which 80·727 grains are pure silver.

MIRROR. This term is nearly equivalent to *looking glass*, in ordinary application; it applies to flat silvered looking glasses, as well as to the convex and concave mirrors which used to form articles of ornamental furniture. But it is, or ought to be, equally correct a name for any polished plate of silver, steel, or other substance which yields a clear optical reflection. A few details concerning silvered glass mirrors will be found under SILVERING.

MISSISSIPPI (or the Great Water, as the term signifies in the native language), is one of the largest rivers on the globe, which drains with its numerous branches, a surface of about 1,100,000 square miles. It falls into the Gulf of Mexico by six mouths, after a course of more than 3200 miles; but if we consider the Missouri as the principal river, the whole course is at least 4400 miles. Several of its other affluents would, considered singly, be deemed grand and mighty rivers, especially the Ohio, the Wisconsin, and the Illinois.

The rivers Mississippi and Missouri each give name to a state of America, a few industrial statistics of which will be found under UNITED STATES. Perhaps no region in the world is increasing more rapidly in production and commerce than the rich valley of the Mississippi. Steamers now carry heavy freights for a distance of many hundred miles along this great river, in the midst of a valley of almost unparalleled productiveness.

MIST, is the vapour of water rendered visible by the temperature of the air being reduced below that of the vapour. When the mist is very thick it is called a fog. Water, in the state of vapour, is continually rising into the atmosphere at all the usual temperatures; but in very hot weather the air is not easily saturated with vapour, and in cold weather evaporation is slow: thus there is more vapour in the air in summer than in winter, and in hot countries than in temperate climates, in all cases where similar surfaces of water are exposed to the sun's rays. Indeed, it has been found that the quantity of vapour in the air diminishes nearly uniformly with the temperature from the equator to the poles.

MODELLING. Modelling in clay requires the aid of a few tools; but no tool is more useful than the finger; indeed tools have been invented as mere aids to the fingers, and are designed only to do what they cannot perform. Wire tools are the most useful, being fashioned into loops of various shapes and sizes, round and angular, and fixed into wooden handles. The wooden tools are made of box and ebony, of various shapes and sizes—curved, straight, pointed, rounded, and flat and broad; the broad tools being notched, and designed chiefly for working the large convex masses, or large folds in drapery.

The clay used is common potter's clay, but of the best quality. It must be so wet that it will not stand in a mass much higher than its own width without support. The supports for the clay are a most important consideration; for if not properly attended to, the finished work, the fruits of months of labour, might suddenly fall to pieces by its own weight. Sculptors generally model figures of the ordinary size upon a bench or stand called a banker, about 30 inches high, and about 30 inches square,—for a bust it must of course be much higher; above this a solid circular plinth is fixed on a wooden bos, and is revolved upon six or more wheels, or what are better, short slightly conical rollers, fixed to the plinth near the circumference. A revolving plinth is necessary to enable the sculptor to see his work on all sides in any light, and it enables him to work on all parts, in one spot, or in the same light. On the centre of the plinth is built up a skeleton frame-work of iron and wood, projecting in various directions to support the various parts of the figure.

Another essential part of modelling is preserving the moisture of the clay, which should be always uniform if possible; it must never be allowed to dry, and it can be kept moist with very little trouble. While the modeller is at work, and the figure is exposed, especially in warm weather, he should repeatedly sprinkle it with water. A plasterer's brush is the best instrument for this purpose. When the model is complete, the next process is to take the cast, to work the marble from, or to make other casts from. The ancient sculptors used to bake their models, but this is not so good a plan as making plaster casts from them, though less troublesome and much cheaper.

MODILLION is an architectural ornament in the Corinthian cornice, resembling a small bracket placed horizontally, that is, with its back against the soffit of the part it supports, in which respect it differs from the Console. Modillions are placed beneath the corona of the cornice, and although sometimes omitted out of parsimony, are indispensable to the character of the order.

MOIRÉ METALLIQUE. There is a singular and often elegant way of ornamenting metallic surfaces, called by the French *Moiré Metallique,* equivalent to *clouded* or *watered* metal. The metal has a sort of crystallised appearance, somewhat resembling a frosted window on a winter's day, but far more brilliant and diversified. It was first introduced at Paris in 1817, by M. Allard, and was much used soon afterwards as an ornamental covering for Kaleidoscopes and other articles.

The moiré metallique is tinned iron plate, the tinned surface of which has been exposed to a peculiar chemical action from acid. Tin plate consists of sheet iron coated with melted tin; and it is believed that the clouded or watered appearance is produced by inequality of action between the tin and the iron at different parts; but the results are not visible through the whole thickness of the tin; and the art consists in removing so much of the tin as to lay bare the thin film which exists at the junction of the two metals. This is a point of much nicety, for if the acid employed for this purpose be allowed to penetrate too deeply, it will lay bare some of the iron, and there will result dark spots instead of the silvery lustre and pearly appearance of the moiré. Dilute nitro-muriatic acid is one among many acids and corroding liquids employed for the purpose. The plate is exposed to the action of the acid for a few minutes, while heated; then carefully washed, and finally coated with varnish, by which the moiré is preserved.

MOLASSES, is the name given to the uncrystallised syrup produced in the manufacture of sugar and which is suffered to drain from the casks into a cistern, in what is called the curing-house, before the sugar is sent away from the plantation. [SUGAR.] Part of the molasses is fermented and distilled for rum in the West Indies, and part is made to yield a little sugar by crystallisation: the residue constitutes *Treacle*.

The molasses imported during the last three years amounted to the following quantities:—

1848.............	517,535 cwts.
1849.............	1,062,837 „
1850.............	905,054 „

MOLYBDE'NUM, a metal discovered by Scheele, in 1778, is a mineral which resembles and had been confounded with plumbago. This metal is obtained as a porous mass or in globules, and has not yet been procured in the state of a button or bar. The grains are somewhat crystalline; sometimes they are of a silver-white colour. When obtained by the reduction of the oxide, this metal has not much lustre, but acquires it by burnishing. When long exposed to the air at ordinary temperatures, it appears to tarnish, but the oxidation is superficial. Oxide of molybdenum occurs encrusting the sulphuret of molybdenum, and also between its laminæ in thin layers. Its structure is thin, fibrous, earthy, friable, and pulverulent; and its colour is pale yellow or greenish.

Molybdenum combines with many other substances; but neither in its simple nor its compound state has it yet been applied to many useful purposes: it still remains in the domain of scientific chemistry.

MONAGHAN. This Irish county contains a valuable deposit of gypsum; and near this is a small coal-field. Limestone of great variety and excellent quality is quarried; also fine marble, and valuable freestone for building. A fine white sandstone, dug in the Slieve Beagh Mountains, is extensively used for architectural purposes. Ironstone, slate, and lead-ore, exist in small quantities.

The soil of the county varies much. The wheat grown is generally red wheat, and of inferior quality; but the flax crop is important. Clover, vetches, and other green crops, are more attended to than turnips or mangel wurzel. A good deal of butter is made, and sent to England. The population of the county is very dense; the number of labourers has increased; and the decline of the linen manufacture, which once furnished them with employment, has left the great majority with little other work than that which they bestow on the small spot of land which they occupy. Some of the worst features of Irish poverty and improvidence are to be found in Monaghan.

MONEY. At a time when industry has caused the assembling in London of visitors from so many countries, it would not be an inconsistent feature in this work to present a Table of the values of some of the best known European coins. Kelly's *Cambist* is our authority.

Bajocchio; copper coin at Rome and Bologna; worth rather more than one halfpenny.

Butzen; a Swiss coin of inferior silver about 1½*d.*

Carline; Piedmont gold coin; about 5*l.* 12*s.* 3*d.*

Cash; Chinese coin of copper and lead; about 120 to a penny.

Cent; United States' copper coin; about 0½*d.* In France a *cent* or *centime* is not a coin, but a money of account, one-hundredth of a franc.

Cowries; shells used for money in the east; about 120 to a penny.

Crown; the crown coins in foreign countries have been mostly superseded by other denominations.

Crusado; Portuguese coins, both gold and silver; about 2*s.* 6*d.*

Dime; United States' silver coin; 5½*d.*

Doit; Dutch copper coin; half a farthing.

Dollar; United States' silver coin, 4*s.* 4*d.* Also a Spanish silver coin, 4*s.* 3½*d.* See also *Thaler* and *Rix-thaler.*

Doubloon; Spanish gold coin; about 3*l.* 6*s.*

Ducat; there are gold ducats in Russia, Sweden, Holland, and Germany, varying in value from 8*s.* 4*d.* to 9*s.* 5*d.* There are silver ducats in Italy; about 3*s.* 6*d.*

Eagle; United States' gold coin; about 2*l.* 4*s.*

Florin; there are both gold and silver florins in Germany; worth respectively about 7*s.* and 1*s.* 8*d.* to 2*s.*

Franc; French silver coin, 9¾*d.* Also a Swiss silver coin; 1*s.* 2*d.*

Frederick; Prussian gold coin; 16*s.* 4*d.*

Guilder; another name for *Florin.*

Groschen; German silver coin; 1*d.* to 1½*d.*

Imperial; Russian gold coin; 33*s.* 4*d.*

Kopeck; Russian copper coin; rather less than 1*d.*

Kreutzer; German copper coin; three to one penny

Mark; Hamburg silver coin; about 1*s.* 3*d.*

Milree; Portuguese gold coin; about 5*s.*

Mohur; East Indies gold coin; about 33*s.*

Napoleon; French gold coin; 15*s.* 10*d.*

Paolo or *Paul;* Italian silver coin; 5¼*d.*

Pfenning; Prussian copper coin; ten to a penny.

Piastre; Levant silver coin; rather over 1*s.*

Pistole; German gold coin; about 21*s.* Also an Italian gold coin, variable in value in different states.

Real; Spanish silver coin; 5*d.* The *Real vellon* is a smaller coin; 2⅝*d.*

Rix-thaler; German silver coin; about 4*s.* 2*d.* The Danish *Rigsbank thaler* is about 2*s.* 3*d.*

Rouble; Russian silver coin; 3*s.* 1*d.* There are platinum coins of three and six roubles.

Rupee; East Indian silver coin; about 2*s.*

Schilling; German coin of inferior silver; about 1¼*d.*

Scudo; Italian silver coin; about 4*s.* 4*d.*

Sechsling; Hamburg copper or baso silver coin; rather more than 0½*d.*

Sequin; Italian gold coin; about 9*s.* 5*d.* The Turkish sequin varies much in value.

Sou; French copper coin, $\frac{1}{20}$th of a franc; about 0½*d.*

Stiver; Dutch copper coin; about 1*d.*

Thaler; the ordinary name in Germany for the *Rix-thaler* or *Rix-dollar.*

The weights of English gold and silver coins are as follow:—

	Dwt.	Grains.
Sovereign	5	3.274
Half sovereign ..	2	13.637
Crown	18	4.4 - elevenths.
Half crown	9	2.2 - elevenths.
Shilling	3	15.3 - elevenths.
Sixpence	1	19.7 - elevenths.
Fourpence	1	5.1 - eleventh.

MONMOUTHSHIRE. In the north-west part of this county iron and coal are found in considerable abundance; and these form the main elements of the wealth of Monmouthshire. In respect to agriculture, the soil is various, but generally fertile. The agriculture has been a good deal improved of late years. In the north-west a little wheat is grown, but oats and barley are the principal crops. The southern tract bordering on the Bristol Channel is an alluvial soil, which in parts would be overflowed if not protected by great dykes. There are numerous small orchards.

Monmouth, the county town, has a considerable commerce with Bristol, by means of the Wye. There are large iron-foundries in the neighbourhood. *Newport,* near the mouth of the Usk, is the outlet for a large amount of coal, and a still larger amount of iron, which are brought down the Blaenavon, the Ebbw, the Sirhowy, the Rhimney, and other valleys from the mountain district where the mines are situated. Newport has been much improved of late years. Ship building is carried on, the river being so situated that vessels of great burthen can be launched from the docks into deep water. The docks and the river are always crowded with vessels waiting for cargoes of coal and iron. At *Pontypool* most of the inhabitants are employed in the coal mines and iron works.

MONOCHORD, an instrument of one string, is used by scientific musicians for the purpose of ascertaining and demonstrating the relative proportions of musical sounds. It is composed of a board, or rule, divided and subdivided into various parts, and of a string distended between two bridges, one of which is placed at each end of the rule. In Dr. Crotch's 'Elements of Musical Composition' will be found a simple and cheap method of constructing a monochord.

Mr. Higgs's monochord, described before the Society of Arts in 1843, is a single string stretched over a bridge, and tuned to the middle C of the pianoforte; but it is provided with other stops or bridges which enable it to yield all the notes of the diatonic, chromatic and enharmonic scales of the octave. It is calculated to educate the ear of a singer to appreciate musical intervals, and to aid in the tuning of pianofortes and other instruments.

MONTPELLIER, capital of the French department of Hérault, has a very extensive system of commerce and manufactures. Liqueurs, perfumery, preserves, dried fruits, verdigris, alum, cream of tartar, vitriol and aquafortis, woollen cloth, muslins, printed cottons, calicoes, table linen, blankets, hosiery, hats, leather, corks, and paper, are manufactured; these articles, with wool, wine, brandy, oranges, citrons and other fruits, and the oil of the surrounding districts, furnish the chief articles of trade. There are several printing-offices, sugar refineries, potteries, oil-mills, paper-mills, and saw-mills. In the central prison, which receives convicts from 20 departments, several articles of silk and cotton are manufactured.

MONTREAL, the capital of Lower Canada, set the first example of an Exposition of manufactures in America; it was at Montreal that the Canadian Industrial Exhibition of 1850 was held, an exhibition which prepared the Canadians to take part in the far greater Exhibition of 1851.

In respect to commerce, the harbour of Montreal, which is formed by an arm of the St. Lawrence, is small but secure; the difficulty of approach, which the rapid of St. Mary formerly presented to sailing vessels, has been overcome by the employment of steam-tugs. The shipping trade of Montreal is very active whilst the navigation is open. The repeal of the Navigation Laws, and the uninterrupted steam navigation by the Rideau and Welland Canals and the great lakes westwards, as far as Chicago on the south-western shore of Lake Michigan, whereby the produce of Illinois and the western states will find a ready vent to Europe, promises to add greatly to the trade of Montreal. Steamers ply regularly during the season to Quebec.

MOORS. A Moor is an extensive waste covered with heath, and the soil of which consists of poor light earth, mixed generally with a considerable portion of peat. The want of fertility in moors arises chiefly from a deficiency or superabundance of moisture, the subsoil being either too porous to retain it, or too impervious to allow it to escape. Both extremes occur in some moors, which are parched up in dry weather, and converted into a dark mud by any continuance of rain. When the moor consists of a loose peaty earth of little depth incumbent on a rock, as is the case in many mountainous countries, no art can fertilise it. In the valleys, where the waters have brought various earths mixed with decayed vegetable matter from the surrounding hills, the substance deposited is mostly peat; this soil, by careful management, may be made productive. Sometimes extensive moors have been converted into flourishing farms of arable and grass land, as in many parts of Scotland and the north of England; sometimes they have been most advantageously planted with forest-trees, and, where there is a great extent of waste and a scanty population; this is generally the most certain mode of improving a property, although the return is slow and distant.

MORAVIA is one of the richest provinces of the Austrian empire in respect to produce. Agriculture is in an improved condition. Large quantities of very fine wheat, rye, barley, and oats are grown. Flax and hemp are very extensively grown ; but the consumption of these articles is so great, that large quantities of them are imported. Fruit is plentiful and good. The vine flourishes. The forests furnish vast quantities of timber. The pastures are extensive. Formerly mines of gold and silver were worked. At present iron, sulphur, vitriol, alum, coals, marble, pipeclay, and precious stones, particularly topazes, are the chief mineral products.

The woollen, linen, and cotton manufactures are very flourishing, and on a large scale, and furnish supplies for an extensive export trade. The manufacture of thread is likewise considerable. Dyeing is carried on at Brünn, which is particularly celebrated for dyeing Turkey red. Moravia enjoys also the benefit of a great transit trade. The imports are colonial produce, wool, Vienna silks, Russian furs, tallow, wine, oil, porcelain, glass, &c.

MORDANTS. [DYEING.]

MOREA. The produce and industry of the Morea are briefly noticed under GREECE.

MO'RPHIA, the first discovered of a numerous and important class of vegetable products, or alkalies, sometimes termed *alkaloids.* It was obtained in 1803 by Sertuerner, a German chemist, from opium, in which it exists in combination with a peculiar vegetable acid, the meconic acid, and probably also with sulphuric acid. Morphia is a colourless crystalline substance, with a bitter taste. When heated strongly, it emits a resinous smell, smokes, and burns with a lively red flame, and leaves charcoal. Morphia is probably the most active principle of opium, but being very slightly soluble in water, is never used alone medicinally. Having, however, like other alkalies, affinity for acids, it readily combines with them and forms salts, which are now extensively used in medicine. The acetate and hydrochlorate of morphia are those salts which are usually employed medicinally.

The uses of morphia and the other alkaloids are almost exclusively, up to the present time, medicinal.

MORTAR. Common mortar is the substance placed between the stones or bricks of a building to cement them together. Mortar is essentially composed of slacked lime and siliceous sand. The hardness which mortar acquires is owing to the gradual conversion of the lime into carbonate of lime, which takes place very slowly by the absorption of carbonic acid gas from the atmosphere. In this state it adheres very firmly to the particles of silica diffused through it, and both are strongly united with the material employed in the building. When limestones contain considerable portions of silica and alumina, they form what has been termed *Hydraulic Lime*, and the mortars made with them are called *Hydraulic Mortars.* Of these, Parker's cement is a well-known kind: it will *set*, as it is termed, or become solid, in a quarter of an hour, either in the air or under water. In France artificial hydraulic lime has been prepared, and appears to answer the purpose extremely well.

A second application of the name *Mortar* is to a vessel in which substances are either reduced to fragments, pulverised, or dissolved, by beating or trituration with a pestle. Mortars are made of cast-iron, stone-ware, glass, agate, flint, or porphyry, according to the use to which they are to be applied.

It is not very easy to shew why such should be the case; but the same name has a third and wholly different signification, as applied to a gun or cannon. A mortar is a piece of ordnance which, compared with guns, is very short, and is employed to throw shells or carcasses at considerable elevations (generally at 45°). Mortars are either of iron or brass; they rest upon solid beds, and the trunnions or cylinders upon which they turn, in giving the required elevation, are placed at the lower extremity of the piece. The calibres of mortars in the British service are 4⅖, 5½, 8, 10, and 13 inches. All these different kinds of mortars are used on land, and the two last are also employed in the navy; but in this latter service the pieces are about 16 inches longer than the land-service pieces of the same calibre. The first two are sometimes called royal mortars. The Dutch engineer Coehorn invented small mortars for throwing grenades. They were capable of being carried about and served by one man; consequently they could be readily brought up to a convenient spot, and rapidly fired.

MORTICING MACHINE. The cutting of a mortice in wood-work, for joining or framing the pieces together, is under ordinary circumstances performed by hand; but in the remarkable operations at the Palace of Industry, a morticing machine has been employed, patented by Messrs. Furness and Lanton. It consists of an upright frame, with ledges and supports suitable to retain in a proper position the piece of wood to be morticed. The morticing chisel is fixed to the lower end of a vertical rod; and its mode of adjustment is such that it can be turned round in any direction, and may be made to cut a deep or a shallow mortice at the discretion of the workman. The machine is not wholly automatic, but may be compared to a lathe; the workman puts his foot upon a treadle, by which the morticing chisel is brought down to the wood; and in that position it is retained until the mortice is cut. There are many ingenious minor appendages, to facilitate the action of the machine.

MOSAIC. This very elegant production is a species of inlaid or tessellated work, made with minute pieces of coloured substances, generally either marble or other coloured stones, or else glass more or less opaque, and of every variety of hue which the subject may require. The former mode was that chiefly employed by the Romans for their costly tessellated pavements, many of which have at various times been discovered in England. Mosaics of this description, that is, for pavements, generally consist only of a series of ornamental borders inclosing one or more compartments containing some figure or device, or occasionally a group or subject. Others consist entirely of a pattern, generally in two colours, sometimes in three—black, white, and red. Examples of pavement mosaics in each of these modes have been discovered at Pompeii. Mosaic continued to be used both for pavements and ornamenting walls to a late period in the middle ages, and was greatly practised in Byzantine buildings, and by Byzantine artists who were also employed in Italy.

A kind of mosaic or coloured inlaid work was occasionally employed in Italy during the middle ages for external decorations also; as an instance of which the façade of the Duomo at Pisa may be mentioned, where, though the pattern is chiefly in black and white, brilliant reds and blues are intermixed at intervals.

Although nearly similar as to their process, mosaic pictures, especially some of those of later times, may be considered as a distinct branch of the art. Whether actually employed as pavements or inserted in walls, mosaics of this class consist chiefly of ornament and pattern, executed in few and simple colours, with hardly any attempt at variety of tints and due graduation of tones, even in the figures, human or animal, occasionally introduced in them. For a long period after the decline of the arts, mosaic painting continued to be employed in Italy, both externally and internally, for the decoration of churches, as for instance, on the façade as well as within the basilica of St. Mark at Venice. Some have supposed that such productions were entirely the work of Byzantine or Greek artists, but the contrary opinion is maintained by Cicognara, who asserts that mosaic was practised by native Italians, and that it was well known to the earliest Venetians.

Copies of celebrated works by Raphael and other masters have been executed in mosaic, and have the effect of paintings produced in the usual way, though they are attended with infinitely greater cost, and are beyond all comparison more laborious and tedious in their process. As each separate piece of glass is of the same colour throughout, the graduation of tints, the melting off of any one colour from its highest light to its darkest shadow, can be obtained only by an immense number of small pieces, of which those contiguous to each other exhibit scarcely any perceptible difference to the eye. The sole advantage, in any degree proportionate to the cost attending it, is the extreme durability of the work when once accomplished.

Similar mosaic is employed sometimes on a miniature scale, for pictures on the lids of snuff-boxes and articles of that kind, or tablets in chimney-pieces, which are at the best mere curiosities and very laborious trifles. *Florentine Work* may also be mentioned as a species of mosaic, chiefly used for inlaying or veneering marble slabs for tables and decorative purposes of that sort, upon a moderate scale.

The Mediæval Exhibition of 1850 presented many beautiful specimens of mosaic, mostly on a small scale. In our own day, the chief mosaic work produced is in the form of tesselated tiles for pavements.

MOSCOW. In this important Russian province, agriculture is the chief occupation of the inhabitants, and Moscow is one of the best cultivated as well as one of the most populous provinces of the whole empire. Flax, hemp, and hops are cultivated. Horticulture is carried on to a great extent, and the produce is nearly adequate to the consumption. Timber and wood-fuel are plentiful. Horses, cattle, calves, and poultry are reared. The minerals are freestone, potters' clay, brick-clay, lime, gypsum, alabaster, and bog-iron.

Manufactures of various kinds are carried on to a great extent, both by the country-people for their own supply as well as for sale, and also in the villages and towns, and especially in the capital. The province has an extensive inland trade.

Of the far-famed city of Moscow we need not speak in this work; for it is rather a political metropolis than an emporium of manufactures. It is, however, the centre of an immense inland trade, by which the produce of Europe and Asia is interchanged; for there is no city in which the luxuries of the East and West meet in more singular proximity than Moscow.

MOSELLE. This is an interesting department of France, in respect to produce and commercial industry. The valleys and hill-sides are covered in general with a rich soil, and are carefully cultivated so as to yield great quantities of wheat, rye, and oats, of which a considerable surplus over the home consumption is sold for exportation in the great corn-market of Metz. Other crops raised are vetches, millet, peas, beans, and lentils. Several Champagne wine merchants, settled at Metz, purchase Moselle wine, and manufacture from it what they call champagne wine for the German and Russian markets. Pears, peaches, and other fruits are grown in large quantities, and exported in the form of dry, liquid, and crystallised conserves from Metz, where preserved fruits form an important article of commerce. Flax is extensively grown, both for the sake of the fibre and of the seed, which is pressed for oil; rape and turnips are also grown. The forests consist of oak, beech, hazel, &c. Bees are very numerous, and much honey is gathered.

Several iron mines are worked, and the ore is smelted and made into malleable iron. Lead and copper are found, but no mines are worked. Building stone, quartz, gypsum, crucible and pottery earth are quarried. Marl is found in great masses in the north and north-west of the department, and is extensively used in manure. Plaster-of-Paris is also much used as a top-dressing for meadow land. The industrial products consist of sheet and bar iron, block-tin, nails, glass, unbleached and table-linen, embroidered muslin, canvas, paper, beer, tobacco, oil, starch, room paper, beet-root sugar, tiles, pipes, pottery, leather, hosiery, and common woollen and cotton stuffs. These articles, together with timber, and the products previously mentioned, support an active commerce. *Metz*, the chief town of the department, is a place of considerable manufacturing and commercial enterprise.

MOTHER OF PEARL. The nature of this singular and beautiful substance is illustrated under PEARLS; SHELL.

MOULDINGS are any assemblage of narrow surfaces projecting from the face of a wall or other surface, and advancing one beyond the other. They are bounded by straight lines, either horizontal or vertical, according to their situation, but the surfaces themselves are plane or curved, and if the latter, concave or convex, or else compounded of both forms; and again are either plane or curved. The *Fillet*, *Tænia*, *Band*, are all plane or flat mouldings. The *Corona* is also a mere plain band, except that it is occasionally enriched in Roman architecture. Lesser convex mouldings are termed *Beads*, but the longer mouldings of the same kind in the bases of columns are termed *Tori* or Torusses. The *Cyma Recta*, or *Cymatium*, is a compound moulding, concave above and convex below; while the *Cyma Reversa*, is convex below and concave above. The *Cavetto* is a mere hollow or sweep intervening between and serving to connect two mouldings, one of which projects beyond the other. The *Ovolo* is a simple convex moulding, so called because it is generally carved into *Ova*, or ornaments in the shape of eggs, within hollows. All the other mouldings may be carved or enriched, except the cavetto and fillet; the pattern being accommodated to the surface of the moulding. The cyma recta, or *Talon*, as it is sometimes called, is cut with a peculiar kind of tongued or arrow-headed ornament.

MOVING POWERS. The means employed to give motion to machinery, (independently of the cases in which the force of gravity is applied directly, as in turning the cylinder of a clock,) are chiefly the following:—the *strength* *of men and animals*, the *pressure of the atmosphere*, the *expansive force of steam*, and the *action of wind or water*. It is even probable that the recently proposed actions of the galvanic fluid and of fired gunpowder or gun-cotton, will in time be numbered among motive forces for impelling carriages, vessels, or machines.

Originally the larger kind of engines, except such as were impelled by wind or water, were moved by the power of horses; and when other agents were employed, the gross effect of the engine was estimated by the number of horses to whose action it was equivalent. A strong horse being able to draw 125 lbs. at the rate of 3 miles per hour during 8 hours; the product of these numbers, multiplied by the number of feet in a mile, and divided by the number of minutes in 8 hours, gives 33,000 lbs. for the weight carried or raised 1 foot per minute continually. This last number is the usual representation of the power of a horse; but the 'horse power' of engineers' estimates is felt to be a vague standard, and will probably give way to something more scientific. The force of steam-engines is estimated according to the volume of water evaporated, the pressure of the steam, the length of the stroke, &c.

Wind and water are employed as prime movers by means of the momentum arising from their velocity; and the latter, occasionally, by the pressure arising from its weight. The force of wind is made to act on sails in giving motion to vessels on the surface of water, and also in producing the revolutions of windmill sails. The velocity of a vessel impelled by steam, in which paddle-wheels are employed, might easily be found if it were possible to determine, nearly, the number of square feet of paddle which, on both sides of the vessel, are at every moment acting efficiently against the water. To determine the exact amount of moving power available at any given time and place, and under any given circumstances, is one of the most important duties of the engineer; since upon it must depend the power of his machinery.

In 1850 Mr. Cottam patented an apparatus for ascertaining the amount of motive power employed in working machinery. It is composed of a plate, to which a circular spring is attached by one end, while the other end is made fast to a lever. The lever is also attached to a pointer which moves over a scale, whereby the power exerted will be indicated. The pointer also carries a pencil, which travels over the top of one of a pair of cylinders, round which a roll of paper is wound. The curve described on the roll of paper indicate the force applied. The cylinders are made to revolve by toothed gearing.

MUFFLE is the name given to a vaulted flat-bottomed earthen vessel in which substances may be strongly heated, and at the same time protected from the contact of the fuel. In the muffle smaller vessels are placed, containing the substances to be acted upon. Muffles are used in chemical operations, in glass-staining, in enamel-painting, and in a few other processes.

MÜHLHAUSEN, a large manufacturing town in the French department of Haut-Rhin, has obtained deserved celebrity for its printed cottons, for the manufacture of which there are several important establishments. The other manufactures are cotton and woollen yarn, muslin, silk, woollen cloth, hosiery, straw hats, morocco leather, soap, damask, linen thread, &c. There are dye-houses, tan-yards, metal-foundries, and large establishments for making steam machinery. There is also a considerable commerce in corn, wine, brandy, groceries, hardware, iron, &c. The canal which unites the Rhône to the Rhine, passes by the town. A railroad, 13 miles in length, runs westward from Mühlhausen to the busy little manufacturing town of Thann.

MULBERRY. The black or common mulberry is the fruit of *Morus nigra*. It is a native of Persia, and its indigenous range appears to be extensive. Its introduction to this country dates about the middle of the 16th century. Under great vicissitudes it proves very tenacious of life; and under ordinary circumstances it attains, even in this climate, a considerable age, for some trees planted in 1548 are still alive. The fruit is used in medicine. It contains much mucilage, with an astringent resin, and is sweetish and subacid, owing to the presence of some malic or tartaric acid. As the cooling properties depend on the acid, the fruit should be gathered before it is quite ripe. It may either be formed into a syrup, or a vinegar may be made with it similar to raspberry vinegar.

But a more important species is the *Morus alba*, or White Mulberry. This is a native of China, where it forms a small tree, and whence it has been gradually carried westward, till it has become a common plant in most of the temperate parts of the Old World, forming in the south of Europe a pollard-tree by road sides. It is on this species that the silkworm is chiefly fed; and in silk countries many varieties are cultivated for the purpose, some of which are said to be much better than others. Some years since a mulberry was introduced into France from Manilla, whence it has gained the name of the Philippine Mul-

SHEAR AND TILT HAMMERS

KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 30.

berry, the great excellence of which seems universally acknowledged. It grows much faster than the white mulberry, and strikes from cuttings as freely as a willow, which is not the case with the white mulberry. The abundance of its leaves is much greater than in any other known variety, and it is not only freely eaten by the silkworms, but perfectly agrees with them. Its culture is now superseding that of all others in the south of Europe, and it is even taken as a stock on which to graft the common white mulberry, when the latter is wished for.

MULE; MULE-JENNY. The purpose of this oddly-named machine is described under COTTON SPINNING.

MULLION. In gothic architecture mullions are the upright bars, or rather stone shafts, dividing the general aperture of a window into secondary openings, which are again frequently subdivided by a similar shaft crossing the mullions horizontally, and therefore called a *Transom;* whereby the whole space beneath the head of a window (supposing it to be an arched one) is formed into a series of panels in which the glass is fixed, and which are sometimes technically distinguished as *lights*. For instance, the façade of York Cathedral is divided into eight lights or compartments by seven mullions, while that above the entrance to Westminster Hall has eight mullions.

MUMMY CLOTH. At one period there was much discussion as to the nature of the woven material in which Egyptian mummies are found to be enveloped. The early history of the cotton and flax manufactures is interested in this question. The bandaging, to which all the Egyptian mummies were subjected, was one of the most remarkable parts of the process of embalming. Their envelopes are composed of numerous bands, each several feet long, applied one over the other fifteen or twenty times, and surrounding first each limb, and then the whole body. They are applied and interlaced so accurately, that one might suppose they were intended to restore to the dry shrivelled body its original form and size. The only difference in the bandages of the different kinds of mummies is in their greater or less fineness of texture; they are applied on all in nearly the same manner. The bandages and wrappings have been examined with the microscope within the last few years; and in every instance they are found to be made of flax or linen; this has set at rest an opinion formerly held, that cotton was employed by the Egyptians for such purposes.

MUNICH, the capital of the kingdom of Bavaria, owes its present beauty and celebrity as a seat of the fine arts, chiefly to the late Ludwig I. Architecture, sculpture, and painting have been most munificently patronized; and the arts of painting in fresco, in encaustic, and on glass, have been revived and carried to their former perfection. The treasures of the Glyptothek, the Pinacothek, the Königsbau, the Festbau, the Chapel Royal, and other buildings in Munich, deserve the attentive study of the admirers of high art; but we have here only to do with the industrial features of that town. The manufactures of Munich are of many different kinds, chiefly for the consumption of the city and neighbourhood; the articles made are linen, woollen cloth, calicoes, damask, silk, ribands, household furniture, piano-fortes, playing-cards, articles of gold and silver, coaches, excellent mathematical, surgical, optical, and astronomical instruments. There are likewise breweries, distilleries, tanneries, paper-mills, snuff-mills, and the celebrated Fraunhöfer's (now Utzschneider's) manufactory of astronomical and optical instruments.

A magnificent figure of a lion, by Frederick Miller, of Munich, adorns the Exhibition of 1851. The lion forms one of a *quadriga*, or group of four, to surmount a new town gate at Munich. It is 14 feet long by 8 feet high. Two lions of this enormous size were cast at one melting—among the largest casting operations ever known. Of the private manufacturing establishments, there are a few which have sent to the Exposition works of much beauty. By one establishment for the manufacture of glass, has been contributed an enamelled vase of large size and extraordinary workmanship. The design of the vase is Moresque, and made expressly for this production. The articles of furniture manufactured in inlaid work at Munich are extensively known and appreciated.

MURCIA. In this province of Spain sandstone, marl, lignite, and gypsum are found. Porphyry, slates, fine marble, rock-crystal, freestone, bole, alum, and nitre, are also met with. Near Hellin is a mine of sulphur, at Villena a saltpit, and saltpetre abounds in the neighbourhood of Cartagena. Several argentiferous lead mines are worked; iron and copper are found. The most commonly cultivated trees are the mulberry, the date-palm, and the olive; evergreen and other oaks, poplars, and carobs are in some parts numerous. The sugar-cane thrives, but is not cultivated to any extent. The pines on the Sierra de Segura form the largest forest in the south of Spain. Great quantities of barilla are produced on the sea-coast; silk and oil are extensively produced, and also saffron and wine. The manufactures are few and unimportant. Agriculture and mining give employment to all the disposable industry of Murcia. Corn and wine are exported when the harvest or vintage is good, otherwise they are imported from Valencia. Raw silk, barilla, some cutlery, saffron, and articles made of the esparto-rush, are the principal exports. The imports are vegetables from Valencia, beef and mutton, oil, spices, ironware, linen and woollen goods, and silk stuffs; for there is not industry enough in the province to manufacture the raw silk produced. In the city of Murcia there are several potteries, cloth-factories, tanneries, oil-mills, establishments for the spinning of silk and for the manufacture of soap and white lead. There are also royal factories of gunpowder and saltpetre. There are important glass works in the environs of the town. Wine and provisions of all kinds are exceedingly cheap. The manufacture of the esparto-rush into baskets, cordage, sandals, &c., employs many hands.

MURIATIC ACID. Under CHLORINE the chemical nature of this valuable acid has been described; but it will be instructive to trace the mode of manufacturing the acid, as conducted at the great chemical works of St. Rollox, near Glasgow.

The same chemical operation which produces *soda* will also produce *muriatic acid*. Common salt is *chloride of sodium;* and by a certain train of operations, the chloride combines with hydrogen to form muriatic acid, while the sodium combines with oxygen to form soda, and with carbonic acid to form carbonate of soda. Common Cheshire salt is put into a pan in a reverberatory furnace, and sulphuric acid is slowly dropped upon it through a leaden pipe passing through the roof of the furnace. The action of the acid on the heated salt generates a new product, muriatic acid gas, by bringing into play the various degrees of chemical affinity between the substances employed. The substance then remaining in the furnace is, by further treatment, converted into soda. In the infancy of the manufacture, when the soda was the chief object of attention, the muriatic acid gas was a source of infinite trouble to the manufacturer. It is so deleterious, that if allowed to mingle with the atmosphere near the ground it would do great mischief: hence we have a clue to the history of the lofty chimneys which distinguish chemical works. But after a time it was found that this deleterious gas might be made a valuable commercial article, by changing it into liquid muriatic acid, or *spirit of salt*, as it is somewhat expressively termed, in familiar use. This change has been brought about as follows: all the soda furnaces discharge their muriatic acid gas into a bulky stone tower, about 40 feet high, by 8 feet square; this tower is filled with coke, upon which a stream of water is constantly falling from above; and the gas, ascending the tower from the flues of the furnaces, meeting with an innumerable series of little streams of water trickling through the coke, becomes absorbed by the water, and thus gives rise to the formation of liquid muriatic acid, which falls to the bottom of the tower.

The tendency of modern chemistry has been to change the name of *Muriatic* to *Hydrochloric* acid, since the latter name expresses the composition of the acid (hydrogen and chlorine). In the same way the salts formed by the combination of the acid with gases are gradually changing their names; instead of the *muriates* of soda, potash, ammonia, tin, &c., we have the *hydrochlorates* of those substances.

MURRHINE (sometimes written *Myrrhine*) VASES, vessels used by the ancients, were made of the stone or hard substance, whatever it might be, termed *murrha* (*μυρρα*). They are frequently noticed by the classic writers, and usually described as transparent, though sometimes spotted or clouded, like our cups of agate. Pliny speaks of them as coming from the East, from Parthia and Carmania; but there is very little now known concerning them.

MUSHROOM. A few details concerning the uses of the mushroom will be found under AGARICUS.

MUSICAL INSTRUMENTS. All the principal musical instruments are described under their proper headings in this work. Music, as a science and a fine art, is of course beyond the range of the present volume.

Musical instruments occupy from 3000 to 4000 feet at the Great Exhibition. There are various specimens of organs from the various London builders; among the rest, especially to be noticed, is a gigantic church organ, containing upwards of eighty stops, with an independent pedal organ upon the largest scale. The cost of this instrument has been several thousand pounds. There is also an interesting instrument, designed by Col. P. Thompson, M. P.—an enharmonic organ—the object of which is, by minute subdivision of the scale, to attain a perfect intonation; there is also an enharmonic guitar. No class of musical instruments is left unrepresented. As might be expected, pianofortes are most numerous. In this department the most eminent manufacturers have exerted their utmost powers to exemplify the superiority of native instruments. There are several improvements exhibited, both as regards tone and mechanism.

MUSK. This very powerful perfume is the odorous secretion contained in a peculiar abdominal sac, in the Male Musk Deer. This species is a native of Tonquin, Tibet, Nepaul, the mountain regions of Siberia and China, &c. By the analysis of Geizar and Reiman musk appears to consist of a peculiar volatile principle, which can exist in a free state; ammonia; a peculiar fixed uncrystallisable acid; stearine and oleine; chloresterine; a peculiar bitter resin; osmazome, with several salts; a mouldy-like substance, in part combined with ammonia and several salts; sand; water, acid, &c., with some volatile odorous matter.

The name of *pod musk* is given to the bag in its natural state containing the musk; while *grain musk* is the musk without its bag.

The musk of the shops is said to be rarely pure; it is adulterated either with dried bullock's blood or with chocolate, under ordinary circumstances; but a multitude of other substances are occasionally employed. The Chinese are said to be skilful adepts in this nefarious practice.

Taken in the dose of a few grains, musk rouses the energy of the digestive organs; and it soon afterwards produces sympathetic phenomena, the powers of the whole animal system appearing suddenly increased.

MUSLIN is a thin cloth made of cotton. The name is supposed to be derived from Massalia, since called Masulipatam, from which place such fabrics were first imported into Europe. Until the early part of the present century all the muslin used in Europe was of the manufacture of India. Some of the muslins of India, and especially those of Dacca, are of the most astonishing degree of fineness, so as to justify their poetical description as 'webs of woven wind.' Such however has been the result of the mechanical inventions of England in this branch of industry, that not only are muslins of British manufacture now used at home, to the exclusion of those woven in India, but large quantities are exported to all parts of the world, and find their way even far into the interior of India.

There is essentially no other difference between *muslin* and *calico* than in the fineness of the fabric; but the spinning, the weaving, and the dressing, are all concerned in the production of this fineness. The embroidering of muslin is becoming an extensively diffused employment for females in Ireland [EMBROIDERY.] The 'Armagh Gazette' lately stated:—'According to the statement of a respectable agent, there are in Armagh and its vicinity about 1,800 girls and young women engaged in this occupation. Agencies have been established in Keady and other rural towns in this county. The demand for the sewed or embroidered muslin would appear to be unlimited. In many cases, where the heads of poor families are out of employment, the average earnings of their daughters protect all from that last refuge of poverty—the workhouse.'

MUSQUASH FUR. The *Musquash* or *Musk-rat* is a small North-American animal, the fur of which is employed in hat-making and for other purposes. The number of musquash furs imported in 1847 was 420,946; the number for 1848 increased to 766,764. Some of these are re-exported to various European countries, but most of them are worked up in England.

MUSTARD. This name is given to two species of *Sinapis*, the *black* and the *white*. The black mustard plant is most used, and is extensively cultivated in Durham and Yorkshire; it is this which yields the powerful condiment for the table; whereas the white species, when a young plant, is eaten with water-cress as a salad.

The seeds of the black mustard are an intricate compound of myrosine, fixed oil, a fatty matter, a gummy matter, sugar, colouring matter, and many other substances. By bruising the seeds a fixed oil may be obtained; and by distilling the *marc* or refuse from this process, a volatile oil results. The fixed oil is very bland; but the volatile oil is stimulant and irritating. About 28 per cent of the black mustard-seed consists of fixed oil; to obtain it the seeds are crushed in a mill or between rollers; the skins being subjected to pressure as well as the farina or flour. The remaining cake is sifted and reduced to a fine powder, which retains all the pungent qualities of mustard. The fixed oil is a good fuel for lamps, and it forms a firm and useful soap with alkalies.

Flour of mustard, mixed with water, forms the well-known condiment of the dinner table. *French* mustards and *patent* mustards have, however, usually something else added to them —vinegar, parsley, cherril, celery, tarragon, garlic, anchovies, sugar, ginger, salt, horse radish, and cayenne, being among the list of addenda so employed.

Mustard, like too many other commodities at the present day, is often adulterated; flour and salt are employed to increase the bulk, turmeric to colour, and cayenne to season it.

N

NAIL MANUFACTURE. Until a comparatively recent period almost every kind of nail was produced by hand-labour: each nail, however minute, was separately forged from a thin rod of iron, a process which is still followed in the production of what are technically known as *wrought* nails. As nails so formed possess certain advantages, for particular kinds of work, over those formed either by casting, or by cutting or stamping out of rolled sheet metal, there is no reason to anticipate the total abandonment of this process, notwithstanding the continual improvement of nail-making machinery.

For some purposes nails formed by the much cheaper process of *casting* have been long used. Common cast nails are, however, so clumsy and so brittle that they can only be used for a few coarse purposes, as in plasterer's work, and in the nailing up of fruit trees. By the introduction of great improvements in the manufacture, however, a very useful kind of cast nail, of an exceedingly pure malleable cast iron, has been successfully introduced for certain descriptions of woodwork. Nails of this kind are very neat and regular in their appearance, being cast with great accuracy; and they are annealed to such perfection that the metal will bear far more bending than ordinary wrought-iron without injury. This extraordinary degree of tenacity is, however, obtained at the expense of rigidity, such nails being often nearly as soft as copper, and therefore quite unsuitable for use in hard woods.

In the making of cut-nails, the nails are cut from sheet-iron of suitable thickness, which is first reduced by cutting transversely, into strips or ribands of a breadth equal to the intended length of the nails. These strips are then applied to a machine in which a chisel-shaped cutter descends with sufficient force to cut off from the end of the strip, at each downward stroke, a narrow piece sufficient to form one nail. As the nails are required to be of a tapering form, the cutter must be so fixed as to form a slightly oblique angle to the direction in which the strip is pushed into the machine, and this obliquity must be reversed or varied after each stroke, by means similar to those adopted in comb-cutting machinery.

Nail making is conducted upon a very extensive scale in Birmingham. Within the town itself, *cut* nails are made by the aid of machinery; whereas in the neighbouring villages *wrought* nails are made by hand. There is one particular establishment at Birmingham, the machinery of which was, a few years ago, adequate to the manufacture of two thousand millions of nails annually. The machines so employed are the following:— Sheets of iron are cut up into strips, each strip as wide as the length of the nail to be made; this cutting is effected by a kind of enormous shears, worked by steam power. The strips are then cut up into nails. In one kind of cutting machine, the cutter or blade vibrates up and down, cutting off a piece of iron from the strip at each descent; and it has also a swinging motion horizontally, so as to make the cuts at an acute angle with each other instead of parallel; the consequence of this is that the cuts, being alternately oblique in different directions, give a wedge shape to the pieces of iron cut off, and these pieces thereupon constitute the nails. In another form of machine the blade has not a swinging movement; but after each cut the strip of iron is turned over, so as to present the other side uppermost for the next cut; an arrangement which brings about the same wedge-shape to the cut nail, but by different means. In a third form of machine, the piece of iron, after being cut from the strip, is caught by a kind of clasp, and exposed to a pressure which gives a head to it. *Spike* nails are made by machinery in a different way. A square rod of iron, of the proper thickness, is cut into lengths; and each length or piece is exposed to such powerful pressure as to squeeze it into the form of a nail: this more resembles a *wrought* than a *cut* nail. All cut nails are annealed before being fit for use.

A newspaper paragraph has lately stated, 'William Laugher, a nail-maker, of Bromsgrove, has received orders to make a thousand gold, a thousand silver, and a thousand iron 'tacks,' for exhibition in the Crystal Palace, the whole three thousand not to weigh more than three grains. They will be the smallest nails ever produced.'

NAMUR is one of the busiest provinces of Belgium. The iron mines which lie between the Sambre and the Maas, are very productive, and give employment to a large portion of the population. Lead-mines are worked near the city of Namur. A great number of coal-mines are worked. Marble is quarried in different parts of the province; it is of various colours, red, gray, blue, and black; the greatest part of what is raised is exported to France. Potters' clay is found.

Namur, the capital, being situated at the confluence of two navigable rivers, is favourably circumstanced in relation to commerce. The chief manufactures are—superior cutlery, surgical instruments, tin and brass ware, copper utensils, tools of all kinds, agricultural instruments, ironmongery, and leather. The iron, lead, and coal mines and marble quarries of the neighbourhood give employment to a large portion of the population.

NANKEEN is a kind of cotton cloth, usually of a yellow colour, imported from China, and taking its name from the city of Nanking, in which great quantities are made. The peculiar colour of these cloths is natural to the cotton-wool of which they are made, and not the effect of any dye. An imitation of nankeen was largely manufactured in England twenty or thirty years ago; but it has now almost entirely ceased.

NANKING. This famous Chinese city has a great number of manufactures, especially silk, nankeen, paper, and Indian ink, and also carries on a very considerable commerce, being situated in the most populous part of the empire, about half-way between Canton and Peking. Through the ports of Soo-Cheou and Shang-Hae it receives great quantities of corn and other articles. They are brought by water to Nanking, as there are several canals which connect the town with the river.

NANTES, a large seaport town in France, is admirably situated for commerce, having communication with the interior by railway, and by steam boats up the Loire, which forms the harbour of Nantes, and admits at high water vessels of 200 tons up to the quays which line its banks. Vessels of larger size unload at Paimbœuf. Besides these facilities for traffic, Nantes has communication by canal with Brest. The industrial products of Nantes are, white and printed cottons, cotton twist, refined sugar, ship cordage, glue, chemical products, blankets, serge, flannel, ship biscuits, &c. There are several ship-building yards, copper foundries, tan-yards, brandy distilleries, bleach-mills, and dye-houses. Vessels are fitted out for the whale and cod fisheries. The foreign and coasting trade is active. The chief articles of export are wine, brandy, woollen cloths, silk, paper, linen, gold and silver lace, hardware, prepared meats, provisions, furniture, small wares, books, &c.; the imports are composed of ship timber, planks, hemp, pitch and tar, steel, copper, lead, wool, raw cotton, oil, Spanish wine, cochineal, dye-stuffs, gum, ivory, perfumes and colonial produce. Other articles of commerce are salt, butter, coal, building stone, hoops, flour, vinegar, and agricultural implements.

NAPHTHA. This remarkable substance is a volatile oil, which issues from the ground in various parts of the world, and is on that account called *rock-oil* or *stone-oil*. Colourless naphtha issues at Baku near the Caspian Sea, where the vapours which arise from it are kindled, and the flame applied to domestic and manufacturing purposes. In ultra-Gangetic India there is a spot where no fewer than 500 naphtha springs are met with; each spring yields nearly 150,000 lbs. of naphtha yearly. The city of Parma is said to be lighted with naphtha. Naphtha possesses a penetrating odour and generally a yellow colour; but it may be deprived of colour by distillation. It boils at about 160° and is very inflammable. It mixes easily with alcohol and with oils, but not with water; and it dissolves a great variety of substances. It forms with caoutchouc a gelatinous varnish. Naphtha is chiefly employed for purposes of illumination, as a solvent for caoutchouc, and in the preparation of a very superior black pigment.

NAPLES. The productions of the soil, in this rich region of southern Italy, are various. The staple products are corn, wine, oil, wool, and silk. The plains of Apulia produce vast quantities of corn and wool for exportation. Gallipoli is the great oil mart. Silk is made in Calabria, in Abruzzo Citra, Terra di Lavoro, and Principato. Cotton is produced in the provinces of Bari, Principato, near Castellamare, and other places. Wine is made all over the kingdom, and in great abundance and variety, but most of it is consumed in the country and within the year. Some brandy is made and exported to America. The country produces most kinds of fruit, such as figs, chestnuts, almonds, oranges, lemons, pomegranates, melons, peaches, and apricots. Tobacco is cultivated chiefly near Lecce, saffron in Abruzzo, and the sugar-cane in Calabria. Flax, hemp, and rice are also raised in considerable quantity in the low grounds. Indian corn is also much cultivated. Cheese is made chiefly in Abruzzo and Apulia. In some favoured spots, such as in the neigbourhood of Naples, at the foot of Mount Vesuvius, near Monteleone and Reggio in Calabria, the fertility of the soil seems inexhaustible. A little coal and iron are found. The forests have been much neglected.

The city of Naples has manufactures of hats, straw-hats, gloves, leather, earthenware, coral, and jewellery; but the kingdom generally is far from being a manufacturing or commercial one.

The British produce and manufactures exported to Naples and Sicily in 1848 amounted in value to 695,660*l*. The imports thence into Great Britain in 1848 comprised among the larger items sulphur (625,032 cwts.), olive oil (3455 tons), oranges (57,283 packages), silk (54,193 lbs.), wine (589,369 gallons), wool (641,608 lbs.).

NARCOTI'NA is an alkaline principle found in opium. It is procured in light white flocks, or in pearly acicular crystals. It is insoluble in cold water and very sparingly soluble in hot water; its taste is not bitter.

NARWHAL IVORY. The teeth and tusks of the narwhal form one of the best kinds of this beautiful substance. [Ivory.]

NASMYTH'S HAMMER. This mighty engine, one of the most remarkable inventions of the last few years, is described under Steam Hammer.

NATAL. The time is probably approaching when this new colony will present interesting commercial and industrial features. The settlement lies eastward, and is within the territorial limits, of Cape Colony; but it has many of the elements of a distinct settlement. Mr. Christopher, a settler at Natal, has lately published a description of the settlement, in which he states that nine kinds of cotton have been grown there, and that *all* kinds may probably be cultivated. There were exported from the colony 1740 lbs. of cotton in 1846, 5821 lbs. in 1847, and 13,931 lbs. in 1848; these are small beginnings, certainly; but they *are* beginnings, and of an interesting character. Besides cotton, the colony already produces Indian corn,aloes,columbo root,castor oil, gum acacia, coffee, honey, bees' wax, wild olive, ivory, tallow, hides, mimosa bark for tanning, wheat, beans, butter, tobacco, and many varieties of timber and dye woods. The principal towns yet established in the new settlement are D'Urban and Pieter Maritzburg. Accounts from the colony to December 1850, report very favourably of its progress and prosperity. The markets at D'Urban were beginning to show the effects of the skill and labour of the settlers by an abundant supply of vegetables of all kinds. The cabbages, turnips, lettuces, spinach, and cauliflowers are said to be as fine as any Covent-garden can boast of. Among the new towns which are springing up the most flourishing are Richmond, on the Illovi; Pine Town, near New Germany; and Lady Smith, on the Klip-river. Several others are in progress or projected.

NATRON LAKES. These lakes are in a valley in the western desert which borders on Lower Egypt. The Natron valley contains six shallow lakes, remarkable for the great quantity of salt which they produce. The crystallisations are both of muriate of soda, or common salt, and of carbonate of soda, called natron or trona. The lakes occupy a total length of about 16 miles; they vary in size according to the season; the bottom is muddy, of mixed sand and clay. The lakes are supplied by water which oozes out of the banks chiefly on the side which is towards the Nile. It appears that the water flows abundantly when the Nile is high, and decreases with its decrease, until some of the lakes become quite dry. The natron is collected once a year, and is used both in Egypt and Syria, as also in Europe, for manufacturing glass and soap, and for bleaching linen.

NAVARRE. In this Spanish province the mountains contain jasper and marble. There are many mines of iron and one of copper; one also of rock salt near Valtierra, and several hot springs. Forests of pine cover the slopes of the Pyrenees, and much timber is cut, and sent down by the mountain streams to the Ebro, by which it is floated onward to Aragon and Cataluna. The other principal forest trees are the oak, the olive, the chestnut, the beech, and the box. Wine, cider, and olive oil are among the products of the province. The annual produce of sheep's wool is about 1,500,000 lbs. The manufactures are coarse linen, some woollen cloth, leather, soap, iron, and brandy, of which the quantity annually distilled averages 2,000,000 gallons. There are also some potteries, a royal shot and shell foundry, and some manufactories of Spanish liquorice. The exports are corn, oil, wine, wool, and iron; the imports consist of cottons and silks, cutlery, tobacco, sugar, spices, and other luxuries, which are imported, principally from France.

NAVIGATION LAWS. The recent change in the Navigation Laws is already producing such important results in the commerce of England with foreign nations (and consequently in the industry of all nations) that it will be desirable briefly to notice the subject here.

The system of the Navigation Act, as it is termed, had its foundation during the Protectorate; but the act so called was that of 1672. This act declared that no produce of Asia, Africa, or America, should be imported into Great Britain except in British ships, navigated by a British subject, and having at least three-fourths of their crew composed of British seamen. It also laid higher duties on all goods imported from Europe, than if they were imported in British ships. To this act many persons have attributed the great growth of British shipping. When the American colonies became independent, their ships lost the advantage which they had when the States were colonies, and their shipping was placed on the same footing as other foreign ships. The consequence was that American ships sailing to Great Britain came in ballast, while British ships carried merchandise both ways; and accordingly the United States placed British shipping under the same disadvantages in their ports that American shipping was under in British ports. The consequence of this was that British ships sailed to America in ballast when they went to the United States to get a cargo, and American ships came to Great Britain in ballast when they wanted a British cargo. The consumer of the foreign produce in both countries accordingly paid double freight for it. This lasted till 1815, when it was agreed by treaty between Great Britain and the United States that the ships of the respective countries should be placed on the same footing in the ports of Great Britain and the United States; and all the discriminating duties were mutually repealed. In 1822 Mr. Wallace, president of the Board of Trade, introduced five bills, which were passed into laws, and which made other important alterations; one repealed certain statutes relating to foreign commerce, which were passed before the Navigation Act; a second repealed various laws that had been passed since the Navigation Act, and also that part of the Navigation Act which enacted that goods of the growth, produce, or manufacture of Asia, Africa, and America should only be imported in British ships, and that no goods of foreign growth, production, or manufacture, should be brought into Great Britain from Europe in any foreign ship, except from the place of their production or from the ports from which they were usually brought, and in ships belonging to the country of production or accustomed shipment; a third permitted certain goods then enumerated to be brought to Great Britain from any port in Europe in ships belonging to the port of shipment; a fourth permitted the importation, subject to certain duties, into certain ports, of various articles from any foreign country in America or port in the West Indies either in British vessels or in vessels belonging to the country or place of shipment, and such goods might be again imported to any other colony or the United Kingdom; and a fifth permitted the exportation in British ships from any West India colony to any foreign port in Europe and Africa, of any goods that had been legally imported into the colony, or which were of its growth or manufacture; and it permitted the exportation of certain articles, enumerated in the act, in British ships to any such colony from any foreign port in Europe or Africa.

In 1823 Prussia retaliated, as the United States had done, which led Mr. Huskisson to propose the passing of what are called the Reciprocity Acts, in 1824 and 1825. These acts empowered the king, by order in council, to authorise the importation and exportation of goods in foreign ships, from the United Kingdom, or from any other of his majesty's dominions, on the same terms as in British ships, provided it shall first be proved to his majesty and the privy council that the foreign country in whose favour such order shall be made shall have placed British ships in its ports on the same footing as its own ships. Since that time reciprocal treaties of navigation have been made with the following countries: Prussia, Denmark, Hanover, Oldenburg, Mecklenburg, Greece, Bremen, Hamburg, Lübeck, States of La Plata, Colombia, Holland, France, Sweden and Norway, Mexico, Brazil, Austria, Russia, and Portugal. That with the United States of North America, as already observed, dates from 1815.

An act was passed in 1849, entitled 'An act to amend the Laws in force for the encouragement of British Shipping and Navigation.' The full meaning of this act can only be understood by referring to the acts and parts of acts which it repeals, and to its provisions. It repeals a part of the act of 1824, and the whole of that of 1825. The general purpose is to diminish the restraint on the freedom of navigation. British shipping has already derived great advantages from the enactments above mentioned, and the Reciprocity Acts.

There seems every probability that as British shipping is now fairly brought into competition with foreign, great improvements will be made in ship building: indeed such improvements have already commenced.

NEEDLE MANUFACTURE. This is one of the most remarkable industrial pursuits of our country, both technically and locally. In a technical point of view it is striking for the number of processes which every individual needle passes through; while it is not less noteworthy on account of the grouping of the manufacture in and around the town of Redditch in Worcestershire; where it has been calculated there are 60 to 70 millions of needles made every week!

In commencing the manufacture of a needle, soft steel wire of the required thickness is first cut into lengths of about five inches, and these lengths being placed together in a bundle, are bound together by means of iron rings, five inches in diameter, placed at each end of the bundle. This bundle is then placed on a cast-iron table, and rolled to and fro upon it, under the pressure of a flat bar of iron, by which means the wires are made perfectly straight. About a dozen and a half or two dozens of these wires are then taken by the grinder, and together are pointed on a small dry grindstone. This, like the dry grinding of the Sheffield cutlers, is a very deleterious employment, towards the amelioration of which the workmen render very little assistance, unfortunately for themselves.

When the pointing is finished, the wires are cut into the required lengths, and the holes or eyes are perforated. This operation is usually performed by females. The tools employed are, a small anvil fixed on the work-bench, a hammer, a finely-pointed and well-tempered steel punch, a pair of pliers, a file, and a block of lead. The woman first slightly flattens the unpointed end by a stroke of the hammer, then makes an indentation on one side by means of the punch and hammer; the needle is then taken from off the anvil, and being placed with the indented side downwards on the block of lead, the perforation is completed by striking with the punch and hammer on the opposite side of the needle. Holding then the needle in the pliers, the head is somewhat bent, and with the file the *guttering* is performed, which is the forming of the channel that may be seen on each side where the perforation is made. The head is then smoothed by passing the file over it. Needles to which the name *drilled-eyed* is applied are perforated in the manner here described, but the additional process is used of smoothing the eye by means of a drill after it is perforated.

For making the eyes and gutters in large needles, machinery is employed. The wires used for making these needles are pointed at both ends, and the channels and eyes are formed in the middle, when the two needles thus made are cut asunder, and their heads smoothed with a file.

These operations being performed when the steel wires are in a soft state, they are more or less bent, and must be straightened, which is done by rolling them on one plate of metal under the weight of another. The needles are then placed, many thousands together, in a kind of crucible, and covered over with ashes, when they are put into a close furnace and exposed to a cherry-red heat. When this degree of heat has been obtained, the crucible is withdrawn, and the needles are dropped into cold water, from which they are taken out and put upon an iron plate almost red hot, where they are turned about so as to cause the heat to apply equally to all, and as fast as the needles become of a blue colour, they are removed as being of a proper temper.

Such of the needles as now appear crooked are straightened on a small anvil by blows from a hammer.

The needles are next ranged in parallel rows upon a coarse cloth, which has been smeared with a mixture of oil, soft soap, and fine emery powder. In this cloth from 40,000 to 50,000 needles are rolled up, and several of these rolls are placed together in a machine like a mangle. The rolling to which they are here subjected is continued, by means of steam or water power, for two and sometimes three days, during which time the cloth wrappers, being worn out, require to be once or twice replaced by new ones. When taken out, after this rolling, the needles are perfectly bright. They are finally sorted, packed, and papered.

NEPAUL. This remote country of India, situated close to the Himalaya Mountains, yields a fair supply of vegetable produce in the river valleys. It also contains several metals in abundance, especially iron, lead, copper, and zinc; the first three are worked rather extensively. Gold is found in the sand of some rivers. Of the inhabitants of the country, the Newars are mostly cultivators of the soil, and exercise many arts and trades. They make coarse cotton-cloth, and work very well in iron, copper and brass, and are particularly ingenious in carpentry. The trade with Tibet is mostly in the hands of the tribe called the Bhot, who transport their goods on the backs of sheep or men over the mountain passes. They bring from Tibet to Nepaul sheep, musk, skins of the musk-deer, chowry-tails, quicksilver, borax, sal ammoniac, Chinese silk stuffs, paper, drugs, gold and silver; and they carry back rice, wheat, oil, iron, copper, cotton cloth, catechu, juniper boards (which are used in fine cabinet-work), pepper, spices, indigo, tobacco, otter-skins, sugar, and some smaller articles. Nepaul exports to British India elephants' teeth, timber, hides, ginger, turmeric, wax, honey, oranges, long pepper, ghee, bastard cinnamon, large cardamums, and some smaller articles. It imports from the British dominions in Bengal cottons and muslins, silks of various sorts, raw silk, gold and silver, laces, carpets, English cutlery, saffron, spices, sandal-wood, quicksilver, cotton, tin, zinc, lead, soap, camphor, tobacco, pepper, and coral.

NET; BOBBIN-NET. [LACE MANUFACTURE.]

NETHERLANDS. In England the *Nether-*

lands and *Holland* imply pretty nearly the same thing, viz. the territory which, after the separation of Belgium, in 1830, remained to the King of Holland. In this remarkably flat country, sufficient corn for home consumption is not raised; hemp and flax are grown in great abundance. There are no minerals except a little bog-iron in Overyssel and Guelderland: there are brick-earth, potters' clay, fullers' earth, and a little sea-salt.

The history of the commerce of the Netherlands properly begins with Bruges in Flanders, in the 14th century. From Bruges the trade was for the most part transferred at the end of the 15th century to Antwerp, which became the greatest emporium in the world. But the ravages of the war with Spain and the capture of the city after the memorable siege in 1585 drove the wealthiest inhabitants to the northern provinces, especially to Amsterdam. The Dutch East India Company conquered kingdoms and islands in the east; and Amsterdam became the first commercial city in the world. From 1795 to 1813 the trade of Holland was much depressed by French domination; but since that period it has partially recovered, though it has not attained its former extent. The inland trade employs 6000 of the vessels called *trekschuyts*, and 15,000 boats.

The exports from the Netherlands consist of colonial produce from the East and West Indies, coffee, sugar, spices, tea, silks, and other articles from China and Japan; together with the home produce of butter, cheese, flax, hemp, tobacco, madder, flowers, cattle, horses, and fish. The chief articles of importation are corn, salt, wine, timber, stone, marble, and various manufactured goods; besides colonial produce of every kind from the possessions in Asia, Africa, and the West Indies. The value of the British and Irish produce and manufactures exported to Holland in 1848 was 2,823,258*l*. The produce imported into Great Britain from Holland is chiefly butter, cheese, flax, madder, and Dutch colonial produce.

The principal manufactures are linen of the best quality; woollens, once the most celebrated in the world; silks, and leather. Sugar refineries, tobacco-pipe manufactories, distilleries, and cotton mills, are numerous. As has been noticed in HOLLAND and other articles, many of the chief towns of the Netherlands take part in the Industrial Exhibition.

NEUTRAL SALTS. Formerly this term included such salts as did not obviously contain an excess either of acid or alkali; but at present the term Neutral Salt includes such compounds as are composed of one equivalent of each of their constituents: thus the subcarbonates of potash and of soda are now termed carbonates, notwithstanding their alkaline reaction, because they consist of one equivalent of acid and one of base. Chemists apply the term *Neutralization* to the decomposition of the alkaline carbonates, by the gradual addition of some acid more powerful than the carbonic, and which of course expels it from the alkaline bases with effervescence.

NEW BRUNSWICK. The great commercial wealth of this North American colony consists in its extensive forests, which are composed of pine, fur, spruce, hemlock, birch, beech, maple, ash, elm, and poplar. Wheat, rye, oats, barley, beans, peas, buckwheat, flax, Indian corn, and common vegetables are cultivated. On the alluvial grounds which occur along the banks of the numerous rivers there are fine meadows and pasture-grounds. The mineral riches are imperfectly known; but they comprise iron, coal, marble, and gypsum. The exports of the province are almost wholly confined to the produce of the forests and the fisheries; they amount to nearly a million sterling annually. Ship-building forms a considerable branch of industry in the province.

The Exports from Great Britain to New Brunswick in 1840 amounted in value to 277,591*l*.

NEW HAMPSHIRE. A few commercial statistics of this American state will be found under UNITED STATES.

The same may be said also in respect to *New Jersey*.

NEW ORLEANS. This American city is one of those which are rising into importance with a rapidity which can scarcely be understood in Europe. Situated near the mouth of the Mississippi, it is the outlet for an immense amount of produce—timber from the north, grain from the centre, cotton and sugar from the south. From New Orleans this produce is diffused to every part of the globe. More cotton is shipped at New Orleans for England than from any other port. From New Orleans the numerous, large, and powerful steamers start, which navigate the great Mississippi for upwards of a thousand miles. From New Orleans to St. Louis the busy traffic of the Mississippi is mainly concentrated; while at St. Louis, which stands at the junction of the Missouri with the Mississippi, commences the commerce of the western prairies, and the emigrant routes over the Rocky Mountains to Oregon and California. At New Orleans the river is too much encumbered with sand banks to enable large ships to sail up to the quays; but they are drawn up by tug-boats. The ships lie in tiers alongside an embankment or quay, called the *Levee*, sometimes three or four deep, presenting the appearance of a forest of masts.

Some years ago the exports from New Orleans were estimated at twelve million dollars annually; but they now greatly exceed this amount. In the environs of the city are large plantations of sugar, cotton, indigo, and rice, which are cultivated in a very perfect manner.

NEW YORK. This most famous portion of the United States is the name both of a state and of a city. In the state of New York, maize, wheat, rye, barley, oats, buckwheat, potatoes, turnips, peas, beans, and numerous fruits, are generally cultivated. In some parts flax and hemp are grown, especially in the Lake Country. A considerable part of the state is still covered with forests, which consist of oak, ash, walnut, pine, maple, beech, chestnut, birch, poplar, elm, cedar, hemlock, and hickory. Several minerals occur in abundance, but only iron, salt, limestone, and marble are worked. Coal is imported from various places, especially from Nova Scotia. The canals and railroads are numerous; the former extend 600 to 700 miles; while the railways are forming a complete network over the state. In 1840 there were 323 woollen manufactories, 890 fulling mills, 186 iron furnaces, 120 forges, 77 paper mills, 1216 tanneries, and a great variety of other works; and in the subsequent eleven years these numbers must have vastly increased. The commerce greatly exceeds that of any other of the States.

But it is the city of New York which appeals most to our notice in respect to commercial and industrial features. The situation of New York as a commercial port is admirable. New York Bay, which is completely landlocked, is about 8 miles long and from 1½ to 5 miles wide, and affords a perfectly safe anchorage. It is easy of approach, and is very rarely closed by ice. The entrance between Long Island and Staten Island, by a channel called the Narrows, is protected by forts, while the approach to it is facilitated by lighthouses. The bay contains several small islands, on which fortifications have been constructed. There is sufficient depth of water, both in the Hudson and East River, for ships of large burden to load and unload at the wharfs. The commercial intercourse with the interior and with the western States of the Union is provided for by means of the Hudson, and the system of canals connected with it.

The most expensive and useful public work undertaken by the city is the aqueduct called the Croton Water-Works, noticed in a previous article. [Aqueduct.]

No fewer than 3,341 vessels, of 1,247,860 tons burden, and manned by 46,158 seamen, entered the port of New York in 1850; and the shipping which left the port presented corresponding numbers. About one half of the shipping was American, one-third British, and the remainder belonging to various countries. The tonnage of the arrivals at four nearly equidistant periods presents the following remarkable differences:—

1821	171,963 tons.
1830	314,716 „
1840	527,594 „
1850	1,247,860 „

The number of persons who arrive every year at New York by sea, chiefly from Europe, is immense. In the ten years, 1841 to 1850, the number averaged 123,784 yearly; in 1849 it reached the high figure of 221,799. A very large proportion of these are emigrants, who land at New York as a convenient point whence to start farther westward. There is, perhaps, no other city in the world which, at the present time, equals New York as a centre of transit, or as a temporary abode for thousands who make it a mere resting point on a journey: this circumstance gives it a peculiar character both in its commercial and its social features. In the single month of September 1850, the exports from New York amounted to five millions and a half of dollars, considerably more than one million sterling. Very nearly one-half of this value of commodities was sent to Great Britain. Half a million went to Panama, *en route* to California, with which an immense commerce is now conducted from New York. In the first nine months of 1850, no fewer than 37 ships were launched at New York, averaging 1150 tons each; and at the end of September in that year there were 31 more building, of about the same average tonnage. Of the whole 68 vessels, 38 were steamers.

The mail steam ships which now run between England and New York are among the finest which the world has yet seen.

NEWCASTLE UPON TYNE. This busy and important town is very well provided with railway accommodation. The Newcastle and Carlisle Railway extends across the island nearly from one sea to the other; the North Shields line passes through North Shields to Tynemouth; the Newcastle and Berwick Railway establishes a communication with Scotland; lastly, the Durham railways, which, taking their departure from Gateshead, open up a communication with South Shields, Sunderland, Durham, York, and the south of England generally. A station near the centre of the town, which is to form a junction with all these lines by means of viaducts, has for some time been in progress. The most important part of this work is a bridge across the Tyne, undertaken by the railway companies, and one of the finest engineering works in England.

It is a double bridge, the lower one at an elevation of 90 feet above the river, for carriages and foot passengers, and a railway bridge at a further elevation of 25 feet. The whole length of the structure is nearly 1400 feet. It has two piers at the margin of the river, and four others in the stream itself, besides smaller piers to support the land arches. The *High Level Bridge*, as it is termed, is one of those creations which will give lasting fame to Robert Stephenson.

The commercial importance of Newcastle arises from its situation on a river navigable thus far by sea-borne vessels of 400 tons. The Tyne forms the haven, and is under the care of the corporation. The river side is lined with warehouses and extensive quays. The chief business is in the shipment of coals, the produce of the surrounding coal-pits. The coals were formerly brought down the river in barges called keels, but vessels are now chiefly loaded from staiths. Coal is exported very considerably; also lead, cast and wrought iron, glass and pottery, copperas and other chemical productions, soap, colours, grindstones, salt, and pickled salmon. The imports are wine, spirituous liquors, and fruit, from the south of Europe; corn, timber, flax, tallow, and hides, from the Baltic; and tobacco and various other articles from North America. The number of sailing vessels registered at the port is about 1500, besides about 200 steamers.

The chief manufactures are of glass bottles and plate and crown glass, steam engines, mill work, and other machinery. A number of persons are engaged in ship and boat building, block, mast, and sail making, flax-dressing, rope making, &c. There are several malt-houses, breweries, flour-mills, iron and lead works, and chemical works.

Newcastle takes up a worthy position at the Great Exhibition. In mineral produce, in machinery, and in manufactures, the town and neighbourhood are well fitted to occupy a high rank.

NEWSPAPERS. Considered in its relation to produce, industry, and commerce, it is scarcely possible to place a limit to the importance of a newspaper. It meets us at every turn, as an example either of the aid which newspapers render to commerce, or of that which commerce renders to newspapers. As a question of paper-making, of taxation on paper, of type founding, of steam-press machinery, of rapid printing, of the advertising system, of the tax on advertisements, of the reporting system, of the statistical tabulating system, of the postage system, of the express travelling system, of the ocean mail system—in all these respects a modern London newspaper is a marvel.

Under the head of PRINTING will be found a little information concerning the vast scale on which the great newspapers are printed in London and in New York. In the present article we shall take a newspaper as the representative of rapid transport, showing how it reaches Dublin at a period of urgent demand. Let it be the Queen's speech of February, 1851, as printed in the morning journals of the next day; and let us trace the mode adopted by Messrs. Smith (who conduct vast operations of this kind), to convey those journals and that speech to Dublin, to Liverpool, and to Manchester. A special engine left Euston station at 6·22 A.M., and after some slight detention for water, &c., amounting altogether to 20 minutes, it reached Crewe at 10·8, the distance of 166 miles having been performed in 3¾ hours, or a running rate averaging 50 miles an hour. From Crewe an engine proceeded to Manchester, 32 miles, in 40 minutes, and another to Liverpool, 44 miles, in 75 minutes. The express to Ireland started from Crewe at the same moment as the Liverpool and Manchester expresses; it proceeded by Chester, where the superintendent of the Chester and Holyhead Railway joined it. Under his management the special engine reached Holyhead at 12·45, having travelled over a great portion of the distance between Chester and Bangor at the rate of 60 miles an hour. At Holyhead the Chester and Holyhead Company's steamer Scotia, commanded by Captain Hirste, was lying ready to start with the express, but in consequence of the violence of the gale she was unable to get clear of the harbour for some minutes. Notwithstanding the delay and the heavy sea, she made Kingstown Harbour by 5·30 P.M., and the morning papers were distributed in Dublin by a little after six o'clock. The mail trains carried them into the provinces —the same mails which conveyed the London letters and papers of the previous evening. It is now proved that the entire distance from London *viâ* Holyhead and Dublin to Cork—upwards of 500 miles—can be accomplished in 16 hours. The Queen's speech was forwarded by Messrs. Smith on the afternoon of its delivery, by telegraph to Crewe, and thence by special engine to Holyhead, and by steamer to Dublin. It was printed in Dublin within eight hours and a half after its delivery, and reached Cork, by special engine engaged by Messrs. Smith, in four hours and a half from Dublin.

NIAGARA BRIDGE. The suspension bridge thrown over the Niagara Falls may be considered, under the extraordinary circumstances of its position, as one of the most remarkable of its kind. The first transit across from bank to bank was made by a kite. A kite being raised on one bank, when the wind was in a particular position, was so manœuvred as to be made to fall on the opposite bank; the string was secured, and was made the means of dragging over a larger string, then a rope, then a cable of 36 iron wires. Several persons crossed the perilous chasm in a car suspended from this wire cable. The bridge was next proceeded with. On each bank is a wooden tower 50 feet high, over which pass 14 cables; viz., 5 of 66 wires each, 5 of 72, 1 of 125, and 3 of 150 wires each, making 1115 wires in all. These wire cables, hanging in the usual curve, support the platform of the bridge, which is capable of withstanding a pressure of 1000 tons, and is traversed by passengers, teams, and droves of cattle. There is however now being constructed a far mightier work over the Falls, to connect the United States railways on one bank with the Canadian railways on the other. A locomotive defying the Falls of Niagara will picture the grandeur of art and the grandeur of nature in singular proximity! The railway bridge will have 16 wire cables, each containing the enormous number of 6000 iron wires,—not twisted round each other, but laid straight, and bound round with smaller wire. It is calculated that the bridge will be able to maintain 6000 tons besides its own weight.

NICHE is a small recess, or concavity in the face of a wall for the purpose of containing a statue. The use of niches seems to have originated with the Romans, for scarcely anything of the kind occurs in the architecture of the Greeks. In Italian architecture niches are of very frequent occurrence. They are usually semicircular in plan, and round-headed, that is, covered by the quarter of a hollow sphere, owing to which the shadow within the concavity produces a highly beautiful curve. Niches exhibit great diversity in the modes of decorating them; but in this country it has usually been the fashion to leave them plain.

NICKEL. This metal was first described by Cronstadt in 1751. It is usually procured from the sulphuret. It has a white colour with a yellowish tint; its lustre is considerable, and it is both malleable and ductile. Like iron, it is attracted by the magnet, and may, like it, be rendered magnetic at common temperatures, but it loses this power when heated to 630° Fahrenheit. The specific gravity varies from 8·28 to 9·0. Nickel is nearly as hard as iron. It suffers little or no change by exposure to the air and moisture at common temperatures. It is very difficult of fusion, but melts at a lower temperature than iron. At a red heat it absorbs oxygen gradually from the air, and also decomposes water at this temperature. Nitric acid is the only acid which readily acts upon nickel. Nickel occurs in meteoric iron and aërolites.

The uses of nickel are very limited, and until within a few years it was scarcely employed at all; but it is now very usefully employed, and to a considerable extent, in forming an alloy with copper and zinc, known by the name of German silver. Its oxides impart a green colour to glass and porcelain. Nickel forms alloys with arsenic, potassium, antimony, zinc, tin, iron, cobalt, mercury, and copper.

NICOTINA is an alkali which exists in the different species of tobacco. It crystallises in small plates, which, by exposure to the air, absorb moisture sufficient to become a transparent colourless liquid. When cold it is nearly inodorous, but when heated it has a disagreeable odour and taste. It boils at 375°; its specific gravity is 1·048. The salts which it forms with alkalies are colourless. There is also a substance called *Nicotianin*, which is concrete oil having a smell of tobacco and a bitterish taste; it is the principle which gives the characteristic odour to tobacco.

NIELLO-INLAYING. This name is given by the Italians to a peculiar kind of ornamental metal-work. Niello is composed of an alloy of silver and lead, or silver and copper, blackened by the action of sulphur. It was first called *nigellum*, but afterwards *niello*. The use of it is occasionally mentioned in documents from the 7th to the 13th centuries, at which latter period it had arrived at a state of great excellence. The process used in working the niello was somewhat similar to that of enamel incrustation. The object intended to be ornamented with niello had incised or cut into its surface the required design, into which niello was inlaid in small grains, and afterwards fused by the action of the fire, and polished. Originally, the channels in the metal were cut broadly, and of an equal depth; giving to the entire work, after the introduction of the niello, the appearance of a rude picture, the outlines only of which were formed, sometimes by the niello and sometimes by the metal; but afterwards the designs on the metal were engraved with great delicacy, and occasionally were carefully shaded by lines. The origin of taking impressions on paper from metal plates is ascribed to the practice of Finiguerra, a Florentine goldsmith, who, in the middle of the 15th century, was in the habit of taking impressions from plates he had engraved for the purpose of ascertaining their fitness to receive the niello. Some few of these old impressions still exist, and equally with the plates themselves are called *nielli*. The metal which was engraved to receive the niello was usually either gold, silver, or copper.

Many beautiful specimens of niello were collected at the Mediæval Exhibition in 1850; including a silver super-altare, a copper-gilt ciborium, a silver brooch, statuettes of saints, silver plates, and a pax.

NILE. The influence of this far-famed river on the industry and commerce of the neighbouring countries has been briefly adverted to under EGYPT.

NIMES or NISMES, the capital of the French department of Gard, has long been an important manufacturing town. Its importance has been lately on the increase in consequence of its being the centre from which the railways diverge that connect the town with Alais, Montpellier, Cette, Arles, Avignon, and Marseille. The principal manufactures are fancy silk goods, silk stockings and caps, hosiery of all kinds, velvet, small wares, printed cottons, shawls, handkerchiefs, chintzes, &c. There are several dye-houses, potteries, brandy distilleries, vinegar-works, and tan-yards; and the town is the great market for the raw silks of the surrounding district. Nimes carries on considerable trade in these productions; and in wine, spices, drugs, oleaginous seeds, medicinal plants, and dye stuffs.

NISCHNEI-NOVGOROD FAIR. This famous fair has already been adverted to [FAIRS]; but it may be well to notice it a little more in detail, as a means of shewing its important influence on trade and commerce. Nischnei-Novgorod is a town in the heart of the Russian empire. The inhabitants carry on various manufactures; but the great and annually increasing importance of the town arises from its fair. This fair, which is opened on June 29 in each year, is one of the greatest in the world. It is held in a group of buildings, formed into a large oblong parallelogram, surrounded with shops, before an edifice adorned with three rows of columns, which is the hotel of the governor, in which the local authorities reside during the fair. Forty-eight blocks of buildings, separated by streets which intersect each other at right angles, extend behind this parallelogram. The number of the shops is about 2524, and over each there is a small apartment, in which the merchant may reside. During the fair, all the streets and warehouses are filled with a countless multitude, who have flocked thither from the two Russian capitals, from various other towns of Russia, from the shores of the Baltic and the Caspian, from Bokhara, Khiva, Kokand, and Taschkend, from Asia Minor, from the mountains of Turkistan and the frontiers of China, and, of late years, from different parts of Western Europe. All these magazines and booths are filled with the produce of the most diverse countries, and thousands of boats are employed in landing the goods, or in taking them on board to convey them to the seas which wash the northern and southern shores of the empire. Other goods, such as wooden wares, are piled up even in the open country, and farther on are long lines of carts with their horses, which serve both as magazines and lodgings for the country-people. From 4000 to 5000 warehouses and booths are let during the fair. The goods sold amount to 10,000,000*l*. to 12,000,000*l*. annually.

NITRE. [POTASSIUM.]

NITRIC ACID was formerly called *Spirit of Nitre*, or Glauber's Spirit of Nitre; and when much diluted with water, it is called *Aquafortis*. When pure, it is a colourless liquid, but is usually yellowish. Its smell is strong and disagreeable, and it emits white fumes. It is so acrid that it cannot be safely tasted without being much diluted, and is even then very sour. In its concentrated state it stains the skin of a yellow colour, and eventually the skin is destroyed and peels off. When mixed with water it gives out considerable heat. When colourless nitric acid is exposed to the action of the light, it undergoes partial decomposition.

Nitric acid is used for numerous purposes; such as the refining of gold and silver, in preparing various metallic and saline solutions for medicinal purposes, and the use of the dyer and calico-printer; in scientific chemical researches it is most extensively employed. Its saline compounds are termed *Nitrates*; and both the acid itself and the nitrates are used in medicine.

The gas called *nitric oxide*, which contains less oxygen than nitric acid, has not yet been much applied to useful purposes. The same may be said of *nitrous acid* and *nitrous oxide*, which differ from each other and from the two nitric compounds chiefly in the amount of oxygen contained.

NITROGEN, or AZOTE, one of the most abundant and extensively diffused of the gases, is transparent, colourless, inodorous, and insipid. It is lighter than atmospheric air. Its refractive power and its specific heat are both lower than those of common air. Water dissolves but a very small quantity of this gas. It is fatal to animals when respired by itself, as is implied by the term *azote;* it extinguishes flame immediately. No degree of cold and pressure to which this gas has been subjected has condensed it to a fluid form. It resembles all other elementary bodies in being destitute of acid or alkaline powers. It enters into the composition of a great number of important compounds. Thus it constitutes $\frac{79}{100}$ of the volume of *atmospheric air.* With oxygen it forms five definite compounds, viz., *nitrous oxide*, *nitric oxide*, *nitrous acid*, *hyponitrous acid*, and *nitric acid.* With hydrogen it constitutes the alkali *ammonia;* with chlorine and iodine it gives rise to *detonating* compounds; with carbon it forms *cyanogen;* and with phosphorus a *phosphuret.* It enters into the composition of most animal matter except fat and bone; and, though not a constituent of the vegetable acids, it forms a part of most of the vegetable alkalies. Although by itself fatal to animals, yet it is a most important constituent of the air, as serving to moderate the action of oxygen during combustion, and the too great excitement which that gas, respired unmixed, would produce on the animal system. It appears also from the experiments of Majendie that animals will not live on food that contains no azote.

NORD, the most northern department of France, raised the following quantities of agricultural produce in 1848: 2,124,549 quarters of corn; 2,960,264 bushels of potatoes; 13,330 hogsheads of flax seed; 352,429 cwt. of flax fibre; 142,398 tons of hay; 612,401 tons of straw; besides a fair average of vegetable crops and fruits. Authority was given to plant 2498 acres with tobacco in the year 1849, calculated to furnish 63,070 cwt. of leaf. A good deal of the barley grown in the department is used for malting, beer being the common beverage; other grain and potatoes are also used in the gin and other spirit distilleries.

The mineral wealth of the department consists chiefly of its coal and iron mines; of the former, 19, all situated in the valley of the Escaut, were worked in 1848, and of the latter, 3 were worked in the arrondissement of Avesnes. Steam-engines are used for draining the mines. Marble, paving-stones, brick-earth, potter's clay, peat, and fossil ashes, which are used as manure, are found. There are mineral waters and baths at St. Amand. The industrial products are of the most varied description, including all kinds of woollen, cotton, and linen manufactures, ticking, duck, velveteen, printed cottons, and handkerchiefs, woollen, flaxen, cotton, and hempen yarn, lace, tulle, cambric and lawn, soap, refined sugar and salt, beer, oil, nails, glass, paper, tiles, bricks, earthenware, ropes, leather, toys, small wares, cannon, small arms, saltpetre, &c. These numerous products form the items of a large home and foreign commerce. The imports are chiefly raw cotton, wool, flax, colonial produce, wine, brandy, and timber. At the principal points on the Belgian frontier, custom-house officers are stationed, who are under the direction of the custom-houses of Dunkerque and Valenciennes.

The manufactures of this department give rise to great activity in the towns of *Lille*, *Auzin*, *Roubaix*, *Tourcoing*, *Douai*, *Dunkerque*, *Valenciennes*, and *Cambrai*, all of which are distinguished for their industry and commerce.

NORFOLK. This agricultural county contains little of what may be designated mineral wealth. Chalk is dug for lime in many places; excellent sand for glass-making is procured between Snettisham and Castle Rising; some potter's earth is found and excellent brick-earth; marl is dug in the valley of the Bure; and the Fen districts of the west furnish peat for fuel and manure. The district in which the true Norfolk system of cultivation was first adopted, and where turnips and clover were introduced in the regular rotations, was that on the north-west, where the better kinds of sand prevail; from this district it has gradually spread; and there are now few soils in Norfolk which are considered too heavy to bear turnips, especially after having been well underdrained. The crop which is raised in the greatest perfection in Norfolk is barley.

Among the towns of Norfolk there are but few which present a manufacturing character. At *Lynn*, rope and sailcloth are almost the only articles of manufacture in the town; but the trade of the place is considerable, owing to the harbour. The exports are principally corn and agricultural produce, sent coastwise, and a fine white sand ground near the town, and used for making glass. A vast quantity of shrimps, caught on the shores of the Wash, are sent to London. The imports are corn and coal; timber from America, timber, deals, hemp, and tallow from the Baltic; wine from France, Spain, Portugal, &c. There are about 180 vessels belonging to the port. *Thetford* has few manufactures; but there is a good deal of malting, and the trade of the place is favoured by the river Ouse being navigable up to the town; by means of which an export of agricultural produce and an import of coal are carried on. At *North Walsham* the silk manufacture is prosecuted to some extent. In *Norwich* the most important trade consists of the manufacture of silk and worsted into shawls, crapes, bombazines, damasks, camlets, and imitations of the Irish and French stuffs. A School of Design has been established to aid in the production of elegant woven goods; but the textile manufactures are in a declining state at Norwich; and there is a want of enterprise and spirit observable in the manufacturing operations.

In 1850 the county of Norfolk contained 2 cotton factories, and 11 worsted factories, employing altogether about 1700 persons.

NORTHAMPTONSHIRE. Although this county presents some remarkable features in respect to the boot and shoe manufacture, it must be regarded as an agricultural county. The soil is generally adapted to produce both corn and pasture of a superior quality. The pastures are both rich and sound, and the cattle grazed in them in summer repay the capital laid out on them with good interest. The fattening of cattle is a principal object of the Northamptonshire farmer.

Among the towns there are a few in which manufactures are carried on. At *Kettering* wool-stapling and wool-combing are carried on; there is a considerable manufacture of shoes; and that of silk shag for hats has been also introduced. At *Northampton* the principal branch of trade carried on is boot and shoe-making; the articles are sent to London and other parts of England, or are exported; and considerable business is also done in currying leather. Stockings and lace are made. There are iron foundries. The trade of *Wellingborough*, and of other towns in this county, is dependent mainly on the boot and shoe manufacture. The only reasonable explanation of the settlement of this branch of industry in this county seems to be that Northamptonshire is a grazing county, and yields hides fit for tanning; but whether this be the correct explanation or not, it is a well-known fact that the ready-made boots and shoes of the London shops are supplied to a very large extent by the county of Northamptonshire. The work is done on the *piece-work* system. There are not large factories where men are employed at weekly wages; but the manufacturers give out leather cut to the proper shapes to the workmen, who return the finished or partially finished boots and shoes, and receive so much per dozen pairs for their labour. Competition between these workmen has brought down the wages to a very low average.

NORTHUMBERLAND. The south-eastern part of this county, bounded by a line drawn from Warkworth, at the mouth of the Coquet, by the head of the river Blyth, to the Tyne, and thence southward to the bank of the Derwent, is included in the great coal-field of the counties of Northumberland and Durham. [COAL-FIELDS.] This coal-field is the great source of wealth to the county, and gives it a high rank among the shires of Britain. The salmon fishery of the Tweed is very important, and a considerable number of boxes of that fish packed in ice are sent from that river to the London market, besides what is salted. The county of Northumberland has been one of the foremost of the English counties in adopting the improved system of agriculture, the chief feature of which is the cultivation of turnips for the rearing and fattening of cattle. So great has been the advantage derived from this change from the old triennial system, that many fields now yield heavy crops of this useful root, which in most other parts of England would be considered as totally unfit for its cultivation. The instruments of tillage are mostly of improved make. The ploughs are generally iron swing-ploughs, on the principle of the old Rotherham plough, which was originally copied from the Belgian plough, and afterwards improved. The harrows, rollers, scarifiers, &c., are as in other counties. Threshing-machines, moved by water, wind, or horses, are thought essential on the larger Northumberland farms.

The manufactures of the county are noticed in connection with its chief industrial centre [NEWCASTLE]; but there are other busy towns worthy of note. *Allendale* lies near the lead mines, and has establishments for the smelting of that metal. *Alnmouth* has a considerable export of wool to the West Riding, and of corn to the metropolis. *Blythe* has ship-building yards for small vessels. *North Shields* has a great trade in coal, and a very active shipping commerce, by which it is becoming every year a place of more and more importance. All along the Tyne, but especially from Newcastle to the German Ocean, the number of manufacturing establishments is very great. Besides the enormous shipment of coals, there are very extensive chemical and alkali works, soap works, lead and shot works, white and red lead works, potteries, plate and window glass works, oil mills, starch mills, &c.

NOTTINGHAMSHIRE. This county, as noticed in a former article [COAL] contains a portion of one of the midland coal-fields. It contains also a small supply of gypsum, building stone, and paving stone; but the county can hardly be deemed rich in minerals. There are many hop plantations in the county, which in some years give a good profit to the grower. There are excellent market gardens in the neighbourhood of Newark, Nottingham, and other towns, the sandy soil being very favourable to the cultivation of roots and vegetables.

There are also some good orchards on the heavier soils.

In respect to manufactures, Nottinghamshire derives importance from being the centre of the cotton hosiery and bobbin-net trades. [HOSIERY MANUFACTURE; LACE MANUFACTURE]. Not only in the town of Nottingham itself, but in all the towns and villages in the southern half of the county, these manufactures are carried on. Nottingham itself is the focus of these trades, where the wholesale manufacturers and dealers reside. The bobbin net is mostly made in factories; but the hosiery is made at the houses of the operatives, with cotton yarn supplied by the manufacturers: the workpeople being paid so much per dozen pairs for their labour, out of which they for the most part have to pay a frame-rent for the machines.

In 1850 the county of Nottingham contained 19 cotton factories, 4 silk factories, and 1 worsted factory; these 24 factories employed about 2200 persons.

A School of Design has been established at Nottingham; and it is stated in the annual report of the Inspector of these schools for 1850, that the effect of the school in improving the taste of designers in the lace trade is becoming very evident. It will be gratifying if the Great Exhibition should verify this improvement.

NOYAU, or *Crême de Noyau*, is a favourite liqueur or cordial in France. It is formed of bitter almonds, proof spirits, coriander seed, lump sugar, cinnamon, ginger, and mace. One variety, called *Crême de Noyau de Martinique*, is said to consist of the following ingredients:—

Loaf sugar............	24 lbs.
Water.................	$2\frac{1}{2}$ gallons.
Proof spirit...........	5 gallons.
Orange-flower water....	3 pints.
Bitter almonds........	1 lb.
Essence of lemon......	2 drachms.

NUMBERING MACHINE. Different forms of apparatus for recording or marking numbers are described under CALCULATING MACHINES; REGISTERING MACHINES.

NUTMEGS. The two favourite spices of *nutmeg* and *mace* are derived from the same plant. This plant is the *Myristica Moschata*, a tree native of the Molucca Islands, especially of Banda, but cultivated in Java, Sumatra, and elsewhere in the East, and of late years in Guiana and several of the West India Islands; but the best are produced in the first-mentioned islands. The fruit is of the size and form of a peach, and when ripe the fleshy part separates into two nearly equal halves, exposing the kernel surrounded by an arillus, the former being the *nutmeg*, the latter the *mace*. The odour of the mace is strongly aromatic; the taste aromatic, but sharp and acrid. It contains both a fixed oil (in small quantity) and a volatile oil. One pound of mace yields by distillation one ounce of volatile oil. The fixed oil is not an article of European commerce, and what is termed the *expressed oil of mace* is obtained from the nutmeg, and should bear its name. An inferior mace is obtained from various species of *Myristica*. The properties of mace are similar to those of the nutmeg.

Two or three gatherings of the nutmegs are made in the year, generally in July, or August, in December, and in April. The third period yields the best nutmegs. The collected nuts are dried in the sun or by the heat of a moderate fire till the shells split; they are then sorted and dipped in lime-water, to preserve them from the attack of insects. Those of good quality should be heavy, each weighing on an average 90 grains.

The quantities of these spices imported in the last three years were as follow:—

	Mace.	Nutmegs.
1848	47,572 lbs.	336,420 lbs.
1849	45,986 „	234,021 „
1850	76,365 „	312,418 „

NUTS. A few words concerning the chief varieties of nuts are given under the proper names; and an instance of the large consumption of hazel nuts in London will be found under MARKET GARDENS. In respect to the commerce in nuts, the following were the quantities of the three best known kinds, imported in 1848:—

Hazel Nuts......	150,022 bushels.
Chestnuts.......	63,033 „
Walnuts.........	29,604 „

Of the quantities grown in England, there are no means of forming an estimate.

NUX VOMICA. This very powerful medicine is one among many products of the plant *Strychnos*. Among these products is *strychnia*, a vegetable alkali which exists in the plant combined with *strychnic acid*; it is colourless, inodorous, crystalline, unalterable by exposure to the air, and extremely bitter; it is extremely poisonous; one-eighth of a grain is sufficient to kill a dog, and a quarter of a grain produces a dangerous effect upon a man. The *strychnos* itself is a kind of *nightshade*, of which there are several species. The best known is *strychnos nux vomica*, or *poison nut*, or *ratsbane*. The wood of this plant is very hard and durable, and on that account is applied to many purposes by the natives on the coast of Coromandel and other places where it grows. The fruit is about the size of a St. Michael's orange, with a bitter astringent pulp, and containing from three to five seeds. The pulp may be eaten, but the seeds are poisonous and officinal. Another remarkable species is the *strychnos toxifera, Wooraly, Urari,* or poison plant of Guiana, a native of Guiana. It had long been suspected that the poison used by the American Indians for their arrows was a species of Strychnos, but such is the secrecy with which they gather the plant and prepare the poison, that all enquiries have been frustrated. Sir R. Schomburgk's long stay in Guiana has enabled him to decide this point: by bribing some of the natives, he induced them to guide him to a spot where their famous Urari flourished, and on arriving at the place, found it to be the species of Strychnos above described. In the preparation of the poison, the Urari is not the only ingredient, but forms about half of the bulk of the ingredient used.

As a medicinal agent, nux vomica possesses valuable qualities; but it is so extremely poisonous except in very minute doses, and much diluted, that its use is deemed dangerous except under great precautions.

O

OAK. The oak is perhaps the most celebrated and the most valuable of all timber trees; no others are applied to so many useful purposes. The timber is more durable than any other of extensive growth in Europe. It is hard, tough, tolerably flexible, strong without being too heavy, not easily splintered, and not readily penetrated by water. When the grain is twisted, no other timber is so well adapted for posts, piles, shingles, palings, laths, casks, and all articles exposed to the action of moisture may fittingly be made of oak. It is extensively employed for the spokes of wheels, and for all kinds of poles. The young tree yields slender rods, well calculated for hoops, walking sticks, and whip handles. Old specimens produce a very beautiful effect when carved, as is well shewn in many of our churches and ancient mansions. Of all other modes of application, however, *ship building* is that to which oak is most extensively devoted in this country, and in which it renders the most important services. During the height of the last maritime war, it was calculated that the ships of the Royal Navy existing at one time contained more than eleven hundred thousand loads of oak. Fifty acres of oak plantation are required to produce the timber for a 74-gun ship; and the consumption must therefore have been enormous during the war. Specimens of oak of magnificent dimensions are to be met with in some English mansions. At Dudley Castle is (or was) an oak table 75 feet long by 3 feet wide, formed of one plank of oak. At Goodrich Castle is a beam of oak 66 feet long by 2 feet square throughout its whole length. The mainmast of the Royal Sovereign, built in the reign of Charles I. was 99 feet long by 3 feet diameter at the lower end, and formed out of one piece of oak.

The *root* of the oak is applied to ornamental rather than useful purposes. Evelyn says that of the root of the oak were formerly made handles to daggers and knives, tobacco boxes, mathematical instruments, panels for pictures, and various minor articles. At the present day the root of oak is cut into veneers which, when polished, shew exceedingly beautiful veins and markings.

The leaves of oak, gathered green and dried, furnish in some places a winter fodder for sheep, goats, deer, &c. They are also used as a substitute for tanners' bark in hothouses, hotbeds, &c. Concerning the acorns of the oak, we have spoken elsewhere [ACORNS].

The *bark* of the oak is a valuable tanning ingredient, as noticed under BARK. The stripping of the bark is effected by women in the following way. The barkers are each furnished with a light short handled wooden mallet, sharpened at one edge like a wedge. With this edge an incision is made all along the bark; and cross-cuts are then made with an instrument called the barking-bill, so as to separate the bark into pieces two or three feet long. A shovel-shaped instrument is then thrust beneath the bark, so as to force it off in sheets or pieces. These pieces are carefully dried for two or three weeks, and piled in large stacks until sold to the tanner.

The substance called *nut-galls* is yielded by a species called the Gall Oak. The gall is a morbid excrescence, produced in it by the puncture of an insect. There are two kinds of gall nuts known in commerce; those which still contain the insect, and which are known under the names of *black* or *blue* galls; and those from which the insect has escaped, called white galls. Both are used extensively in dyeing; but the dark contain much more astringent matter than the white. The English oak yields galls, but not so valuable as those of the east. Most of them known in commerce are from Syria and Asia Minor.

OAKUM. When the various cables, stays, shrouds, ropes, &c., belonging to a ship have gone through their term of service, and are no longer strong enough to be used, they are cut up into pieces, and then pulled asunder, all the hempen threads being loosened and disentangled one from another. In this state the hempen threads are called *oakum*, which varies in quality according to the kind of rope from which it is produced. The old ropes of a ship are sold to dealers; and when picked into oakum they are again sold to ship-builders. The work of oakum-picking is a kind of forced employment in many prisons. The oakum is sold to the ship-builders in large bundles, and is then spun into loose threads. These threads are of a very primitive kind; a small bundle of fibres is rolled by the hand on a sloping board, till it assumes the form of a loose irregular kind of rope, from half an inch to an inch in thickness. These oakum ropes are used for driving into the crevices or seams in the outside of a ship, to prevent the entrance of sea-water. This process is called *caulking*, and is effected by the aid of a large mallet or hammer and a caulking chisel; by which a dense layer of oakum is forced into the crevice—afterwards to be well tarred.

OATS. The great use of oats, and the ease with which they are raised on almost every kind of soil, from the heaviest loam to the lightest sand, have made them occupy a place in almost every rotation of crops. The best oats are raised in Scotland and in Friesland, and in both countries the land is carefully cultivated. In Scotland, oats are generally sown on a grass layer which has been in that state for some years, and sometimes on old pastures, which are broken up for the purpose. A heavy loam is best suited for oats: they require a certain degree of moisture, and a deep soil is very favourable to their growth. On poor moist land oats are more profitable than barley. Clover and grass seeds may be sown among them with equal advantage, as they will seldom grow so high as to be laid and smother the young clover; and barley is very apt to fail on land subject to retain the water. Six bushels of oats are often sown on an acre; but if they are drilled, four bushels are sufficient, and when dibbled, which is sometimes the case in Norfolk and Suffolk, much less seed is used. The produce of an acre of oats varies according to the soil and preparation, from four to eight and even ten quarters.

In respect to the use of oats, they are given in some countries to horses in the straw without thrashing them; and where the quantity can be regulated the practice is good. The horses masticate the corn better in the chaff, and the straw is wholesome; but where horses do hard work, they would be too long in eating a sufficient quantity, and it is better to give them oats thrashed and cleaned, with clover hay cut into chaff. It is estimated that a pound of good oats gives as much nourishment to a horse as two pounds of the best clover, or sainfoin hay. A truss of hay of 56 pounds is therefore equal to 28 pounds of oats; or a bushel of the best oats will go as far as one truss and a half of hay; and if this quantity is worth four shillings, which is at the rate of 4*l*. 16*s*. per load of thirty-six trusses, the equivalent price of oats is 32*s*. per quarter.

The oats and oatmeal imported in 1849 amounted to 1,292,707 quarters, at an average price of 17*s*. 6*d*. per quarter. The imports were almost entirely from Northern Europe—Russia, Sweden, Norway, Denmark, Prussia, Hanover, and Holland. The quantity imported in 1850 was rather less than that in 1849.

OBELISK. An obelisk is a lofty monumental four-sided shaft diminishing upwards with the sides gently inclined, but not so as to terminate in an apex at the top. Small obelisks were sometimes of sandstone or granite, but the larger Egyptian obelisks are all of the red granite of Syene; and it is certainly astonishing how such enormous masses of that material could be quarried out and afterwards removed and placed in their position. When the Romans became masters of Egypt, they removed many of these monuments to their own capital, among others that now known as the Obelisk of the Lateran. This is the largest obelisk now known, its shaft being 105 feet (although it has been reduced, a portion at the lower part having been cut off in consequence of being fractured), and two of its sides 9 feet 8½ inches, the other two 9 feet; it weighs about 445 tons. In the present century, the labour of bringing away and re-erecting an obelisk nearly equal to some of the largest removed by the Romans has been accomplished by the French. The raising of this obelisk upon a granite platform prepared for it in the Place de la Concorde at Paris was a remarkable operation. An inclined plane leading from the river Seine up to a platform of rough masonry level with the top of the pedestal was formed, and the obelisk, having been placed on a kind of timber car or sledge, was dragged up by means of ropes and capstans. One edge of its base having been brought to the edge of the pedestal, it was reared perpendicularly by ropes and pulleys attached to the heads of ten masts, five on each side; and within about three hours the operations were completed.

The largest Egyptian obelisk hitherto brought over to England is that which was removed from the island of Philæ by Belzoni, and which is now erected at Kingston Hall, Dorsetshire. It is a monolith or single stone of red Egyptian granite, 22 feet 1 inch in length, and its larger end or base 2 feet 2 inches square, the other being 1 foot 5¾ inches.

OBOE, is a musical instrument blown through a reed, like a clarionet. It is a tube of boxwood 22 inches in length, slender in the upper part, but spreads out conically at the lower end. It consists of three joints or pieces, besides the reed. Its compass is usually two octaves and a fifth, from C below the treble clef, to G, the fourth added line above it. The instrument, which has been in use since the time of Edward III., was long known only by its French name of *Hautbois.*

OBSIDIAN, is a mineral which occurs in beds, in large and rolled masses and in small grains. Its structure is compact, colour greenish or grayish, and before the blow-pipe it swells up strongly and fuses into a transparent glass. It occurs in veins and beds traversing rocks, and consists chiefly of silica and alumina.

OCHRE. This earthy substance is somewhat complex in its nature. It consists of silica and alumina, coloured by oxide of iron and occasionally by other oxides. It generally occurs in beds several feet in thickness, which overlie the oolite, and underlie sandstones and iron sands. The ochre obtains commercially the names of *yellow* and *brown*, according to its tint; and it is used by painters and colour makers. It is prepared for use by grinding and washing. The yellow ochre may be reddened in tint by calcination. Native red ochre is called *red chalk;* it is more strongly impregnated with oxide of iron than either of the others. At Shotover Hill, near Oxford, there is an ochre bed, about six inches in thickness, at a depth of twenty feet below the surface. *Armenian bole*, obtained in a few places in Greece and Italy, is a kind of ochre; the pigment called *terra di Sienna* is obtained from it.

About 7184 cwts. of ochre were imported from France in 1847.

ODESSA, is one of the most famous commercial cities of the Russian empire. It is on the borders of the Black Sea; and in the year 1817 it was declared a free port for thirty years. Though not situated at the mouth of any great river, Odessa, in consequence of its excellent harbour and convenient situation, is the emporium where the surplus produce of southern Russia is collected for exportation, and where foreign products required for the interior are imported. The products brought down the Dniester, the Bug, and the Dnieper, are all exported from Odessa; but because of the difficulties of the river navigation, a vast quantity of the corn brought to the town from the neighbouring provinces is conveyed on carts drawn by oxen. The trade of Odessa extends to all parts of the Mediterranean and western Europe. The chief exports are—corn, tallow, linseed, wool, iron, hides, copper, wax, caviar, potash, beef, furs, cordage, sail-cloth, tar, butter, isinglass, &c. The imports consist of coffee, sugar, and other colonial products; cotton, silk, and woollen goods; oil, wine, brandy, spices, dyestuffs, tobacco, fruits, raw cotton, tin, cutlery, timber, &c. In ordinary years about 800 foreign ships enter and leave the harbour; the value of the imports is close upon a million sterling, that of the exports is nearly two millions annually. The trade of Odessa has increased greatly within the last few years—a circumstance which is no doubt in a great measure, but not altogether, owing to the failure of the crops in western Europe, and the consequent demand for foreign supplies. In the first six months of 1847, 709 foreign ships arrived with imports worth 893,917*l.*; and 734 sailed with 1,056,493 quarters of corn, and a total value of exports amounting to 2,716,969*l.* The exports are usually more important during the last six months of the year. The privileges of a free harbour are continued to Odessa till 1854, by an imperial ukase issued in 1849; this freedom of the port has an immense influence on the nature and extent of the trade. Odessa has considerable breweries, distilleries, and manufactories of woollens, silks, tobacco, soap, and candles.

OHIO. A few industrial statistics of this rapidly rising state will be found under UNITED STATES.

OIL COLOURS. The colours used by house-painters are chiefly mineral or vegetable; seldom of animal origin. They are purchased from the colour merchants, mostly in the state of powder or of crystal; and after being ground as fine as possible, are mixed to the requisite degree of liquidity with turpentine and linseed oil. Other liquids besides these are occasionally employed; but the two here named constitute the principal.

The oil colours for artists comprise a more extensive range than those used by house-painters, and are prepared with more care. Such colours are sometimes prepared in the form of *cakes*. To prepare these cakes, the colours are ground with oil of turpentine, in which has been dissolved about one-sixth of its weight of powdered mastic. The mixture is left to dry, and is then exposed to the action of a slow charcoal fire until the mixture is softened. It is then made into a paste by the addition of a warm solution of spermaceti dissolved in half its weight of poppy oil. The whole mass is worked up together until it is stiff enough to be pressed into cake-moulds. When used by artists, the cakes are ground up with oil of turpentine and poppy or some other oil. The oil colours which are sold in bottles or bladders are prepared to a certain stage like the cake colours, but they are thinned with pale drying oil before being put in the cases.

The principal colouring substances employed by painters are described under their proper headings. See also COLOURS.

OIL MILL. The extraction of oil from seeds—such as linseed, hempseed, rapeseed, &c.—requires considerable pressure. The mode of obtaining linseed oil from lin or flax seed includes many singular processes.

When the flax plants have grown to that stage which imparts to the seed the greatest amount of oleaginous quality, they are pulled, and partially dried in the air; and the capsules which contain the seed are stripped off by a kind of comb called a ripple. The capsules are dried, thrashed, and winnowed, to separate the seeds from the husks or capsules. The seeds are exceedingly hard and smooth, and require one of two kinds of press to crush them; one the *wedge press*, and the other the *hydraulic press*. In the wedge press, a wedge is driven very forcibly between two bags of seed; and it is found that the oil is driven out of the seed by this process more readily than by the use of a mill-stone. But in modern oil mills the hydraulic press is gradually superseding the wedge press. In preparing the seed for the hydraulic press, the following is the routine of processes. The seed is bruised by two crushing-rollers, so placed side by side that the seed, introduced between them from a hopper at the top, becomes crushed by the rotation, and falls into a chest beneath. The seeds are further ground or crushed by ordinary edge-stones, and assume the state of an oily pulp. The pulp is heated, and put into oblong flannel bags. These bags are flattened slightly by the hand, and piled one on another in cast-iron cases, which are placed in the hydraulic presses. The presses are then worked, and the oil speedily begins to ooze from the pulp through the bags. When as much oil has been obtained as will flow by these means, the press is loosened, the bags removed, and the pressed cake of pulp taken out of each bag; and this cake is ground, re-heated, re-bagged, and re-pressed, to yield more oil. The refuse pulp now forms valuable manure, and commands a good price as *oil-cake*. What is called *cold-drawn* linseed oil is obtained by pressing the seed immediately after it has been crushed, without any intermediate heating; it is obtained in small quantity, but of very fine quality. Flax-seed varies from 48 to 52 lbs. per bushel, or about 400lbs. per quarter; the seed yields 13 to 19 gallons (98lbs. to 122lbs.) of oil per quarter, the average being about 16 gallons.

No other kind of vegetable oil requires so heavy a pressure as that procured from flax and similar seeds. In Italy and other northern countries where *olives* grow abundantly, the produce is crushed beneath an edge-mill-stone, and then pressed, to force out the oil, in a screw-press. *Oil of almonds* is procured by shaking the almond kernels in bags, so as to separate the brown skins, and then grinding and pressing them. *Palm oil* is procured from the fruit of many species of palm, which the Africans collect into a heap, and steep in hot water, by which the oil is liberated and made to swim on the surface of the water, from which it is afterwards removed. *Nut oil* is procured from walnuts and hazel-nuts, which in the south of Europe contain sufficient oil to be worth the process of pressing.

OILS. These useful substances are obtained from very different sources and under various circumstances. First, animal fats are to be regarded as varieties of oil. There are also animal oils more properly so called, as *whale* and *spermaceti* oil. Secondly, there are the oils of vegetable origin, as those of *olives* and *linseed*, obtained by pressure, and called fat, fixed, or expressed oils, and those procured by distillation, termed volatile, essential, or ætherial oils. Thirdly, there are various oils produced by heat from animal, mineral, and other bodies, such as *Dippel's oil* and *naphtha*. Lastly, there are certain oils produced by chemical action, as *oil of wine*, &c. Most fats and expressed oils consist of *olein*, by some chemists called *margarin* and *stearin*.

Animal Oils.—One of the best known and most extensively used of these is common whale or train oil, obtained by melting the blubber of the animal. As met with in commerce it is of a brownish colour, rather viscid, and has a disagreeable fishy smell and taste. Like other oils, it is very combustible, and it is largely employed for the purpose of giving light. *Spermaceti Oil* is obtained from an oily matter lodged in a bony cavity of the head of the Spermaceti Whale. When this substance is subjected to pressure in bags, a quantity of pure limpid oil is expressed; and the residue after being melted, strained, and boiled with a weak solution of potash, is well known by the name of *spermaceti*. The other animal oils are of less importance.

Fluid Oils.—The *Vegetable Expressed Oils* vary in their properties. *Olive Oil* is yellowish, the odour and taste but slight. *Linseed Oil* is expressed from the seeds of the common flax. When no heat is employed in the pressing, it is more viscid and has a greenish-yellow colour; it is then called in commerce *cold drawn* linseed oil. Its smell and taste are stronger and more disagreeable than those of olive oil. Linseed oil is largely employed in oil painting and in varnish-making. *Almond Oil* is of a light yellowish colour, more fluid than olive or linseed oil; its odour and taste are very slight. It is employed sometimes in soap making, and also in medicine. *Castor Oil* is the expressed oil of the seeds of the *Ricinus communis*. When expressed without the assistance of heat, it is transparent and nearly colourless. It is very considerably viscid, and becomes solid when exposed to about 0° Fah.

Solid Oils.—One of the chief of these is *Cocoa Nut Oil.* It is white, has a slight pleasant smell, and its taste is rather agreeable; it melts at 122° Fahr., and of late years it has been employed in soap making. *Palm Oil* is of the consistence of butter, and of on orange yellow colour; its smell is agreeable. It melts at about 103° Fahr.

Volatile or *Essential Oils.*—These oils are fluid at the usual temperature, and with few exceptions are obtained by distillation. Essential oils are distinguished principally from the expressed oils by the following properties:—Usually they are more perfectly fluid, more combustible, have an aromatic or fragrant odour, and an acrid taste; they are volatile *per se* without decomposition, and may be distilled with water at 212°, although their boiling-point is much higher. In some instances the volatile oils are obtained by pressure, without the application of heat: this is the case with the oils of lemons, oranges, and bergamot. In general however they are procurable only by distillation, and this is effected by putting the herb or bark into a still with water, when the oil and water are volatilized and condensed together. Like the fixed oils they appear to contain a harder and a softer principle; the former has been called *stearopten*, the latter *eleopten*. The most important oils of this class are those of *Turpentine*, *Lemons*, *Marjoram*, *Cinnamon*, *Cloves*, and *Almonds*.

Both volatile and fixed oils are very extensively diffused through vegetables; the former in almost every part of a plant except the cotyledons of the seed, and the latter in the seeds chiefly, but also in their fleshy covering as in the olive, some palms, and other plants. Some families of plants abound especially in fixed oil. Among the *Cruciferæ* are mustard seed, rape seed, and colza seed oils, with other species especially cultivated in Europe, India, and Japan, of which some have of late years been imported into this country. Several of the family of *Compositæ* secrete oil in quantities large enough to render it desirable to cultivate them for this purpose alone, as the Sun Flower and Jerusalem Artichoke; also some species of *Carthamus* or Bastard Saffron, and also the *Verbesina sativa* of India. *Madia sativa* yields Madi Oil, and its seeds are said to contain more oil than any plant introduced into Europe. Most of the *Cucurbitaceæ* also, as the melon, gourd, cucumber, and the numerous varieties, cultivated especially in India, contain a large proportion of oil, which is expressed in the east as it formerly was in Europe. The *Rosaceæ* also store up a large proportion of oil in the kernels of their fruit, as in the almond, the apricot, as well as the Briançon apricot, and other species of *Prunus*. In the Himalayas oil is also expressed from the apricot kernel, and has been sent to this country, of a fine quality. Among the *Amentaceæ* several species yield oil of good quality, and in sufficient quantity to repay the expense of expression, as hazel-nut oil, beech-nut oil, and walnut oil. Besides these poppy oil, Ben-nut oil (*Hyperanthera*), ground-nut oil (*Arachis*), physic-nut oil (*Jatropha*), are well-known. The cotton seed yields oil, and also the seeds of the tea plant, especially of the species called *Thea oleifera*, and some of the Camellias.

The imports of the principal oils and of oil cake for the last two years have amounted to the following quantities:—

	1849.	1850.
Whale Oil . .	20,001 tuns.	21,328
Olive Oil . . .	16,964 „	20,783
Palm Oil . . .	493,331 cwts.	448,580
Cocoa Nut Oil .	64,452 „	98,040
Oil Cake . . .	59,462 tons.	65,055

The linseed, hempseed, and rapeseed oil exported in 1850 amounted to 3,292,206 gallons.

OINTMENTS. In their mechanical preparation, ointments differ slightly in consistency; some being very stiff, while others are softer in substance. They are mixed and used in the same manner as cerates, but are of different consistence; in this respect cerates occupy a middle place between plasters and ointments. [CERATES.] Ointments have in general the consistence of good butter in an average temperature. The active ingredient which gives name to the ointment is sometimes a powder, sometimes a liquid; if the former, it is usually mixed with lard; if the latter, it is mixed with suet and lard, with occasionally a little wax. Ointments may be preserved from rancidity by adding to them a little gum-benzoin or benjamin.

OLEIN, or ELAIN, is one of the two constituents of most fats and expressed oils: the other being *Stearin*. Olein has scarcely any taste or smell when procured from oils which possess these properties only in a slight degree. It solidifies at 27° Fahr., and crystallises in needles. On account of the very low temperature at which olein congeals, it is well adapted for lubricating the wheels of watches, and its value in this respect is enhanced by its not readily becoming rancid by the action of the air.

The very pure olein or liquid oil used by watchmakers is thus prepared. Almond or olive oil is mixed with eight parts its weight of proof spirit, and heated nearly to boiling; it is then agitated, allowed to settle, and the clear upper stratum decanted off; it is cooled, filtered, and all the spirit driven off by distillation. Oil so prepared will not thicken or freeze at any ordinary temperatures, and is thus well fitted for the delicate work of the watchmaker. Oil prepared in this way has sometimes been sold so high as 1*s*. 6*d*. per drachm. Watchmakers' oil of a cheaper kind is prepared by placing a clean strip of lead in a small white glass bottle filled with olive oil, and exposing it to the sun's rays for some time; the action between the lead and the oil, aided by the solar rays, throws down a curdy matter, and leaves the rest of the oil limpid and colourless.

OLIBANUM. It appears that the gum resin called *Olibanum* is the *frankincense* that was used by the ancients in their religious ceremonies. The Greeks obtained their frankincense from Arabia. The Arabians call olibanum both *Lubân* and *Cundur;* but, as benzoin is most used at the present day for religious purposes, the Mohammedan writers of India on materia medica apply only the term *Cundur* to olibanum. This *Cundur* has been ascertained by Messrs. Colebrooke, Hunter, and Roxburgh to be the *Boswellia thurifera*, as botanists call it, a large timber-tree found in the mountainous parts of India, yielding a most fragrant resin from wounds made in the bark. From this Roxburgh distinguishes, as a different species, *Boswellia glabra*, a plant also yielding a resin which is used for incense, and as pitch in some parts of India. A substance analogous to olibanum, and used in a similar way in various parts of the world, is procured from several different trees. Olibanum occurs in commerce of two kinds, the Arabian and East Indian: the former kind is now seldom met with; the latter is obtained from the *Boswellia thurifera*. There are two varieties of it. Olibanum is now seldom used in medicine; it is principally employed as incense in Roman Catholic churches.

OLIVES; OLIVE OIL. In most plants which yield fixed oil, the oil is obtained from the seed; but in the olive it is yielded by the pericarp. Olive trees sometimes attain a great age. There is one near Nice, the lower part of the trunk of which measures 38 feet in circumference.

The oil which is expressed from the ripe fruit immediately after being gathered is most esteemed, and is called *virgin oil.* When the oil is extracted by a stronger pressure, or by the aid of heat or of slight fermentation, it forms the common *olive oil,* the properties of which vary in proportion to the mode adopted. An oil of still inferior quality is obtained when the husk of the olive, after the former treatment, is boiled in water; this inferior oil is used in making soap. Virgin oil is a very pale yellow, limpid, and inodorous; common olive oil is darker, thicker, and less pure in smell. Olive oil is frequently adulterated with rape oil, a cheaper product.

Olive oil is used by watchmakers; by the manufacturers of soap; as a substitute for whale oil in lamps; as a salad oil; and to form cerates and plasters in medicine. A few additional details concerning olive oil will be found under OILS.

OMNIBUS AND CAB. The street travelling of London is one of the most remarkable commercial features of our age. It would be impossible to estimate the value of the *time* saved (and consequently *money* saved), by the use of these vehicles; but there can be no question that it is enormous.

In respect to *coaches* or *cabs*, the changes have been remarkable. A few years ago every vehicle on a coach stand was drawn by two horses: there is now not such a thing to be seen (we here speak of the Metropolis). Hackney coaches first began to ply in 1625; their number had increased to 200 in 1652, to 400 in 1661, to 800 in the beginning of the following century. This number has gradually increased to about 3000. In 1813 a

KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 31.

lighter kind of vehicle, drawn by one horse, was brought into use in Paris. In 1823 licences were obtained in London for eight *cabriolets*, which were started at fares one-third lower than those of hackney coaches; the 'vested interest' of the old hackney coachmen was made the groundwork of a strenuous opposition; but the convenience of the new vehicles gradually bore down all difficulties. A limit was made to the number of each kind until the year 1832, when all restriction was removed, and any one could obtain a licence (under proper regulations), by paying for it.

It is curious to mark the gradual improvements in cabs, or cabriolets, as the system established itself. They were at first hooded chaises, in which a liveried driver sat on the same seat with the person who had hired the cab. Then came an alteration by which two persons could be accommodated; the driver having a little seat fitted for him at the right hand of the body of the vehicle. Next came the boxed-up vehicle, which presented the appearance of a slice off an omnibus; it was on two wheels, with a door at the back. After a few minor changes, the four-wheeled cab presented itself, and has ever since remained the type of the class generally; it is well built, and will contain four persons. Lastly came the dashing *Hansom's* patent; a two-wheeled vehicle, very low, opening in the front, having a seat for the driver behind the top, and having large wheels, which enable it to rattle on at a great speed.

It is believed that the returns which a cab brings to its proprietor average about half a guinea a day, besides that portion which goes to the driver for his wages. Many attempts have been made to provide means for testing the honesty of the drivers by some mechanical arrangement connected with the vehicle; either a sort of tell-tale, to shew how often persons have entered or left the vehicle, or how many miles the wheels have rotated; but hitherto nothing of this kind has been found available. A company is, we believe, in process of formation, for constructing cabs which shall admit of equitable arrangements for the proprietors, the drivers, and the public; there is to be some kind of passenger-index, which will afford means for determining the distance run.

The *Omnibus* system is still more remarkable than that of cabs. It is only about twenty or twenty-five years ago that one stage coach, and one only, ran from Paddington to the Bank. All the villages round London had in like manner their small array of slow coaches. In 1829 Mr. Shillibeer introduced the omnibus, a Parisian invention, in London, under an amount of opposition which nearly ruined the projector, while he was benefiting the public. His first omnibus ran from Charing Cross to Greenwich, and was drawn by three horses abreast; but the number two was soon adopted; and the stage-coach proprietors, unable to beat the omnibuses off the road, adopted them, and the system became firmly established. It was soon found that an omnibus, with its easy means of entrance and exit, is a very convenient vehicle in the public streets, where passengers enter and alight at various points along the route; and hence omnibuses have effected what the old stage coaches never did or could effect, viz., the establishment of cheap routes through all the principal commercial arteries of London. The fares became gradually settled at sixpence per passenger for any distance in and near London; but the last few years have witnessed a reduction to 3*d.* (recently 4*d.*), in respect to short distances.

The principle of competition has led to an instructive result in respect to metropolitan omnibuses. When each proprietor had only a few vehicles, he opposed, and was opposed by, his neighbours on all sides; and a scene of recklessness ensued which endangered the lives and limbs of passengers as well as pedestrians. But this has given way to large combinations or associations, in which each proprietor brings his contribution of vehicles and horses to the common stock, and agrees to obey certain rules laid down for the guidance of all. The result has been admirable. With a few exceptions here and there, the omnibus system is now conducted with a regularity, a precision, a civility, and a safety, which was never before equalled. Through the main avenues of London, especially the New Road, Holborn, and the Strand, omnibuses proceed every two or three minutes throughout the day. There have lately been omnibus maps published, in which there appears a surprising number of routes. There are at least two Associations or Companies, each of which possesses a hundred omnibuses, with considerably more than a thousand horses to work them. It has been found by experience, that to buy good horses, and to treat them well, is a more economical practice than the opposite system. Most of the horses employed in the Paddington and City trade (we believe about three thousand in number), make but one journey each a day in each direction.

Mr. Pownall has lately invented a *passenger-index* for omnibuses. It consists of an electric battery placed in the bottom framing of the vehicle, near the door. Every passenger on entering the omnibus steps upon an elastic spring, which acts upon the battery, and this in its turn acts upon an index or dial. At the end of a day's work, the machinery of the dial will shew how many times persons have entered and left the vehicle. Such is the theory of the apparatus; but there seem at first sight to be many difficulties in the way of its practical use. A new kind of omnibus has also been recently started, in which each passenger has a separate and distinct seat, and in which there are increased facilities for ascending to the roof of the vehicle.

ONYX. [AGATE.]

OOLITE is the characteristic rock of one of the great systems of secondary strata. The fine yellow *freestone* of Kettering, the *Bath freestone*, and the *Portland stone* are good examples of oolite; and these serve to illustrate the economic uses of the strata.

OPACITY is a condition of bodies by which they are incapable of transmitting light through them. According to Newton, it may arise from the unequal densities of the particles of certain substances, in consequence of which the rays of light on entering those substances suffer such refractions and reflexions as cause them to be finally absorbed. The scientific determination of this question, however, does not concern us here. As a circumstance of relative opacity or transparency, the quality of manufactured goods is often affected by it.

OPAL. Of this mineral, which is essentially a hydrate of silica, there are nearly a dozen varieties, named *Precious Opal*, *Fire Opal*, *Hydrophane*, *Common Opal*, *Semi-Opal*, *Wood Opal*, *Cacholong*, *Opal Jasper*, *Menilite*, *Hyalite* or *Muller's Glass*, and *Geyserite*. The varieties differ greatly in colour and transparency. The *Precious Opal* exhibits a beautiful play of colours.

OPHICLEIDE. This powerful musical instrument is made of brass or copper, and is intended to supersede the *Serpent*—of which it is a decided improvement—in the orchestra and in military bands. It is a conical tube, the longest nearly nine feet in length, terminating in a bell, like the horn. It has ten ventages, or holes, all of which are stopped by keys, similar to those of the bassoon, only of larger dimensions, and is furnished with the same kind of mouth-piece as the Serpent. The scale of the base Ophicleide is from B, the third space below the base staff, to C, the fifth added space above it, including every tone and semitone within this compass of three octaves and one note. The volume of sound it emits is immense, but the tone is rich and round, and blends well with the voices in choruses.

OPISOMETER. This name has been given to a recently-invented apparatus by Mr. Elliott, for measuring the length of roads, rivers, walls, &c., on maps and plans. There is a horizontal steel axle, which is cut with a screw-worm from end to end. On this is placed a wheel, which works along the screw like a nut. The axle is fixed to a convenient handle for holding. When a map or plan is laid down flat on a table, and a road or river is to be measured, the wheel is made to traverse carefully over the whole length of the tortuous line, following the windings as carefully as may be. This movement causes the wheel to shift its position on the screw; if it be at one end of the axle when the movement begins, it will have advanced a certain distance towards the other end by the time it is finished. If the wheel be now applied to a scale of miles or yards, or any other units on the map, and made to rotate in a *reverse* direction until it is brought back to its original position on the axial screw, it will determine the length of the road or river. The principle is strictly correct, and requires nothing but careful application.

OPIUM. This remarkable substance, which has had so much influence both on the commerce and the wars between England and China, is yielded by one species of plants of the genus *Papaver*. Of the 25 species of this genus, the *papaver somniferum*, or *white poppy*, which produces opium, is the most important. It is a native probably of Asia Minor, but, having been so long cultivated, it is found wild in many parts of Europe. There are two varieties of this species, both of which yield opium. The juice of the poppy seems to have been used on account of its narcotic powers from a very early period, first in the East, of which it is a native, and afterwards in the West.

The mode of collecting the opium in Asia Minor, is by puncturing the green capsule, and allowing the juice to exude, which is then scraped off, and deposited in small earthen vessels, and beat up with saliva. It is afterwards enveloped in dry leaves, and in this state is sold. In India the juice is mixed with oil obtained from the seed of the poppy, to hinder the rapid drying of the juice. The produce of the first incisions is of a light yellow colour; the others are fainter in odour and darker coloured. In general all three gatherings are mixed together, and sent to market in small baskets. The quantity obtained varies not only with the soil and mode of cultivation, but also with the season and the time of collecting. In wet, gloomy seasons, not only is the quantity less, but it does not keep well; in such a case the proportion of *morphia*, the active principle of the opium, is also less. The quantity of morphia depends likewise very much on the time of gathering; if the harvest be postponed till the capsules begin to turn white and hard, it is greatly deficient; and by the time the capsules are mature and the seeds ripe, it has entirely disappeared. It is not, as in the case of many of the vegetable alkaloids, transferred to the seeds, as they are altogether devoid of any narcotic principle, the oil which is obtained from them being bland and wholesome, and abundantly used as food.

The varieties of opium met with in commerce are—*Smyrna* or *Levant* opium; *Constantinople* opium; *Egyptian* or *Alexandrian* opium; *Trebizond* or *Persian* opium; *Indian* opium; and *English* opium. The chemical or organic constituents are extremely numerous, the most important being morphia. Good opium is not perfectly soluble in water; $\frac{1}{12}$th generally remains undissolved, consisting of the caoutchouc and resin. Constantinople opium however leaves no residuum of caoutchouc. It is very inflammable, and burns with a clear flame, and forms a transparent alcoholic solution: opium from the bruised capsules is not inflammable, and forms a turbid alcoholic solution.

The poppy is cultivated in many parts of Europe on account of its seeds, which yield a bland oil much esteemed in France. In England it is cultivated chiefly for the capsules, which are used medicinally. In India the cultivation takes place in the cold weather, that is, during the winter of Europe. The collecting of the opium is commenced very soon after the flowers fall, as the capsules rapidly enlarge.

It forms no part of our object here to trace the extraordinary effects of opium on the human system, nor the modes of preparation by which opium is converted into a valuable medicine. As an article of international commerce, there can be no question that opium caused the late war between England and China, however it might be disguised by other circumstances. India produces large quantities of opium, which the Chinese are willing to purchase for eating or smoking, or both; but the Chinese Government has never willingly sanctioned the purchase, and has often strictly prohibited it. By about the year 1831 the purchase of opium had become so large, that the sale of *tea* was insufficient to pay for it, and Chinese silver had to be paid to settle the balance. The Chinese authorities commenced a series of petty insults towards the English merchants at Canton, with a view to expel them altogether, if possible; and these insults gradually brought the attention of the British Government to that quarter. So matters continued for some years; the merchants persisted in bringing opium, which the Chinese people were ready to buy; the Emperor effected all he could to prevent the import; and the British Consul tried to hold the balance even between all parties. At length, in May 1839, the European factors were expelled from Canton, and all the opium in the ports, amounting to 20,283 chests, was seized by the Chinese authorities and destroyed. This gave rise to a war which lasted, on and off, for three years. The Chinese Emperor was compelled to pay the value of the opium destroyed.—There is a *moral* aspect in this opium war, which can never be quite satisfactory.

The consumption of opium in this country is comparatively small. The imports in the last three years were as follow:—

1848	200,019 lbs.
1849	105,724 ,,
1850	126,318 ,,

And of these quantities, about two-thirds were re-exported to other countries.

OPORTO. The principal trade of this Portuguese city is in port wine, which takes its distinctive name from the town. Oil, sumach, lemons, oranges, wool, refined sugar, cream of tartar, salt, leather, cork, &c., are also exported. The imports are—corn, rice, beef, woollen, cotton, iron, and hardware manufactures; salt fish, hemp, and flax; sugar, coffee, deals, &c. There are at Oporto some manufactories of hats, silks, linen stuffs, and pottery, besides ropewalks and dockyards, none of which however are in a thriving condition. The wine and brandy trade is a monopoly of the Oporto Wine Company. The export of wine is from 30,000 to 35,000 pipes annually; of this quantity four-fifths go to England. The customs duties of Oporto for the year ending June 30, 1849, amounted to 1,891,347 dollars.

OPTICAL INSTRUMENTS. Optics, as a science, forms no part of the subject of this volume. The chief among those delicate instruments, by which the science is brought within the range of practical operations, are briefly noticed under their proper headings [Camera Lucida; Kaleidoscope; Lens; Magic Lantern, Microscope; Telescope; &c.] It is believed that one of the happy consequences of the removal of the duty on glass will be to enable manufacturers to produce glass better fitted than before for optical purposes; not that the amount of duty is of much importance in an expensive lens, but that the manufacturer was deterred from making experiments by the interference of the Excise with his freedom of operations.

ORANGES, LEMONS, CITRONS. There are several beautiful fruits belonging to the genus *Citrus*. Among these are the *sweet orange*, the *bitter orange*, the *lime*, the *shaddock*, the *lemon*, and the *citron;* and these again are divided into many varieties. Of the sweet orange there are the *China*, the *pear-shaped*, the *Nice*, the *blood-red*, the *ribbed*, the *sweet-skinned*, the *Mandarin*, the *St. Michael*, and several other kinds. Of the bitter orange there are also many kinds: such as the *horned*, the *curled leaf*, the *purple*, the *double flowered*, the *Seville*, and the *Bizarre* orange. The *China* orange is the common sort of our English markets, and of the Portuguese. The *sweet-skinned* orange is the *Pomme d' Adam*, or *forbidden fruit*, of the Paris shops. The *Mandarin* orange, in which the ripe pulp is completely loosened from the rind, is much cultivated in China and in Malta. The *St. Michael's* orange has small, round, pale yellow, seedless fruit, with a thin rind and an extremely sweet pulp. This, when in a state of perfection, is perhaps the most delicious of all the oranges, and it is by far the most productive. Great quantities are imported from the Azores, where it appears to be exclusively cultivated as an object of trade. It is said that 20,000 of these oranges have been picked from a single tree, exclusively of the large quantity which were blown down or rejected as unfit for sale. The *Seville* orange has an exceedingly bitter rind; in England it is employed in the manufacture of bitter tinctures, and in the preparation of candied orange peel; the bitter aromatic principle gives flavour to the liqueur called *Curaçoa*. The *bergamot* orange has a remarkable fragrance, and is employed in making an essence of delicious quality.

The *lime* has different varieties, according to the thickness of the rind; it is employed chiefly in flavouring punch, sherbet, and other drinks. The *shaddock* is among the largest fruits which are known, and is commonly cultivated both in the East and West Indies, for the sake of the delicate subacid juicy pulp in which it abounds. When shaddocks arrive at their greatest size they are called *pompoleons*, or *pompelmousses*. When at the smallest, they form the *forbidden fruit* of the English markets. Another small variety, with the shaddocks growing in clusters, forms a larger tree than any other citrus; the fruit is about as large as the fist; it is what the West Indians call the *grape-fruit*. The *lemon* does not present many varieties; its appearance and use are well known. The *citron*, grown chiefly in the east, is noticeable for the fragrance of the rind, from which a delicate sweetmeat is prepared.

Of the invaluable use of lemon juice or lime juice in the navy, due to the citric acid contained in the fruit, a little has been said under Citric Acid. In a commercial point of view, the orange trade has greatly benefitted by the introduction of steam-boats and railways. Oranges are brought in large quantities to Southampton, whence they are transmitted very quickly to London. During the last three years (1848, 1849, 1850) about 400,000 boxes or chests of oranges and lemons have been annually imported into this country.

ORCHARD. Apples, pears, and cherries are the fruits principally cultivated in orchards. The term orchard is likewise used to signify inclosures in which filberts or walnuts are grown. Orchards of apples and pears are more numerous, because more productive, on the old and new red sandstone formations than on any other strata. A very large proportion of all the cider and perry that is manufactured is grown upon these soils. The principal orchards of England are in Devonshire, Somersetshire, Gloucestershire, Herefordshire, and Worcestershire. For an orchard of apple-trees, a deep unctuous soil is selected, in a situation sheltered from the north and north-west winds, and open to the south and south-east; and a bank is preferable to a low spot. For pear orchards a lighter soil is desirable than for apples; the same rules may be observed for their planting and preservation. The principal cherry-orchards in England are in Buckinghamshire and Kent; from the latter county a large supply is sent to the London markets.

ORCHIL, or ORCHELLA, also written *Archil*, is the name of a dye as well as of the plant (one of the tribe of Lichens, or Rock-moss) which yields it. [Archil.] It is often corrupted in commerce into *Rochilla Weed*. Several kinds are employed for the same purpose, which are distinguished according to the country from whence they are imported, and also by manufacturers into *Weed* and *Moss*, the former name being applied to the filiform lichens of botanists belonging to the genus *Roccella*, while the terms Moss and Rock-Moss are applied to the crustaceous lichens belonging to the genus *Lecanora*, which include the *Cudbear* and *Parelle* of dyers. *Dyers' Roccella*, or *Orchil*, and *Flat-Leaved Orchil*, are both found on maritime rocks, as well on the coast of England as of other parts of Europe, and also of Asia, Africa, and America. They are also found on dry stone walls exposed to the influence of the sea-breeze. The more arid the situation the better is the quality of the lichens. The presence of the colouring matter is ascertained by steeping the weed broken up in small pieces in diluted solution of ammonia, in a bottle half filled with liquid, which should be kept corked, but frequently opened in a temperature not exceeding 150° Fahrenheit.

ORDNANCE. All great guns used in war, such as cannons, carronades, howitzers, and mortars, are called by the general name of *ordnance*. The materials of which ordnance is formed are iron and brass, properly bronze, the latter metal being composed of copper and tin, in the proportion of from 8 to 12 parts of tin to 100 parts of copper. Iron guns are stronger than those made of brass, and consequently they are better able to resist the effects of the long-continued firing which takes place at the sieges of fortresses. Brass guns, on the other hand, being lighter, are more conveniently transported from place to place with troops in the field. Ordnance is now cast either in loam or in dry sand; a model, or pattern, of the gun being made of wood or brass, about which the mould is formed. In twelve hours after being cast the mould may be removed and the gun may be bored. Iron guns are cast from pig-metal of different qualities, which are melted together in order to produce a composition possessing only that degree of hardness which will permit the boring to be effected. Ordnance formed of cast-iron and of gun-metal being apt to run at the vent in consequence of the heat produced by rapid firing, the vent in guns of cast-iron is drilled in a bolt of wrought-iron, and in those of gun-metal in a bolt of pure copper; the bolts are then screwed into the pieces for which they were intended.

The length of a cannon is divided into six parts:—That which is behind the base ring (the ring of greatest diameter) at the larger end is called the *cascable;* and from the base ring to the next mouldings towards the smaller end, is the *vent-field.* The two succeeding portions, separated from one another by a moulding, are called the first and second *reinforce;* and near the extremity of the latter are situated the *trunnions,* two cylinders at right angles to the axis of the gun, and by which it rests on its carriage. From the second reinforce moulding to another near the smaller extremity of the gun is the *chase,* and the last portion is called the *muzzle.* The hollow of the gun is called the *bore,* and the diameter of the bore is designated the *calibre* of the piece. It has of late been found practicable to diminish considerably the quantity of metal in iron guns; and for this purpose some of the ordnance then existing was *reamed-up* (scraped out), so as to bring each kind of gun to the next highest calibre. Thus the old iron 6-pounders have been converted into 9-pounders, 18-pounders into 24-pounders, and so on. The application of locks to naval ordnance was introduced by Sir Charles Douglas, and their efficiency has since been fully recognised. A lock carrying two flints, invented by Lieut.-Gen. Sir Howard Douglas, in 1818, was afterwards introduced, and percussion locks are now much used in the British service.

The following are the lengths and weights of different kinds of iron and brass ordnance, known by particular names :—

Iron Ordnance.	Length. ft.	in.	Weight. cwt.
13-inch mortar, sea-service	3	0½	36½
10-inch do. land-service	2	4	16½
8-inch do. do.	1	10½	8¾
5½-inch do. do.	1	3	2½
4⅖-inch do. do.	1	0¾	1½
10-inch howitzer do.	5	0	41
8-inch do. do.	4	9	21
Monk's 56-pr. gun do.	11	0	97
Millar's 10-inch gun do.	9	4	84
8-inch gun, sea-service	9	0	65
32-pr. gun, land-service	9	6	56
24-pr. do. do.	9	6	48
18-pr. do. do.	9	0	42
12-pr. do. do.	9	0	34
32-pr. carronade, sea-service	4	0	17
24-pr. do. do.	3	7	13
18-pr. do. do.	3	4	10
12-pr. do. do.	2	8	6¾
Brass Ordnance.			
9-pr. gun, land-service	8	6	13½
6-pr. do. do.	5	0	6
3-pr. do. mountain-service	3	0	2½

The *carriages* for ordnance are of several kinds, according to the nature of the gun or the manner in which it is employed. Field *gun-carriages* consist of two cheeks, or side pieces, of elm, firmly attached together by transoms, and resting on the axle-tree of the wheels; the trail, consisting of a solid piece of oak, is firmly attached at one end to the side pieces, near the axle, and its other extremity rests on the ground when the gun is in a state for action. The limber is a bed, with shafts, mounted on two wheels, and carrying two ammunition boxes for the service of the gun; the horses are harnessed to the limber, and the gun with its carriage is drawn after the limber. An ammunition waggon also accompanies each piece of ordnance, and there are others always in reserve. Field *howitzer-carriages* and their limbers are similar to those just mentioned, but stronger, and the cheeks of the carriage are farther asunder. The travelling carriages for *siege-ordnance* are made wholly of oak, and the limber carries no ammunition. Carriages for *garrison service* and for the *navy* consist of two short cheeks or brackets, connected by transoms, and they move on four truck-wheels. *Mortars* are placed upon solid beds of wood or iron, which are made as heavy as is consistent with the power of transporting them from place to place, for the sake of obtaining steadiness when the piece is fired.

OREGRUND IRON. A little information concerning the valuable oregrund or Swedish iron will be found under STEEL MANUFACTURE.

ORES. The ores of the principal metals, and the processes whereby the extraction of the valuable constituent is managed, are described under the names of the metals themselves. [COPPER, IRON, LEAD, MERCURY, &c.]

ORGAN. This is incontestibly the noblest of musical instruments, whether considered in regard to the grandeur and beauty of its sounds, the variety of its powers, or the sacred purposes to which it is usually dedicated. It consists of a vast number of metallic and wooden pipes, divided into different *stops*, the wind being admitted into the pipes from a bellows. It is played on by means of a keyboard.

It must have been early discovered that air may be forced into a closed cavity, and then distributed at will into one or more tubes; and pursuing the contrivance a little further, something like a modern organ was likely to be produced. That an instrument similar in principle, though not in details, to the modern organ, was known in very early times, there is abundant evidence to show. The period when the organ was introduced into the churches of Western Europe is very uncertain. Pope Vitalian is supposed to have been the first to admit the instrument, about the year 670; but the earliest account, to be at all relied on, of the introduction of this instrument in the West is, that about the year 755 the Greek emperor Copronymus sent one as a present to Pepin, King of France. In the time of Charlemagne however organs became common in Europe. Before the 10th century they were not only common in England, but of large size. They were however very rude in construction, and extremely limited in means. The keys were four or five inches broad, and must have been struck by the clenched hand, in the manner of the carrilons: the pipes were of brass, harsh in sound, and the compass did not exceed a dozen or fifteen notes in the 12th century; and to accompany the plain-chant no more were required. About that time half notes were introduced at Venice, where also the important addition of pedals or foot-keys, was made in 1470.

Most of the early English organs were destroyed by the Puritans. The tone of the pipes of the old builders—depending on what is technically called the *voicing*—has never been excelled by later makers; but in point of *touch*, and mechanism generally, the moderns are much superior to their predecessors. In mechanical skill and delicate finishing the English organ-builders far surpass their continental rivals, while in tone they at least equal them.

The following are some of the largest foreign organs:—

	Stops.	Pipes.
Seville cathedral........	100	5330
Goerlitz, in Upper Lusatia	82	3270
Hamburg, St. Michael's..	67	
Amsterdam, the old church	64	
Weingarten, in Suabia...	60	6666
Rotterdam (150 feet high)		5500
Tours cathedral	60	
Haarlem...............	60	5000

Among the principal organs in England are those of York Minster, Birmingham Town-hall, St. Paul's Cathedral, Westminster Abbey, Exeter Hall, Christ's Hospital, and Mr. Willis's noble organ at the Great Exhibition. See also APOLLONICON.

The mechanism of the organ is complicated. The *principle* of it is—that when the finger of the player presses down a key, or the foot presses down a pedal, a valve opens the lower end of a pipe or pipes, into which air rushes from a chamber wherein it has been condensed by bellows. The length and form of each pipe are so arranged that it may yield a certain definite note. Each *stop* is a particular set of pipes, differing in pitch, but all having the same character of sound. Some stops imitate the flute sound, some the trumpet sound, and so on. It is the combination of many stops with many octaves of notes that gives rise to the large number of pipes in an organ.

The *barrel-organ* is an instrument by which most of the effects of a small keyed-organ are produced by certain machinery. Instead of keys for the fingers, the keys, if so they may be called, are inside the organ, and acted on by means of a cylinder, or barrel, *pinned*, or studded, in a particular and singularly curious manner. This barrel is made to revolve by a winch, and in those of an expensive kind by wheel-work, moved by a spring.

Under AUTOPHON, it is stated that Mr. Dawson's ingenious contrivance called by that name is an appendage to the barrel organ; whereas it should have mentioned that the autophon is the complete instrument itself.

It is a self-acting organ, in which a handle regulates—not the motion of a barrel with pins on its surface—but the admission of air through holes in a perforated card. It will play as many tunes as there are cards provided, without limit; and as the cards are sold at 6*d.* each, a player with no more skill than is required to turn a handle regularly can play a range of music, either sacred or secular, to which there is (or need be) no assignable limit.

The organ builders of England and the Continent justly think that the present is a fitting opportunity for showing the power of the noblest of instruments in the noblest of exhibition rooms. The east and west ends of the Palace of Industry each contains one of the finest specimens of modern organ-building—the one English and the other foreign; while the north and south transepts have organs of somewhat smaller dimensions.

ORIEL. This term is applied to that particular kind of bay-window which is made to project from the upper story of a building. The distinction therefore between a *bay* and an *oriel* is this: by the former is understood a projecting window, or rather a projection pierced with window openings in its entire width, and rising immediately from the ground, whether it be confined to the lower part of the building or carried up through one or more stories above the ground-floor; whereas an oriel is a bay which does not descend to the ground, but is suspended over the face of the wall beneath it. Bays generally terminate in either a plain or embattled parapet; but oriels are for the most part made to show some sort of roof, either rising behind or resting upon the mouldings which serve as their cornice. Occasionally this roof or crown is rendered an ornamental part of the design, and terminated by some kind of finish.

ORLÉANS is one of the old manufacturing towns of France. The chief manufactures are—hosiery for exportation to the Levant, refined sugar, vinegar, bleached wax, blankets, and counterpanes. To these articles of manufacture must be added cotton and woollen yarn, fine woollen cloths, flannels, hats, files, rasps, and other tools, glue, leather, tin ware, and earthenware. There are numerous breweries and dyehouses. Trade is carried on in the above articles, and in wine, brandy, corn, flour, wool, hides, iron, salt, hoops, dye-stuffs, saffron, fire-wood, timber, oak planks, coals, groceries, and spices. Its situation on the Loire, which is navigated by small steamers, and communicates with the Seine by means of canals, and on the railway, to which the lines connecting Bourdeaux, Nantes, and the centre and South of France with Paris converge,—renders Orléans the centre of a very considerable commerce and of a large transit trade.

ORPIMENT is a yellow *sulphuret of arsenic.* The finest specimens come from Persia, in brilliant yellow masses, of a lamellar structure. Artificial orpiment is manufactured in Saxony by subliming a mixture of sulphur and white arsenic; it is a yellow compact opaque mass, of a glassy aspect: it affords a pale yellow powder. The finest kind of orpiment is prepared into a yellow pigment for artists, while the coarser varieties are used as a colouring substance for house-painting and other purposes.

ORRERY. This name has been applied to four different kinds of machines for representing the phenomena of the solar system. A *planetarium* exhibits the orbital motion of the planets about the sun; a *tellurian* and *lunarian*, when combined, exhibit, respectively, the motion of the earth about the sun, and of the moon about the earth; and a *satellite machine* exhibits the motion of Jupiter's satellites about their primary. Planetary machines were in use at a very remote period, and appear to have consisted for many centuries of moveable spheres having the earth in their centre. In the 17th century Huyghens and Roemer employed themselves in the construction of planetary machines in conformity with the Copernican doctrine. Roemer also invented a satellite machine prior to the year 1679. In England, about the year 1700, Mr. George Graham constructed a machine which exhibited the motion of the earth about the sun, while the moon revolved about the earth; one of these machines was made for the Earl of Orrery, from which circumstance the term Orrery originated. A large planetarium was, in 1801, made for the Royal Institution of London, and a more complete instrument was constructed by Dr. Pearson in 1813.

To produce the revolution of the planetary bodies about the sun, a system of vertical concentric tubes is usually employed, which are adjusted very near to each other, but yet so far removed as not to influence each other's motion. These tubes are of different lengths, the innermost being the longest, and to the superior extremity of each a radius or projecting wire is attached, and thereby made to revolve once during each revolution of the tube. The lower extremities of the tubes form the arbors or axes of as many toothed-wheels, which are either immediately driven by pinions adjusted to a verticle axle called the "annual arbor," or derive their motions indirectly from those pinions by means of an interposed train of wheels. The determination of the relative number of teeth which must be given to the wheels and pinions, in order to produce the required motion, depends upon the relative velocities of the motion to be imitated; and here the machinist must depend upon the astronomer. As an aid to astronomical studies, orreries are less highly estimated than they formerly were.

OSIER is the name given to various species of *Salix* or *Willow*, employed in basket-making on account of their tough flexible shoots. [BASKET-MAKING; WILLOW.]

OSMAZOME. This name has been given to a spirituous extract of meat. According to the experiments of Chevreul, osmazome contains a peculiar substance, to which he has given the name of *créatin;* but the chemistry of this subject is yet very little known.

O'SMIUM. This metal was discovered by Mr. Tennant, in the year 1803, in the grains of native platinum. It is white, with a bluish gray tint. It may be reduced to leaves. Its specific gravity is 10. It is unalterable in the air at common temperatures, but if strongly heated it oxidizes. This very peculiar metal forms several compounds with oxygen, chlorine, and sulphur; but none of them are of much importance.

OSTRICH FEATHERS. There are many uses which this noble bird renders to man, in the hot countries which the ostrich inhabits. The flesh when young is good and palatable. The eggs are considered a great delicacy, especially when eaten with butter. In the luxurious suppers of the wealthy Romans, in the time of the Emperors, the brains of Ostriches formed a favourite dish.

But it is for the feathers that these birds are chiefly valued. [FEATHERS]. The Africans who hunt the ostrich for the sake of the feathers proceed systematically to their work. They hunt on horseback, and begin the pursuit by a gentle gallop; for should they, at the outset, be rashly eager, the ostrich would start off at such a speed as would carry him wholly beyond reach of his hunter; but when the pace is more steady, the ostrich makes no particular effort to escape. It does not go in a direct line, but wavers from one side to the other; and this enables the hunter to save distance. The chase often continues several days, at the end of which time the strength of the ostrich becomes exhausted, and he yields. The feathers on which value is placed are chiefly those of the tail; and the hunters are careful not to disfigure these in the process of capture.

OTTER SKINS, are employed, but only to a small extent, in this country; or rather they are imported by the Hudson's Bay Company, and re-exported to the Continent. About 15,000 were so imported in 1848.

OVENS. The general character of ovens will be found sufficiently explained under BREAD, FURNACE, and STOVES.

OXALIC ACID. This acid was discovered by Scheele, in 1776, in the *Wood Sorrel*, *Common Sorrel*, and other plants. The crystals of oxalic acid are prismatic, colourless, and transparent; the primary form is a right rhombic prism. The taste is extremely sour; and the crystals are very poisonous. Oxalic acid is the most highly oxygenated of all the vegetable acids, and is also the most rapid and certainly fatal of any which are capable of being crystallised. As the crystals are not unlike those of the Sulphate of Magnesia, or Epsom Salts, mistakes between the two are of very frequent occurrence. Being likewise much used in the arts, and commonly known by the name of *Acid of Sugar*, it is taken either accidentally, or under the supposition that it is akin to sugar, and therefore pleasant and innocent. This acid, and the salts obtained by its combination with bases, are employed to a limited extent in the arts.

OXFORDSHIRE. This county may be reckoned amongst the most productive agricultural counties of England; and some of the land is of a quality which can scarcely be surpassed anywhere. The red land is partly in old grass, in which state it is very valuable, and partly cultivated as arable land. The low lands in the valleys through which the rivers flow are in many places covered with the finest herbage, and maintain much cattle. The course of crops on the light loams is based on the Norfolk rotation, but generally with the addition of an extra crop or two after the wheat, such as beans and oats. The cultivation of sainfoin on the chalky loams is one of the great resources of the farmers on such soils, and is much appreciated in this county. The meadows in this county which lie along the banks of the rivers are productive of excellent herbage; and the hay of some of the upland meadows cannot be surpassed.

Oxfordshire is not a manufacturing county. In the city of *Oxford* itself, such manufactures alone are carried on as are indispensable to the daily wants of a somewhat wealthy and luxurious city. *Burford* has diminished in wealth and importance from the decay of the coarse woollen manufacture and the malting business, which once flourished there, and from the diminished traffic along the line of road which passes through the town. At *Witney* wool-stapling is extensively carried on, and there is a considerable malt trade. The manufacture of blankets—for which the place has been long celebrated—still continues to flourish. At *Woodstock* the only manufacture is that of gloves, which, though it has declined of late years, is still carried on to a considerable extent.

OXYGEN. The properties of this most remarkable elementary body are best known in its elastic or aëriform state, in which it is termed *Oxygen Gas*. The discovery of this important substance was made by Dr. Priestley in 1774, and somewhat later independently by Scheele. To this gas Dr. Priestley gave the name of *dephlogisticated air*, Scheele called it *empyreal air*, and Condorcet *vital air*. Lavoisier gave it the name of *oxygen*, which it still retains. Dr. Priestley first procured this gaseous body by heating the binoxide of mercury in an air-jar over mercury, by means of a lens, and he afterwards obtained it from other substances. It is now prepared in various ways, according to the purposes to which it is intended to be applied.

Oxygen possesses great power of combination with other elementary bodies, there being scarcely one with which it is not known to combine either by direct union or indirect chemical action. The compounds to which it gives rise by combining, for example, with certain metals, and also indeed with some other bodies, may be classed under the three heads of *Oxides*, *Acids*, and *Alkalies*. There are many bodies which, by a moderate degree of oxidation, become first oxides, and by an increased degree, acids; such substances are charcoal, phosphorus, chromium, &c.

Oxygen Gas is devoid of colour, taste, or smell. It is transparent and invisible. It possesses the mechanical properties of common air. It is capable of being respired, and a given volume of it will support life much longer than an equal bulk of common air. It is heavier than atmospheric air, 100 cubic inches at a medium temperature and pressnre weighing 34·4 grains, whereas an equal volume of atmospheric air weighs 31 grains. It is but slightly soluble in water, requiring about 27 times its bulk for solution. Light has no effect upon this gas. By heat, like all gaseous bodies, it is merely expanded. The most remarkable property of oxygen gas is the facility and splendour with which bodies, when previously ignited, burn in it; substances which do not undergo combustion in the air, will readily do so, and with great brilliancy, in oxygen gas. Iron, for example, burns very readily in it when previously made red-hot.

Until after the discovery of oxygen nothing was or could be known respecting the nature of the air, of water, or of earth, all of which, formerly reckoned as elementary bodies, are now known to be compound, and to contain oxygen as one of their constituents. It has also thrown great and unexpected light on the nature of combustion and respiration.

The principal compounds which oxygen forms with metals and other elementary bodies, are briefly treated under their respective heads. To notice the useful purposes subserved in the arts by oxygen is neither necessary nor possible; since it takes part, in some way or other, with every combination and every process.

OYSTER TRADE. The management of the oyster fishery presents many peculiar features. The best kind of oysters in this country are the small variety called *Natives;* they are found in the rivers Colne, Medway, and Swale; or rather, they are really French oysters, the produce of the coast of Normandy, whence the spat or spawn is gathered, and laid down on the oyster beds in the Essex and Kent rivers. The spawn, when first cast, somewhat resembles in appearance a drop of suet; it is composed of an immense number of minute oysters, each of which becomes about a quarter of an inch long in three days, as large as a shilling in three months, as a half crown in six months, and as a crown in twelve months. The oyster is found in the seas of most countries, but never at any great depth, and seldom far from the mouth of a river. The fishing for oysters is permitted from the first of September to the end of April.

So far as regards the London supply, the oysters are brought principally from the Essex coast and rivers; but the Milton oysters are most highly esteemed. None are sent from the north of England; but broods are sent from thence to be fattened in Kent and Sussex. The sale at Billingsgate is enormous; it is estimated to average, in ordinary years, about 300,000 bushels, of 4 pecks to a bushel, and 400 oysters to a peck; amounting to nearly five hundred million oysters. A remarkable feature is now being developed in the oyster trade. At Southampton there is a wide margin of muddy shore at low water. A Company has leased part of this shore as an oyster bed. Oysters are brought from the Jersey fishery, laid down on those beds to fatten, turned and attended to every day, taken up when wanted, opened, placed in tin cans, and sent up to London by railway. These oysters are used for pickles and sauces, and not eaten in the ordinary way. A tramway extends from the South-Western Railway to the oyster beach, so that the dispatch of the oysters is very rapidly managed. An electro-telegraphic message can be sent at any hour, and a supply of filled oyster-cans transmitted to London with a rapidity which sets all former doings at defiance. The oysters are sent without their shells, to save freight; there is a corps of oyster-openers in the service of the company.

The opening of an oyster, like many other simple operations, has been brought within the scope of machinery. M. Picault, of Paris, invented an oyster-opener in 1849. It consists of an apparatus something like an ordinary pair of sugar nippers; but pointed together at the top of the curved part instead of the bottom. One of the curved parts is made hollow, or indented, to receive the front edge of the oyster, which is placed therein with the flat shell uppermost; while the other part is fitted with a curved knife, which, when the handles are brought together, enters the hinge of the shells, separates them, and, severs the oyster from the flat shell, which then falls into the deep one. One of the sides may be made a fixture, supported on a standard, if deemed necessary.

P

PACKING. It is worthy of note, as it illustrates the immensity of the manufacturing operations in Lancashire and the West Riding (especially the former), that the trade of a packer is one for which there is constant demand, and which is conducted on a large scale. The packing of bales of goods for the London and provincial markets, and for shipment to foreign parts, requires great skill, to enclose the greatest mass in the smallest space, and to enable the bale to bear any ordinary amount of rough usage without yielding. The cases or wrappers are of strong canvas, and the bands for binding are often strips of hoop-iron instead of rope. The case, the bands, and the goods are placed in their proper position upon or within a peculiarly shaped hydraulic press; and when the mass has been brought by intense pressure into a cubical form, the fastenings are secured before the pressure is removed. In the earlier stages of this system, the hydraulic presses were worked by hand; but on such a scale of magnitude are the operations of the Manchester packers now conducted, that this is too slow a method; steam-power is applied. There are perhaps few operations conducted in our manufacturing districts more illustrative of economy of power, than this employment of hydraulic presses to supersede the old screw presses; and the working of the hydraulic presses by steam instead of manual power.

PADLOCK. [Locks and Keys.]

PADUA, is one of those rich provinces, the produce and industry of which are briefly noticed under Lombardy.

PAGODA is a name applied by Europeans to temples in the East, from China to Hindustan. These structures generally consist of a porch, a vestibule or ante-sanctuary for the priests, and an inner sanctuary, containing the principal idol. Some of the Chinese pagodas are elevated upon a terrace, and consist of two stories, the lowermost surrounded by a peristyle of columns. Others are lofty towers in several stories, diminishing in height and width as they ascend. The Hindoo pagodas are of a pyramidal form.

PAINTING. As a question of high art, of genius, of expression, or even as a means of copying the every day scenes of nature, painting is beyond the province of this volume. And as a mechanical operation we have very little to say concerning it. The preparation of the canvas and the panels is simple; and the management of the colours and the brushes is superior only in degree, not in nature, to that of mere house-painting. A few words are said concerning different kinds of painting, in respect to technical differences, under Enamels, Encaustic, Fresco, and Miniatures; while the chief working materials are adverted to under Brush, Colours, Crayons, Oil Colours, Pencils, and the names of the chief colouring substances.

In respect to *house-painting*, it is executed either in *oil* or *distemper*. In *oil* the principal tools employed are brushes, made of hogs' bristles for large surfaces, and sash tools made of finer hair for small work, as mouldings, window-bars, &c. White lead is used for white colour; it is also the basis of all ordinary colours. The colouring substances in general use are earths, umber, ochre, Siena, Venetian red, purple, brown, &c. The first three are sometimes burnt, a process which reddens and darkens them. Metallic compounds are red lead, vermillion, Prussian blue, chrome yellow, verdigris, Brunswick green, verditer, &c., &c. Animal and vegetable colours are lakes, indigo, ivory black, and lamp-black. The liquids in use are linseed oil (sometimes boiled with litharge to render it drying, and hence called *boiled oil*), and oil or spirits of turpentine, called *turps*. These are combined for use in various proportions, according to circumstances: when the paint is required to bear a gloss, or is intended for outside work, most oil is used; and for black, chocolate colour, green, &c., outside, boiled oil alone, or with a very little turps, is best. For *flatting*, which has no gloss, turps alone is requisite. To all paint a little sugar of lead, or litharge, is added to make it dry quickly.

In painting in *distemper*, the brushes for large surfaces differ from those used in oil: they are wider and flatter, and are termed distemper-brushes; but the tools for small work are similar. Whiting takes the same place in this branch that white lead holds in oil; the colouring substances are similar, but ground in water, and the fluids are water and melted size.

PAISLEY, though far from being a handsome town, ranks the third in Scotland in respect to population and commercial importance, solely on account of its manufactures. In 1707 the principal articles made in the town were coarse linen, chequered cloths, and Bengals, to which succeeded chequered linen handkerchiefs, and goods of a lighter texture, such as lawns. About 1725 the machinery for making white sewing or ounce thread was introduced from Holland. About 1760 the manufacture of silk gauze was introduced upon the plan practised by the Spitalfields houses, and, during the greater part of the following 30 years, was carried on upon a very extensive scale. The reduction in the cost of cotton goods, consequent upon the invention of Arkwright's spinning machinery, lessened the demand for silken fabrics, the manufacture of which at Paisley has since then greatly declined.

Many of the principal establishments of Paisley are now exclusively engaged in the various branches of the cotton manufacture, among which the muslin branch may be particularly mentioned as that of which Paisley is regarded as the chief seat. A considerable portion of the yarn used in making the finer qualities of muslins is imported from Lancashire. Crape dresses and damask and embroidered shawls are also manufactured to a great extent. There are also brass and iron foundries, breweries, distilleries, bleach-fields, &c.

In the report of the School of Design for 1850 it is stated that the branch school at Paisley is gradually shewing beneficial results in the muslin and shawl departments. In the patterns for embroidered muslins a more correct and graceful style of drawing is visible in those executed by pupils of the school.

A few details concerning the shawl trade of Paisley, now one of the most important—perhaps *the* most important—in the town, will be found under SHAWL MANUFACTURE.

PALANQUIN is a kind of covered litter carried, by means of poles, upon the shoulders of men, which forms the principal vehical for personal transport in Hindustan.

The system of *dâk* travelling in India is by means of palanquins. The palanquin bearers are provided by the government postmasters. When Bishop Heber was travelling from Calcutta to Benares he hired a set of palanquin bearers, twelve in number; his clothes and writing-desk were placed in two wicker boxes, which one man carried slung on a bamboo across his shoulders. So cheap is human labour in India, that the bishop paid only twelve shillings for the services of the twelve men for each stage, a distance of eight or ten miles. Only four men put their shoulders to a palanquin at a time; but the services of the others are often required on the wretched roads of India.

PALIMPSEST MANUSCRIPTS illustrate in a remarkable way the money value of paper and printing, as shewn by the want of them in past times. Palimpsest manuscripts are manuscripts from which the original writing has been erased or washed out, and which have been then written on again. This practice is as old as the time of Cicero, as appears from a letter of his to Trebatius in which he praises his friend for having been so economical as to write on a palimpsest, but says that he should like to know what those writings could have been which were considered of less importance than a letter. The scarcity and expense of parchment, and the demand for the writings of the fathers and books of devotion in the middle ages, frequently induced the monks to erase or wash out the writings of the classical authors to make room for those of the fathers. In many cases however they did not obliterate entirely the ancient writing; aud a careful examination of some of these palimpsest MSS. has led to the discovery of valuable works and fragments of the classical authors; among the rest one of the works of Cicero.

PALLA'DIUM. This metal was discovered by the late Dr. Wollaston in the grains of native platinum, in the year 1803. Palladium is of a grayish white colour; it is very malleable, and slightly elastic. It is almost as difficult of fusion as platinum, and does not oxidize by exposure to the air.

This metal forms alloys, most of which are brittle, with arsenic, iron, bismuth, lead, tin, copper, silver, platinum and gold; the alloy with nickel is ductile. Palladium, when fused with six parts of gold, destroys its colour; and this alloy was proposed by Dr. Wollaston for the graduated part of the mural circle of the Greenwich Observatory. Palladium combines with most of the simple substances; and its oxide forms salts with acids; but only a few of these compounds have become practically useful.

PALMS: PALM OIL. There is scarcely a species of palm in which some useful property is not found. The cocoa-nut, the date, and others are valued for their fruit; the fan-palm and many more, for their foliage, whose hardness and durability render it an excellent material for thatching; the sweet juice of the palmyra when fermented yields wine; the centre of the sago-palm abounds in nutritive starch; the trunk of the *Iriartea* or *Ceroxylon* exudes a valuable vegetable wax; oil is expressed in abundance from the oil-palm; an astringent matter resembling dragon's blood is produced by *Calamus Draco;* many of the species contain within their leaves a kind of fibrous matter, so hard and tough that it is manufactured into cordage; and finally, their trunks are in some cases valued for their strength and used as timber, or for their elasticity, or their flexibility, as in the cane-palm.

Of these varied products, *palm-oil* is that, perhaps, which has of late acquired most commercial importance in this country. It is obtained from the oil-palm of Guinea, cultivated in the western part of Africa. The fruit of this tree is about the size of a pigeon's egg, with its outer fleshy covering of a golden yellow colour. The oil is obtained by bruising the fleshy part of the fruit and subjecting the bruised paste to boiling water in wooden mortars; an oil of an orange yellow colour separates, which cools to the consistence of butter, and has, when fresh, the smell of violets. Africans use this oil in cooking, and for anointing the body. When imported into England, palm-oil is used in soap making, candle making, perfumery and medicine. Although liquid in the warm climate of Africa, it is solid in our climate; and the mode adopted for extracting it from the casks is to place the cask over a trough with the bunghole downwards, and to pass a steam pipe into it, by which means the palm-oil is brought to a liquid state. The large imports of palm-oil are noticed under OILS.

PANAMA TRANSIT. One of the most interesting and important enquiries now in progress, concerning the formation of a highway of nations, is the choice of a route across the Isthmus of Panama from the Atlantic to the Pacific. This isthmus connects North with South America. Since the acquisition of portions of Oregon and California by the United States, it has become a matter of high importance to obtain easy access to those far distant regions. The only ship route is round Cape Horn; and this carries the traveller so far southward, that the distance is far more than double what it would be if a passage across the isthmus could be made. Washington and San Francisco are about in the same latitude; but in the ship-route from one to the other, the mariner has to go 95 degrees of latitude southward along the Atlantic, and then 95 degrees northward along the Pacific; whereas if the isthmus could be cut across near Panama, the southing and northing would each be less than 30 degrees. Whether from England, from New York, or from New Orleans, the saving of distance by the Panama route to Oregon and California would be enormous.

But it is not simply in relation to those two regions that the Panama route would become important. The wide spreading Pacific, with its islands and coasts, would be brought within easier reach of the Anglo-Saxon race. The Sandwich Islands, New Zealand, Borneo, Australia, China—all are becoming every year more commercially important; all would be nearer to the United States by the Panama route than any other; and some would be nearer to England than by the existing routes. The same West India Mail which now renders so much service would be available for the ocean mail of the Pacific.

The desirability of a Panama passage being conceded, it became a matter of importance to decide on the best mode of effecting it. In the long string of land which connects North with South America, there are three or four places where the land from ocean to ocean is less in distance than at any other points. The narrowest part is from Chagres to Panama, near South America; a little farther north is a spot where the Lake of Nicaragua occupies the middle of the isthmus, with a river flowing from it into the Atlantic; while still farther north, at Tehuantepec, a river which flows into the Atlantic springs from a point very near another river which flows into the Pacific. All these three have been proposed as sites for canal or railway communication. The Panama route is to have a railway; it was commenced in 1849, and is now in process of formation. The Tehuantepec route is also to have a railway; or rather, the Mexican government is endeavouring to foster a company having this object in view; but there are many reasons for doubting whether this will be carried out. Meanwhile the Nicaragua route is that in which most energy is being displayed. At the Atlantic mouth of the river St. Juan de Nicaragua is Greytown, held by the British as a sort of guardianship over the black King of Mosquito; from this steamers ascend to a certain point up the St. Juan; after which a short land passage brings the traveller to the Lake, whence two routes are marked out to the Pacific. Whether the engineering and commercial difficulties will ever permit a ship canal to be constructed, through which a laden vessel from England or the United States might pass across the isthmus, time alone can shew. Probabilities seem to be against such a supposition. If the Panama Railway be finished, with a tolerable harbour at each extremity, two sets of steamers, an Atlantic line and a Pacific line, would be formed, and there would be two shiftings of mails and luggage (a debarkation and an embarkation) at the isthmus. This great enterprise would be intended, in the first instance for mails and passengers: merchant cargoes will long continue to use the old ocean-routes.

PANORA'MA. This name is given to a picture showing a view completely around the spectator. This ingenious pictorial contrivance was first devised by an English artist, Robert Barker, about the year 1794; and is not so much a new mode of painting—the process itself being similar to scene-painting or in distemper — as a novel application of it. Contrary to the diorama [DIORAMA], the panorama forms the surface of a hollow cylinder or rotunda, in the centre of which is a detached circular platform for the spectators, covered overhead to conceal the skylight, and thereby increase the illusion and give greater effect to the painting itself. The view is not painted on the walls but upon canvas, like the scenes of a theatre, and afterwards fixed up, in order that the picture may be changed. The subjects generally chosen are views of cities, or interesting sites, whose entire locality and buildings may thus be vividly placed before the eye, in a manner no less instructive than interesting.

PANTHE'ON. This celebrated monument of Roman art consists of a rotunda with a noble Corinthian octastyle portico attached to it, and resembles in its general mass the Colosseum in the Regent's Park, London, except that the body of the latter building is a polygon of sixteen sides, and its portico (a Grecian Doric hexastyle) is only a single intercolumn in depth. After being robbed of its rich ornaments, gilded bronze-work, and statues, it was consecrated as a Christian church in the seventh century. It is by far the largest circular structure of ancient times, the external diameter being 188 feet, and the height of the summit of the upper cornice 102 feel, exclusive of the flat dome, which makes the entire height about 148 feet. The portico, 103 feet wide, is octastyle, but there are in all 16 columns. The columns are 47 English feet high, with bases and capitals of white marble, and granite shafts, each formed of a single piece. The interior diameter is 142 feet, the thickness of the wall being 23 feet through the piers, between the exhedræ or recesses, which, including that of the entrance, are eight in number. The dome has a circular opening in the centre, 23 feet in diameter, which lights the interior completely.

PANTOGRAPH, sometimes improperly written *Pentogragh*, is an instrument for copying maps, plans, and other drawings. It is formed of certain rules or bars jointed to each other, with tubes, in which may be fitted a tracer and a pencil. The copy may be made of the same size as the original or smaller, as one fourth, one half, or in any other proportion. There are different forms of the instrument.

PAPER HANGINGS. The word *Hangings* was originally and properly applied to the woven or embroidered tapestry with which the walls of apartments were covered. From the time necessary for their production, these were too costly for any classes but the wealthy. About 200 years ago, however, a mode was devised of printing or painting a pattern on sheets of paper, and pasting them against the walls of a room. These are Paper-Hangings, and they have greatly contributed to the comfort and cleanliness of domestic apartments.

There are three modes of producing the required device:—1. Wooden blocks are carved representing in relief the outlines of the figure; an impression is taken from these blocks, and the device is completed by painting with a pencil. 2. A sheet of paper, leather, tin, or copper, is cut out into the required device, and laid on the paper to be stained; a brush, dipped in a coloured pigment, and worked over the surface of the perforated plate, conveys the pigment through all the perforations, and forms a pattern on the paper. 3. A block is carved for each of the colours to be employed, and an impression from all the blocks in succession fills up the design on the paper. The first of these modes is too slow and costly for ordinary use; the second produces imperfect outlines, and is now chiefly employed, under the name of *Stencilling*, to paint a pattern on the plaster walls of a room, without using paper-hangings; the third is the mode almost exclusively employed at the present day. Each block is furnished with small pins at the corners, by the aid of which the successive impressions are made to correspond properly. As many as seven or eight colours are sometimes employed in one pattern, and, generally speaking, there must be as many blocks as there are colours.

Progress is, however, now being made towards the application of cylinder-printing to paper hangings. Hitherto these papers have not vied in beauty with block-prints; but some of the London houses have recently succeeded in producing beautiful specimens by the cylinder, in which six or eight colours are printed by one passage through the machine. A single machine is capable of printing in one hour 200 pieces of paper, each 12 yards long; or 18,000 yards per day. It serves to illustrate the advance both of paper making and of paper-staining, that the paper upon which the patterns are printed by cylinder is manufactured in lengths of 2880 feet; each length is, after printing, cut into 80 pieces of 12 yards long each.

A reduction of the duty charged on all kinds of paper has had a considerable effect in extending the use and improving the manufacture of paper-hangings.

PAPER MANUFACTURE. In early times the materials used for writing upon were chiefly such as only required some little mechanical fashioning to fit them for that purpose. Smooth flat stones, clay afterwards burnt, waxed boards, plates of iron or metal, leaves and bark, skins and intestines, papyrus, and parchment, were all employed. The art of making paper from fibrous matter reduced to a pulp in water appears to have been first discovered by the Chinese about the year 95 A.D. In the time of Confucius they wrote with a style, or bodkin, on the inner bark of the bamboo. The Chinese paper is made from the inner bark of the bamboo, but the Chinese also make paper from cotton and linen rags, and a coarse yellow sort for wrappers is made from rice straw.

In respect to the rise of this manufacture in England, a Mr. Tate is said to have had a paper-mill at Hertford early in the 16th century: and another mill is stated to have been established in 1588 at Dartford in Kent, by a German, who was knighted by Queen Elizabeth. Great improvements were introduced in the manufacture by Thomas Watson, in 1713; but it was not till recent times that the manufacture reached any high degree of excellence.

In the making of paper any fibrous vegetable substance may be used, such as bark, stalks, tendrils, hop-bine, and wheat-straw. Nothing however has yet been found to answer so well as linen, hempen, or cotton rags. The sweepings of the cotton-mills are also much used.

In all kinds of paper-making, whether from the bark of trees or other fibrous matter, or from rags, the general process is the same. The fibrous material is cut and bruised in water till it is separated into fine and short filaments, and becomes a sort of pulp. This pulp is taken up in a thin and even layer upon a mould of wire cloth, or something similar, which allows the water to drain off, but retains the fibrous matter, the filaments of which are, by the process of reduction to pulp and subsequent drying and pressing, so interwoven or felted together, that they cannot be separated without tearing, and thus form paper. The rags of our country do not constitute a fourth part of the quantity which we use in making paper: Italy and Germany furnish the principal supplies.

In every paper-mill the first business is to sort the rags and cut them into small pieces. This is done by women, each of whom is provided with a large knife to cut the rags. Threads and seams are carefully put by themselves: if ground with the cloth they would form specks in the paper. The rags, when cut, are thrown into five or six different compartments of a large chest, according to their qualities. Only the finest linen rags are used for the best writing paper, but cotton as well as linen rags are now used for printing-paper. Hempen rags are used for coarse paper, and old cordage and tarred ropes for brown wrapping papers.

The rags are now to be washed, which is done either with hot water in a fulling-mill, or they are subjected for some hours to the action of steam. The colour is taken out of them by a careful use of chlorine. The rags, after being washed, are subjected to the action of a revolving cylinder, the surface of which is furnished with a number of sharp teeth or cutters, which are so placed as to act against other cutters fixed beneath the cylinder. The rags are kept immersed in water, and subjected to the action of the cutters for several hours, till they are minutely divided and reduced to a thin pulp.

The pulp, or *stuff*, as it is technically called, is now ready to be made into paper, which is done either by hand or by machine. In the hand method, the stuff is put into a large vat, and is kept at a proper temperature either by a stove or steam-pipe, and the fibrous matter is held in suspension by stirring. The paper is made with a *mould* and *deckle*. The mould is a shallow square frame covered with wire-cloth, and a little larger than the sheet intended to be made upon it. The deckle is a very thin frame of wood which fits close upon the mould, and is required to retain the stuff on the mould, and to limit the size of the sheet. The dipper, or *vatman*, inclining the mould a little towards him, dips it into the vat with the deckle upon it, and lifts it up again horizontally. He shakes it to distribute the stuff equally, and the water drains through the wire. He lays the mould on the edge of the vat, and takes off the deckle, which he requires to apply to another mould. After remaining two or three seconds to drain the mould is taken by another workman, the *coucher*, who, having deposited the sheet of paper upon a piece of woollen cloth, returns the mould to the dipper, who in the meantime has made another sheet, which stands on the vat ready to be couched upon another felt spread over the former sheet. Thus they proceed till they have made a pile of sheets, called a *post*, consisting of six or eight quires. This post, with its felts, is placed in the *vat-press*, and subjected to a strong pressure to force out the superfluous water, and to give firmness and solidity to the paper. The pile is then removed from the vat-press, the felts taken out, and the sheets are pressed again by themselves. They are then taken from the press and hung up, five or six together, in the drying-room.

Writing-paper is dipped, five or six sheets together, into a tub of size, and afterwards pressed to force out the superfluity. It is then hung up again in the drying-room. Printing paper is sized in the stuff. Every sheet is now examined, imperfections removed, and bad sheets taken out. A large pile of paper is then made, and pressed with great force, to render the sheets quite flat and smooth. The pile is then taken down, sheet by sheet, and another made, by which new surfaces are brought in contact with each other, and the pile again pressed strongly. This operation, which is called *parting*, is done two or three times for the best papers. The paper is now counted into quires, folded, and packed up into reams.

Various wire-marks, or water-marks, as they are called, were formerly applied to paper to distinguish it. Hand-made paper is now commonly marked with the name of the maker, and the date of the year when it was made.

The paper making machine, invented by Fourdrinier, and improved by Dickinson and others, is a very beautiful combination of mechanism. The pulp is first made to flow from the vat upon a wire frame or sifter, which moves rapidly up and down so as to force the fine filaments of pulp through the wire whilst it retains any knots and lumps. The pulp then flows over a ledge in a regular and even stream, and is received upon an endless web of wire gauze, which presents a surface of five or six feet long. The wire web moves forward with a motion so regulated as to determine the thickness of the paper; at the same time a lateral motion is given to the wire web, which assists to spread the pulp evenly, and also to facilitate the separation of the water; by which means the pulp solidifies as it advances, and is at the same time prevented from flowing over the sides by straps which regulate the width of the paper. Before the thickened pulp leaves the wire web, it is pressed by a roller covered with felt, and is then taken up by an endless web of felt which forms an inclined plane; the web absorbs a further portion of the moisture. The pulp is now seized by a pair of rollers, between which it is pressed, and then it passes upon another inclined plane of felt, which conducts it to another pair of pressing rollers. The pulp is now paper, aud only requires to be made dry and smooth. To effect these objects the machinery conducts it over the polished surface of a large cylinder heated by steam ; from this cylinder it passes to a second, larger and hotter; and then to a third, which is still hotter than the second. After this it is subjected to the pressure of a woollen cloth, which confines it on one side while the cylinder smooths it on the other. It is then conducted by another roller to a reel, on which it is wound, perfectly dry and smooth, and ready to be cut into sheets for use. In two or three minutes the pulp, which is introduced upon the wire web at one extremity of the machine, is delivered at the other in the state of perfect paper. In many of the paper machines, a partial vacuum is produced under the endless wire web by means of large air-pumps or of revolving fans ; and the atmosphere is thus made to press upon the pulp, whereby the moisture is forced through the wire.

Machines for cutting paper into sheets of any required size have been invented, in many varieties: they are separate from the paper making machine, and are beautiful contrivances. One recently introduced by Messrs.

Metcalf, and called the Industrial Cutting Machine, has a sharp blade which works upon a horizontal table. One end of the blade is connected with a lever moved by wheel-work; and as the wheels revolve, the blade is brought down with a cutting action. The machine may be worked either by steam or by hand power; and it is calculated not only for paper makers, but for all trades in which papers or pasteboard have to be cut.

In respect to commercial and fiscal regulations, the paper trade is now deservedly attracting public attention, with a view to the removal of a duty which is found not only to be financially oppressive, but to be hurtful in a literary point of view. The publisher of the present work, and other publishers concerned in the issue of low-priced but carefully prepared publications, have shewn that a premium is paid to inferior literature, to 'literary garbage,' by the existing duty on paper; and that many well planned but not profitable works would have yielded a sufficient profit had not this duty exerted its repressing influence.

The quantity of paper charged with excise duty in the United Kingdom in the last three years was:—

1848	121,820,229 lbs.
1849	132,132,600 „
1850	141,032,474 „

The quantities exported to foreign countries were as follows:

1848	5,180,286 lbs.
1849	5,966,319 „
1850	7,764,534 „

In other words, our exports of paper amount to only four or five per cent of our manufacture.

PAPIER-MACHÉ, is the French term for a preparation of moistened paper, of which many articles are manufactured in England, France, and Germany. Two modes are adopted of making articles of this kind: 1, by glueing or pasting different thicknesses of paper together; 2, by mixing the substance of the paper into a pulp and pressing it into moulds. The first mode is adopted principally for those articles, such as trays, &c., in which a tolerably plain and flat surface is to be produced. Common millboard, such as forms the covers of books, may convey some idea of this sort of manufacture. Sheets of strong paper are glued together, and then so powerfully pressed that the different strata of paper become as one. Slight curvatures may be given to such pasteboard when damp by the use of presses and moulds. Papier-Maché properly so called, however is that which is pressed into moulds in the state of a pulp. This pulp is either paper-maker's pulp, or is more generally made of cuttings of coarse paper boiled in water, and beaten in a mortar till they assume the consistence of a paste, which is boiled in a solution of gum-arabic or of size, to give it tenacity. The moulds are carved in the usual way and the pulp poured into them, a counter-mould being employed to make the cast nothing more than a crust or shell, as in plaster casts.

Our recent Exhibitions of manufactures have presented few articles more beautiful than those formed of papier-maché. The firm of Messrs. Jennens and Bettridge, at Birmingham, is pre-eminent for productions in this department of industry.

PARACHUTE. Under BALLOON a brief account is given of aëronautic ascents; we will here say a few words concerning the attempts to *descend* from a balloon. A parachute is a machine attached to a balloon, and is intended to convey the aëronaut gently to the earth, in case of an accident happening to the balloon. It is in shape like an umbrella, with ropes or stays fastened to the extremities of the whalebones, and brought down to the handle, where they must be fixed, so as to prevent the umbrella from turning inside outwards. Instead of the stick, suppose a metal tube to be fixed in the centre, with a rope passing through it, attached by its upper extremity to the balloon and by the lower end to a tub or car. This machine is a parachute. While ascending it will be like a closed umbrella, but it may at any moment be detached from the balloon by cutting the end of the rope which ties it to the car; the resistance of the air will then cause it to expand, and will at the same time retard the velocity of the descent.

Machines like umbrellas, to break the fall from a high place, were used in Siam two centuries since: but the first experiment in Europe with such a machine was made at Paris in 1783 by M. le Normand, who leaped safely from a window of a house with a stout umbrella of thirty inches in diameter in his hand. M. Blanchard several times caused dogs to descend from great heights by means of parachutes; and, in 1802, M. Garnerin, who five years before had made a like descent at Paris, repeated the experiment in London. The parachute of this gentleman was 23 feet in diameter; and at the height of 8000 feet, he cut the rope which attached him to the balloon. The descent was at first very rapid; but, the machine at length expanding, he came to the ground without serious injury. Madlle. Garnerin, his daughter, descended twice in 1816, from great elevations, apparently without being in the least discomposed

In 1837 Mr. Cocking descended near London, from a balloon, by a parachute constructed in the form of an umbrella turned upside down. The parachute was 34 feet in diameter, and it was kept open by a wooden hoop. As soon as it was cut away, it fell with rapidity; its vibrations were violent, the hoop broke, and the unfortunate aëronaut fell, dreadfully mutilated, to the ground. Other parachute descents have since been made.

PARAPET, is a low or breast-high wall or fence, to serve as a protection on bridges, terraces, platform-roofs, &c. In Italian architecture parapets are generally balustrades. In gothic architecture the parapet is merely a continuation of the wall carried up above the edge of the roof, and finished by a coping; unless machicolated, in which case it projects and overhangs the walls below. In the Lombardic buildings of Italy there is seldom any parapet, the eaves of the roof finishing the elevation. The same is frequently the case in the Norman style. In Elizabethan buildings open-work parapets, forming various fantastical devices, are common. In engineering and in fortification a low wall is often, in like manner, called a parapet.

PARCHMENT is the skin of the sheep, lamb, goat, pig, or calf, prepared for writing upon. When the skin is divested of its hair, or wool, it is placed for some time in a lime-pit, and then stretched on a square wooden frame drawn tight by pegs. When in the frame, it is first scraped on the flesh side with a blunt iron, then wetted with a moist rag, covered with pounded chalk, and rubbed well with pumice-stone. After a short pause these operations are repeated, but without chalk. The skin is then turned, and scraped on the hair side once only. The flesh side is scraped once more, and again rubbed over with chalk. All this is done by the skinner, who allows the skin to dry in the frame, and then cuts it out and sends it to the parchment-maker, who repeats the operations with a sharper tool, using a sack stuffed with flocks to lay the skin upon instead of stretching it in a frame.

The relation which parchment-making bears to tanning is noticed under LEATHER MANUFACTURE. The costliness of parchment in the middle ages is illustrated by the PALIMPSEST MANUSCRIPTS.

PARING AND BURNING, are the two processes of a combined operation in agriculture, which consists in cutting a thin slice from the surface of land which is overgrown with grass, heath, fern, or any other plants which form a sward by the matting together of their roots. The sods are allowed to dry in the sun to a certain degree, after which they are arranged in heaps, and burnt slowly, without flame or violent heat. The result is a mixture of burnt earth, charred vegetable fibre, and the ashes of that part which is entirely consumed. The object of this operation is two-fold: first, to kill insects and destroy useless or noxious weeds completely; and secondly, to obtain a powerful manure, impregnated with alkaline salts and carbonaceous matter, which experience has shown to be a very powerful promoter of vegetation. The instruments by which this is effected are, either a common plough with a very flat share, which may be used when the surface is very level without being encumbered with stones or large roots, as in low moist meadows, or in most other cases a paring-iron used by hand, the cross-bar of which is held with both hands; and the upper parts of the thighs, being protected by two small slips of board, push the instrument into the ground, so as to cut a slice of the required thickness, which is then turned over by moving the cross handle. The labour is severe, and a good workman can scarcely pare more than one-sixth of an acre in a day.

PARIS. This most important city, besides its distinguishing features in other respects, has a considerable manufacturing population; for in the variety and extent of its productions of industry, Paris may vie with most cities of the world. The carpets of the manufactory of La Savonnerie and the tapestry of the Gobelins are well known. Cashmere, silk, and woollen shawls; light woollens, cotton goods, hosiery, gloves, hats, embroidery, lace, and other articles of fashionable attire; jewellery, gold and silver plate and trinkets, clocks and watches, bronzes, and musical, mathematical, and philosophical instruments; paper-hangings, houshold furniture, carriages, sadlery, leather, glue, cutlery, fire-arms, liqueurs, and confectionary, are made. Dyeing, printing, engraving, and lithography; the manufacture of salts, acids, oxides, and other chemicals; the refining of sugar, tallow-melting, the distillation of brandy from potatoes, brewing, and the manufacture of potato-starch,—all are carried on with considerable activity. The Seine furnishes the principal means of water-carriage: it is navigable for barges and other small craft. The canals of the Ourcq, St. Denis, and St. Martin, give to Paris water communication with many parts of the vicinity. The timber brought into Paris is immense. Wood is the principal fuel consumed at present, but the consumption of coal is gaining ground. The markets for the sale of provisions are numerous and generally well arranged.

There are some curious industrial statistics in which London and Paris are compared, contained in a recently published report to the French government, by M. Darcy, divisional inspector of the Ponts et Chaussées, who has been to England to obtain information relative to the macadamized roads. The total surface of London is said to be 210,000,000 square metres; its population, 1,924,000; number of houses 260,000; length of the streets, 1,126,000 metres; surface of the streets, not including the foot pavement, 6,000,000 metres; length of the sewers, 639,000 metres. The total surface of Paris is 34,379,016 square metres; population, 1,053,879; number of houses, 20,526; length of the streets, 425,000 metres; surface of the streets, exclusive of the foot pavement, 3,600,000 square metres; length of the sewers, 135,000 metres; surface of the foot pavement, 888,000 metres. Thus in London every inhabitant corresponds to a surface of more than 100 square metres; at Paris to only 34 metres; which shews that Paris is much more densely populated than London. In London the average of inhabitants for each house is 7½; at Paris, 34. The Boulevards of Paris is the part where the greatest traffic takes place, and the following are the results of the observations of M. Darcy on the subject:—On the Boulevard des Capucines there pass every 24 hours 9,070 horses drawing carriages; Boulevard des Italiens, 10,750; Boulevard Poissonnière, 7,720; Boulevard St. Denis, 9,609; Boulevard des Filles du Calvaire, 5,859; general average of the above, 8,600. Rue du Faubourg St. Antoine, 4,300; Avenue des Champs Elysées, 8,959. Other items are given respecting the traffic in the London streets; but these seem to be of doubtful accuracy.

The numerous Industrial Exhibitions at Paris have been noticed in the *Introduction*.

PAR'THENON. This far-famed structure, the temple of Minerva, is situated on the Acrópolis of Athens. It was erected in the time of Pericles (about B.C. 448). This temple has always been considered the most refined example of the Grecian Doric style, and one of the noblest monuments of antiquity. Yet its grandeur is by no means owing to its extraordinary dimensions, since in point of size it falls far short of many other structures, modern as well as ancient, its extreme length being only 228 feet, and its breadth 100, and the interior of the cella only 145 feet by 63 feet. This temple had columns along its sides and at both ends, viz., eight beneath each pediment, making in all 46 columns, there being, including those at the angles, 17 on each side, or 16 intercolumns. Besides these external columns, there was likewise a range of inner columns at each end. The cella or body of the temple was hypæthral, that is, the central space between the columns along each side was open to the sky. Even in its present shattered and mangled state, the temple is the admiration of all travellers and artists who have beheld it. The chief portion of the sculptures of the edifice were removed by Lord Elgin. [ELGIN MARBLES.] One object of art that originally decorated the interior or shrine was the chryselephantine (gold and ivory) statue of Minerva, 39 feet high, which was the work of Phidias. Since the establishment of King Otho's government (1833), excavations have been made on the Acropolis and around the Parthenon, and a great number of fragments of sculpture and architecture have been brought to light. Some of the fallen columns have also been replaced, and measures taken to restore the structure as far as circumstances will permit. In the British Museum are two models of the Parthenon, on a large scale, one in its ruinous state, and the other a restoration with the sculptures in their respective situations.

PASTILES. These are used either to diffuse an agreeable odour, or more usually to hide some offensive odour. They are made somewhat cone-shaped, so as to burn slowly. Many different combinations of odiriferous substances are employed in their manufacture. One kind is made of gum benzoin, tolu balsam, sandal wood, charcoal, tragacanth, labdanum, nitre, gum arabic, and cinnamon-water. Other kinds resemble this nearly in the solid ingredients, but substitute rose water, essence of orange, essence of vanilla, or oil of cloves, for the cinnamon water.

PASTES. The pastes or vitrifiable materials which are employed to imitate gems for cheap jewellery are noticed under GEMS and GLASS MANUFACTURE.

PASTURE LAND. The pasturage of cattle is now a part of regular husbandry. The land which affords the herbage for cattle forms part of private possessions, and a rent is paid for its use. Pastures are now fenced and protected, and pains are taken to improve them, so as to maintain many more cattle and sheep than they would in their natural state. Whenever pastures are hired, the rent is always reckoned, not by the extent of surface, but by the stock which can be maintained upon it. Thus, in Switzerland, the mountain pastures are divided into portions of twenty, forty or more cows. In Scotland they reckon sometimes by the number of bullocks which can be reared, and sometimes by the number of sheep which can be kept. In many places pasturing has been found much more productive than cultivation; and some large proprietors have converted great tracts of land from arable into pasture farms. Pastures are seldom improved with manure, which is generally reserved for arable land, or grass land intended to be mown for hay: but if richness is valuable in a pasture, it will well repay the expense of manuring.

PATENTS; PATENT LAWS. The object of patents is to encourage useful inventions. Before applying for a patent for an invention, two considerations are necessary: first, what is entitled to a patent; and next, whether the invention has the requisite conditions. In the first place, the machine, operation, or substance produced, for which a patent is solicited, must be new to public use, either the original invention of the patentee, or imported by him and first made public here. A patent may be obtained for England, Ireland, or Scotland, although the subject of it may have been publicly known and in use in either or in both of the other two countries. In the second place, the subject of the invention must be useful to the public, something applicable to the production of a vendible article. The discovery of a philosophical principle is not entitled to such protection: such principle must be applied, and the manner of such application is a fit subject for a patent.

An invention entitled to patent may be a new combination of mechanical parts, whereby a new machine is produced, although each of the parts separately be old and well known; or an improvement on any machine, whereby such machine is rendered capable of performing better or more beneficially; or when the vendible substance is the thing produced either by chemical or other processes, such as medicines or fabrics; or where an old substance is improved by some new working, the means of producing the improvement is in most cases patentable. If the inventor think that the machine, operation, or substance produced comes under any of these enumerations, and that it is new, and likely to be useful to the public, he must proceed in the form required by law to obtain the letters patent.

The chief clause in a patent grants the sole use of the invention to the inventor for fourteen years, whereby all other persons are restrained from using the invention without a licence in writing from the patentee; and persons are restricted from imitating the invention, or making any addition thereunto or subtraction therefrom, with intent to make themselves appear the inventors. Another clause declares that the patent shall be void, if contrary to law or prejudicial and inconvenient to the public in general, or not the invention of the patentee, or not first introduced by him into this country. A patent may be shared among any number of persons up to twelve. The specification of a patent must show exactly in what the invention consists for which a patent has been granted, and it must give a detailed account of the manner of effecting the object set forth in the title; it must describe exactly what is new and what is old, and must claim exclusive right to the former; the introduction of any part that is old, or the omission of any part that is new, equally vitiates the patent. The patent is granted on condition that such full and accurate information shall be given in the specification as will enable any workman or other qualified person to make or produce the object of the patent at the expiration of that term, without any further instructions.

If a patentee finds that the time allowed him by the patent is not sufficient to remunerate him for the trouble and expense of his invention and patent, he may apply for an extension of the term. Any person wishing to oppose the extension, must enter a *caveat* at the Privy Council Office, and the petitioner and enterer of the caveat are heard by their counsel before the Judicial Committee, which reports to the crown; and the crown is authorised, if it shall think fit, to grant new letters patent for the same invention for a term not exceeding seven years after the expiration of the first term.

The assemblage in London, in 1851, of a larger amount of manufactured articles than were ever before collected in one place, has led to anxious discussions concerning the patent laws. It has been long felt that these laws are clumsy, tedious, costly, and unjust: a constant source of vexation to those whose ingenuity has developed new machines or processes, and who wish to receive a fair commercial advantage from that ingenuity. Foreigners are still more anxious that any new combinations or inventions which they may exhibit in England should not be copied by dishonest persons in this country, without some recognized means of securing a right and property to the real inventors. The government, the legislature, the legal profession, and the Commissioners for the Industrial Exhibition, have all felt that changes in the existing patent laws are necessary; and committees have been appointed, by different bodies, to investigate the subject. So far as relates to *designs* rather than to *inventions*, certain improvements have been introduced which are noticed under DESIGNS. A bill is now before the legislature, intended to meet some of the evils of the system generally, and to apply specially in some clauses to the Great Exhibition; but so much diversity of opinion prevails concerning the best mode of carrying out the improvements, that little can be said respecting the probable character of the future regulations on this important subject.

PAVEMENTS. [ROADS; TESSELATED FLOORS.]

PEARLASH. [POTASSIUM.]

PEARLS; PEARL FISHERY. A pearl is a small concretion which is formed within the hard envelope of a shell-fish. The pearl oyster nearly resembles in shape the common English oyster, but is larger, being usually about three inches in diameter. The pearls are most commonly contained in the shell; but sometimes they are found in the thickest and most fleshy part of the oyster. A single oyster will frequently contain several pearls; and it is on record that one has been known to contain a hundred and fifty. The pearl itself is supposed to be the result of some accidental deposit or extravasation of the liquor secreted by the animal in the gradual enlargement of its shell—very small in the first instance, but increased by successive layers of pearly matter.

The beautiful substance called (somewhat expressively) *mother of pearl*, is the hard silvery, brilliant internal layer of shells, especially oyster shells, and more particularly the pearl oyster. In English oysters this substance is too thin to be workable for manufacturing purposes; but the oysters of the eastern seas yield it of considerable thickness. The brilliant hues which distinguish mother of pearl do not depend upon the nature of the substance, but on an exquisitely fine series of furrows upon the surface, which shed a brilliant reflexion of colours according to the angle at which the light falls on them. Much care is required in working this delicate substance; but it may be cut by saws, files, and drills, with the corrosive aid of sulphuric or muriatic acid. It is polished by colcothar of vitriol. In all those ornamental manufactures where *pearl* is said to be used for flat surfaces, such as inlaying, mosaics, buttons, knife-handles, &c., it is not real pearl, but mother of pearl, that is employed.

The *Pearl Fishery*, or the fishing for pearl oysters, is an important employment on coasts where this particular kind of fish abounds. The chief fisheries are on the west coast of Ceylon, on the Coromandel coast, on the shores of the Persian Gulf, on the coast of Algiers, on the shores of the Sooloo Islands, in the Bay of Panama, and on the Pacific coast of some of the South American States. The Ceylon fishery is a monopoly of the British government, and the Coromandel fishery is a monopoly of the East India Company; but the rent at which the fisheries are let out seldom pays more than the expense of superintendance. In the Persian Gulf the fishery often yields nearly 100,000*l*. of pearls in two months. The oysters are procured by diving. In the Ceylon fishery about 1200 or 1400 divers are usually employed. The share of profits gives each individual 5*s*. to 6*s*. per day for the time he is employed: the price of ordinary labour being 6*d*. per day. But each bank being available only for one period, of about 20 days in every 7 years, sometimes the fishery is smaller, and sometimes there is none at all; and in no season does it last for more than 30 or 35 days, commencing with the calm weather about the 5th of March. The divers, in 6 or 7 fathoms water, remain immersed from 50 to 55 seconds, very rarely longer. A reward being offered to him who should remain the longest under water, it was gained by one who remained 87 seconds. The diver's sack is not fastened round his neck, but is attached to a cord held by the man in the boat above; and it is pulled up when full at the signal of the diver, who, if he choose, is drawn up with it. So far from the occupation being unhealthy, it is the belief of the natives that divers live longer than other labourers; and its short season is held as a gainful holiday by the divers themselves, who at other times are engaged in ordinary labour. If the oyster is taken before seven years old, its pearls are imperfectly developed.

When the oysters are brought to land, they are thrown into a pit and allowed to rot, whereby the pearls can be extracted without injury to their delicate structure. The pearls do not undergo much preparation to fit them for ornament, as an irregularly shaped pearl is regarded as being but little inferior to a symmetrical one. Various kinds of drills are employed to bore holes through the pearls; and the powder of ground pearls is sometimes employed to polish them.

A vessel arrived at London in the early part of 1851 from Panama, with no fewer than 2,104,000 pearl shells; to be used, we may presume, as mother of pearl. This was the largest importation ever known.

The mode of imitating pearls is described under GEMS.

PEAT is a substance of vegetable origin, found wherever the soil has been long soaked with water which has no outlet and does not completely evaporate by the heat of the sun. When dried peat is examined, it is found to consist of roots and fibres in every stage of decomposition, from the natural wood to the completely black vegetable mould. From the nature of its formation under the surface of the water, it acquires a portion of tannin, which has the property of preserving animal and vegetable matter from decomposition. Hence large branches and trunks of trees are found imbedded in peat, which have no mark of decomposition, except what may have taken place before the wood was completely immersed in the peat. Peat contains all the elements of the richest manure, and may by an easy process be converted into humus: for this purpose the agency of alkalies is the most effectual. If the tannin be decomposed, that of the vegetable fibre will go on, and soluble humus will be formed. When peat is newly dug up, if caustic lime be added to it before it is dry, the moisture of the peat slakes the lime, which acts on the gallic acid in the peat and neutralises it. If this mixture be then excited to fermentation by the addition of animal matter, such as urine or dung, oxygen is absorbed and carbonic acid evolved; and the residue is converted into an excellent manure, containing much soluble humus. The same may be effected more slowly by mixing peat with clay or marl, and allowing the mixture to remain exposed to the atmosphere for a considerable time, frequently turning it. But nothing accelerates this process like the addition of putrescent animal matter, which acts as a ferment and greatly hastens the decomposition.

The soils for which peat forms the best manure are the chalky and clayey. Sand has too little tenacity; it lets the gases produced by the decomposition escape, instead of attracting them, as clay and chalk do, and thus preventing their escape.

Coincident with the present Flax movement is an enterprise for converting the peat of Ireland into charcoal. The Irish Amelioration Society has already made a good beginning in this work. The charcoal thus obtained is not only highly valuable in the smelting of iron and other metals, but comes into action as a most useful ally in the sanitary and economical measures that are now making such progress. As a deodoriser, it is the best substance yet discovered, and by its agency the most offensive matter is converted into perfectly inoffensive and highly nutritious manure. It has already been largely contracted for, to purify the sewerage of the metropolis, and to convert its nuisances into a source of profit. As the manufacture of this charcoal increases, the inducement to reclaim land will be multiplied. Already round each charcoal factory a rim of cottage gardens spreads, and the land, relieved from the load of otherwise unprofitable peat, produces the crops of a virgin soil.

A British and Irish Peat Company, too, is in process of formation, in which English capitalists propose to assist in the work. This company was suggested with reference rather to Dartmoor peat than to Irish peat; but if available for one, it would also for the other. The company profess to be able to obtain naphtha, paraffine, fixed oil, volatile oil, acetate of lime, and sulphate of ammonia, from peat, at profitable prices; but the correctness of the calculations requires the test of experience.

PEDAL. In musical instruments pedals are of two kinds:—1., those keys which are acted on by the feet of the performer; 2, the levers acting on the swell of the organ, and on the stops; and also those of the pianoforte and harp. The foot pedals of the organ play certain keys; the stop-pedals or levers of the same instrument bring into play distinct groups of pipes; the foot pedal of the pianoforte raises the dampers from certain strings; the foot pedals of the harp raise the tone of the strings half a note.

PEDOMETER. This ingenious instrument, in the shape of a small watch, enables a person to tell what space of ground he has walked or ridden over. The instrument is so constructed that when the body of the traveller is raised, either by the spring of his foot, or the motion of his horse, a lever is made to act upon the wheel-work of the instrument, and an index or hand on the dial-plate points to the figures which denote the number of miles passed over.

PE'KEA is the name of a plant inhabiting Guiana, and furnishing the *Saouari Nuts* of the shops. The shell is brownish and rugged, and contains a kernel of a soft consistence, and of the most delicate buttery quality. It is by far the best of the South American nuts that are brought to England, and much superior to our own walnuts and filberts.

PEMBROKESHIRE. In this Welsh county, forming the south-west projection of the principality, much useful mineral produce is found. The anthracite or stone coal tract bisects the county; it is a continuation of the great coal-basin of South Wales, which extends over the whole coast of Caermarthen Bay. Copper-ore has been found in small quantities in the neighbourhood of St. David's, but not sufficient to repay the cost of working. Slate-quarries are opened in the Precelli Mountains and near St. David's; the quality of the slates is inferior to those of North Wales. Coal is the only mineral besides slate which is worked in Pembrokeshire: it is of that description called anthracite, or stone-coal. The best coal is raised at Landshipping, on the shore of Milford Haven. A considerable quantity of good coal is also raised at Kinsmoor and Kilgetty, whence it is conveyed by a railway to the sea at Saundersfoot, where a dock has been built.

The soil in different quarters is very varied; and the state of agriculture is as various as the soil. Considerable advances have been made of late years, but a general want of capital among the farmers prevents any rapid progress.

Pembrokeshire has not much pretensions to the character of a manufacturing county. *Fishguard* is remarkable for little besides a fine fishing ground near the bay, frequented by small craft from Liverpool. The port is capable of accommodating 100 sail of merchantmen. The principal exports are corn and butter; the imports, coal, culm, limestone, &c. If, however, the South Wales Railway should be carried to Fishguard as originally planned, it would become a place of commercial importance. *Haverfordwest* is principally occupied by shopkeepers, mechanics, and persons of moderate independent fortune, for whom the cheapness of the place is an attraction. The river Cleddy is navigable at spring tides to Haverfordwest, for vessels of 100 tons burthen. *Milford* was a highly prosperous town till the removal of the dockyard and packet establishment.

Pembroke Dockyard is the most important establishment in the county. It is situated at Pater, about two miles from Pembroke, on the shores of Milford Haven. The naval dockyard and arsenal were removed from Milford to this spot in 1814. The two together occupy about 60 acres; the dockyard is one of the most complete in the kingdom, capable of building five or six first-rates and many smaller vessels at the same time. In respect to ropes, anchors, machinery, it is not so celebrated as some of the other royal dockyards. Steamers ply regularly from Bristol to Pater; and the neighbourhood of the dockyard is gradually becoming flourishing.

Milford Haven, near and beyond the dockyard, is being strongly fortified. Towers, forts, and batteries are being constructed at different spots. These works have been commenced because it has been felt that the shipping and dockyard were in a somewhat unprotected state.

PEN MANUFACTURE. Among the small articles of daily use, few are more important than pens, and few exhibit more remarkably the application of the factory system to the production of cheap implements.

Under FEATHERS, the reader will find an account of the mode of preparing goose-quills for pens. Of the common method of making pens by hand it is not necessary to speak; we shall therefore only say a few words upon the manufacture of *quill nibs*. The barrel of the quill in the first place has both ends cut off, and is divided down the centre; the halves are then laid on their convex side and the edges shaved smooth; after this they are divided into three or four lengths each, and the end of each length is made into a pen by a small machine, which at one time makes the slit and cuts the shoulders; they are then finished by being nibbed by hand. Pens are shaped differently according to the kind of writing for which they are intended.

Owing to the constant necessity for mending quill pens, the loss of time consequent thereon, and the inequality of the writing, an immense amount of labour and ingenuity has been employed to produce some more durable substitute. The only substitute which has attained to anything like general use is the steel pen; but long before their general introduction, metallic pens of other kinds were tried; sometimes silver, when intended for presents; sometimes brass, when intended to accompany cheap brass inkstands that used to be made some years ago. One of the first attempts to combine the elasticity of quill pens with increased durability consisted in arming the points with metallic nibs; but the improvement was not adequate to the increased cost. Another class of improvements, or suggested improvements, was the introduction of pens whose nibs should be formed of precious stones. One kind consisted of a tortoiseshell tube or barrel, with small fragments of diamond or ruby imbedded in the nib. Another kind contained a nib of ruby set in fine gold, and such pens have been said to last six years without injury. Some have also been formed of rhodium nibs set in gold. Pens of gold, of silver, and of gold alloyed with silver, are occasionally made.

But, as we have said, steel is the only material which has successfully competed with the quill. The present generation has witnessed a descent from sixpence a piece to sixpence a gross. Steel pens are now manufactured to an amount in quantity and at a

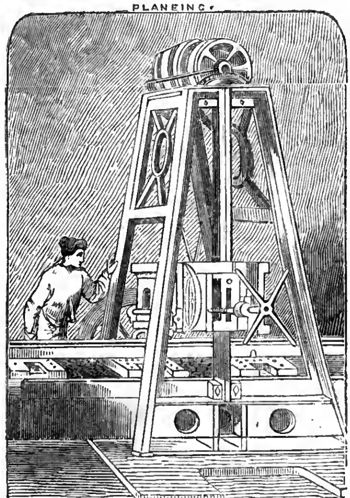
PLANEING.



KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 32.

cost so small as hardly to be credible. Different makers have different modes of operation, but the following will give a general idea of the method employed. In the first place flat pieces of steel are cut out, of the shape required, by a stamping-press; they are then placed under another press, which pierces the holes and cuts the slits; and they are struck into their convex shape by a third press. They are then polished and tempered. The polishing is managed in rather a curious manner; a quantity of pens are shut up in an iron cylinder, leaving a considerable space unoccupied; this cylinder is attached at each end to a crank, the axes of which are connected by a wheel and set in motion by a handle or by machinery. Thus by being rubbed against each other the pens come out well polished, and with all the burrs or sharp angles left by the cutting-presses rubbed smooth. Birmingham is the great seat of the steel pen manufacture; some of the manufacturers have fine manufacturing establishments, and make several hundred millions of pens annually. Mr. Albert Smith in his "Month at Constantinople," gives us a curious instance of the spread of English manufactures all over the world. At Constantinople he saw a Turk, seated on the wall of a cemetery, and exhibiting a tray of Birmingham steel pens for sale.

Fountain pens are so made as to hold a reservoir of ink. Music-pens are formed so as to make large dots as well as strokes. The geometric-pen is an ingenious mathematical instrument for drawing curves.

PENCILS. The well-known *black-lead pencil* is made by cutting black-lead, or plumbago, into thin plates with a saw, and again into strips as wide as the plate is thick. These strips are then laid in a groove in a piece of cedar, upon which is glued another and thinner piece: the whole is afterwards rounded by a plane adapted to that purpose. The finest plumbago is obtained from a mine in Cumberland. [Plumbago.] Some pencils are filled with coloured chalk instead of black-lead.

The *ever-pointed pencil* is an instrument for using cylindrical pieces of black-lead, which are forced forward in the pencil just so far as to allow them to be used without breaking. The leads are manufactured of different thicknesses, and the pencil-cases are marked with a letter to correspond with the lead required for it.

The pencils for using liquid colours or paints are of course wholly different from those just described. They are made of hog's bristles, camel's hair, fitch, sable, &c. Those of a large and common kind are described under Brush Making. The soft pencils for artists are made as follows:—The tail of the animal (sable, badger, marten, &c.) is scoured in a solution of alum; then steeped for several hours in luke-warm water; then dried in linen cloths; and finally combed out regularly. The hairs are seized with pincers, and cut off near the skin; and the little parcels of hair are sorted into groups according to their length. A few hairs are then taken enough for one pencil, and placed in a little receptacle which holds them while a thread is bound round near the roots. The base of the pencil is them trimmed flat by scissors. The hairs thus prepared are fitted either into quills or into tin tubes. The quills are those of swans, geese, ducks, lapwings, pigeons, or larks, according to the size of the pencil. Each quill is softened and swelled in hot water: and the bunch of hairs is introduced at the larger end, and pulled forward by a simple apparatus to the smaller end, where the shrinking of the quill binds the hairs closely. The great art in pencil making is so to arrange the hairs that their ends may be made to converge to a fine point when moistened and drawn between the lips; and it is said that females are more successful then men in preparing the small and delicate pencils.

PENNSYLVANIA. This is one of the most busy and commercial states of the American Union. It abounds in minerals. From the western declivity of the Alleghany Mountains the bituminous coal-fields of Pennsylvania extend into Maryland and Virginia, and occupy many thousands of square miles; this coal is mostly wrought in the neighbourhood of Pittsburg, where it is used for manufacturing purposes. The anthracite coal-field, which lies to the east of the Blue Ridge, is also of great extent, and is wrought to some extent. Iron-ore is in abundance, and limestone occurs in all parts of the state.

The most important manufactures of Pennsylvania are those of iron. So far back even as 1840 there were 213 furnaces, which produced 98,395 tons of cast-iron, and 169 forges, &c., which produced 87,244 tons of bar-iron. There were 235 woollen manufactories, 337 fulling-mills, and 106 cotton manufactories. The quantity of bituminous coal obtained was 11,620,654 bushels. Steam-engines are manufactured to a large amount, chiefly at Pittsburg; and there are numerous other manufactures. The most important canal in Pennsylvania extends from Philadelphia, including a railroad of 37 miles, over the Alleghany Mountains, to Pittsburg, 400 miles. There are several other large canals and numerous small ones. The railroads are still more numerous; from Columbia to Philadelphia, 81 miles; Philadelphia to Reading, 95 miles; Tamaqua to Williamsport, 106 miles; and many others. Pennsylvania is, in short, one of the most enterprising of the states; and Pittsburg (the largest town next to Philadelphia), is a great centre of manufactures. As to the monetary credit of the State, in respect to loans and bonds, we have nothing to do with it here.

PEPPER. This powerful condiment is obtained from an Asiatic plant called *Piper Nigrum*. The best comes from Malabar; the worst from Java and Sumatra. The plant is allowed to grow, trained to the stems of other trees, for four years before the fruit can be collected. The fruit or berries are gathered when yet green, before they are perfectly ripe, and are quickly dried on mats, by which they turn black; and this constitutes *black pepper*.

White pepper is the same fruit freed from the outer rind; for this purpose the ripe berries are steeped in water, which allows the rind to be easily removed.

Black pepper contains a great variety of proximate chemical principles; such as an acid resin, a volatile oil, extractive matter, gum, malic and tartaric acids, piperin, bassorin, and several salts. The white pepper has a less powerful odour and taste than the black. The odour of pepper is attributed to the volatile oil, and the pungent taste to the resin. Pepper is used to some small extent in medicine, but much more as a stimulant or condiment with food. Notwithstanding the large consumption in Europe, the Chinese are the great consumers; for among them it appears to hold a more important place than among European nations.

Cayenne pepper is obtained from CAPSICUM.

The importation of pepper into the United Kingdom during the last three years amounted to the following quantities:—

1848	8,125,545 lbs.
1849	4,796,042 „
1850	8,082,518 „

The smallness of the import in 1849 is not explained in the government tables.

PERAMBULATOR, is an instrument for measuring distances on roads. It consists principally of a wheel upon which it runs, and an index which shows the number of turns of the wheel reduced into miles, furlongs, poles, and yards. The carriage or stock, which is divided in order to receive the wheel, is made of wood, and is about three feet long. At one end is a handle for the person who uses it, and the other is furnished with sockets in which the axle of the wheels turns. Upon the stock and just in front of the handle is the dial-plate, with its two hands by which the distance is registered. The wheel is 8¼ feet, or ½ pole, in circumference; and upon one end of its axis is a small pinion, which works into a similar pinion at the end of a rod passing up the stock or carriage to the works beneath the dial-plate. Motion is communicated by means of this rod to a worm or micrometer-screw, which turns once round for each revolution of the carriage-wheel of the perambulator. This worm works into a wheel of 80 teeth, which is moved forward one tooth for every ½ pole, and carries a hand or index, which makes one revolution for 40 poles or one furlong. On the axis of this wheel is a pinion of 8 teeth, which moves a wheel of 160 teeth. This last wheel carries another hand, which makes one revolution for 80 of the former, that is for ten miles. The movements of the two index-hands thus shew the miles and furlongs passed over.

There are other instruments for the same or similar purposes, bearing different names, as *Waywiser* and *Odometer;* but the construction of all of them is very similar. *Waywiser* is the name generally given to that form of the instrument which is applied to a carriage, in which, by a slight adaptation to one of the wheels of the carriage, the instrument is made to register the number of turns of such wheel, in the same manner as the Perambulator.

PERCH, or POLE. This measure, though now mostly used as a square measure (a perch usually meaning a square perch, or a square of a perch in length and breadth), was originally a measure of length, arising out of the custom of measuring small portions of land by a staff or pole. A perch is the quarter of a chain, and a square perch contains 30¼ square yards.

PERCUSSION CAPS. [CAPS, PERCUSSION.]

PERFUMERY. The pomatums, essential oils, distilled spirits, pastes, pastilles, essences, &c., which make up the fragrant store of the perfumer, require different chemical processes for their manufacture. Distilling in some cases, infusion in others, decoction in a third, pressure in a fourth, evaporation in a fifth, and so on. The reader will find a few details on these subjects under ESSENCE, OIL, PASTILLE, POMATUM, &c.

PERSIA. This ancient and celebrated country is neither in industry nor commerce so important as nature has fitted it to be. The slothful despotism of an Asiatic country is a sad bar to advancement. Agriculture is, however, well understood and carefully attended to, as is evident from the means of irrigation employed, and especially the subterraneous aqueducts. Rice, wheat, and barley are the most usual crops; but there are also millet, maize, tel, or sesamum, dal, a species of vetch, and several kinds of beans and peas. Cotton, indigo, sugar, tobacco, and madder, are raised in many places, but especially in Mazanderan. Fruit trees and garden vegetables are cultivated in great plenty.

Iron is abundant in many places, but it is not much worked. Lead, copper, antimony, rock-salt, and bitumen, are among the mineral products of the country.

Among the commercial towns of Persia, *Tabriz* has fallen from its once flourishing condition. *Kermanshah* carries on a considerable commerce. *Dorak* is celebrated for its manufacture of Arabian cloaks. At *Shuster* there is a considerable manufacture of woollen stuffs. *Shiraz* carries on a considerable trade with Yezd, Ispahan, and Bushire; and has manufactures of cotton, glass, iron, gunpowder, swords, and wine. It is also distinguished for the otto of roses procured from the rose-gardens in the neighbourhood. *Lar* in Laristan, is celebrated for the manufacture of swords, muskets, and cotton cloth. The bazar is the noblest structure of that kind in Persia. At *Kerman* trade and manufactures are considerable. The bazar, which is extensive and well built, is abundantly supplied with articles of every description; and there are nine large caravanserais within the walls, and a number of inferior ones both within and without. *Herat* and *Mushed* are among the most commercial towns of Persia. Near *Nishapoor* are the famous turquoise mines. *Yezd* is remarkable as a commercial and manufacturing town. Its commercial importance arises from the caravan routes, which here cross one another, and thus connect it with all parts of Asia.

The manufactures of Persia, though not adequate to so large an Empire, are still numerous and of various kinds. In the manufacture of some articles the Persians are still distinguished, as in several kinds of silk stuffs, especially brocades, and sword-blades, leather, carpets, felt of camel-hair, and jewellery. No machinery being used in the Persian manufactures, the cotton and silk goods introduced by the British have obtained a ready sale owing to their cheapness.

The internal commerce of Persia is very considerable, though managed in a slow and clumsy manner. The different regions which compose this extensive empire differ considerably in their natural productions, and the transport alone of commodities gives occupation to a great number of merchants and other people. To this must be added the produce of the manufactures, and the numerous articles which are brought into Persia from the neighbouring countries, especially from India, and are distributed all over the country. This commerce is entirely carried on by caravans; which usually comprise a very large number of persons and animals of burden, and have regular defined routes across the empire in various directions.

So completely is Persia shut out from direct intercourse with European countries, that the export of British commodities to that country is extremely trifling; it is only through indirect channels that commercial intercourse is maintained between the two countries.

PERSPECTIVE is the name given to the branch of art in which the rules for correct drawing are laid down. It is usually divided into *Linear Perspective*, in which form and outline alone are considered; and *Aerial Perspective*, in which the effects of the atmosphere, &c., on distinctness are considered. But what is commonly meant by the word is that which appertains to linear perspective. The rules of perspective exhibit a curious combination of principles derived from the science of optics, with others depending on pictorial or artistic principles.

PERTHSHIRE. In this Scottish county the plantations have been much extended of late years, and many districts have been covered with them. Oak, ash, birch, beech, elm, lime, alder, plane, and larch trees, are planted, though not so extensively as the fir tribe. The most valuable tract is the Carse of Gowrie, the district watered by the Isla and its tributaries the Ericht and the Airdle, and comprehending a portion both of Forfarshire and Perthshire. The Carse of Gowrie, Strathearn, and the valleys of the Teith and the Forth, yield good crops of wheat; but in the midland districts oats and barley are the principal grain crops. Turnip cultivation is carried on to a considerable extent. The chief article of agricultural produce is, however, the potato, of which great quantities are yearly shipped for London.

The cotton and linen manufactures are very extensively carried on in this county: Stanley is the principal seat of the one, Dundee of the other, Woollens and silks are also woven, the latter at Perth. It was the cheapness of labour which led to the establishment of the cotton manufacture in this part of Scotland; for it is not so well suited as the Glasgow district, in respect either to the supply of coal or to convenience of shipment, to a manufacture on the factory system.

PERU. In this once celebrated and still interesting country the forests supply, besides timber, vanilla, sarsaparilla, copaiva, caoutchouc, dye-woods, medicinal bark, resins and gums, indigo, and a number of other useful products. The cultivated lands yield, according to their latitude and elevation, olives, sugar, bananas, yams, mandioc, grain, and many other useful plants.

The Peruvian Indians consume a very small quantity of European manufactured articles. Only the creoles dress in European stuffs. There are some manufactures of cordovan leather, and some tanneries and soap-houses. The iron utensils, such as hatchets, scissors, &c., made in Caxamarca, are highly valued. In the large towns many persons are occupied with making vessels, utensils, and ornaments of gold and silver. The country is too mountainous to admit the making of carriage-roads in the interior. Mules and llamas are generally used by travellers and for the transport of merchandise. Six great roads traverse the country from west to east; and the goods imported from foreign countries are sent by these roads into the interior of Peru. The goods exported are chiefly gold, sugar, and saltpetre. The principal harbours from which the exports are made, are—Payta, Lambayeque, Callao, Pisco, Islay, Arica, and Yquique. Peru is beginning to share the advantage of steam navigation on the Pacific.

The British produce and manufactures exported to Peru in 1849 amounted in value to 878,251*l.* The imports from Peru into Great Britain amounted in the same year to (official value) 1,037,903*l.*

PERUVIAN BARK. [CINCHONA.]

PESTH. This, the greatest city in Hungary, has considerable industrial and commercial activity. The manufactures are silk, cotton, leather, jewellery, and musical instruments; that of tobacco is a government monopoly. Pesth has, next to Vienna, the greatest trade of any city on the Danube. It has four fairs, each of which lasts a fortnight. The principal articles sold are manufactures, colonial produce, cattle, wine, wool, tobacco, and raw hides, honey, wax, &c. The disasters of this interesting city during the lamentable war of 1848-9 form no part of our present subject. The relations between Pesth and its sister town are noticed elsewhere. [BUDA.]

PETERSBURGH, ST. This celebrated city is not only the capital but the greatest manufacturing city of the Russian empire. There are above two hundred manufactories of different descriptions, some carried on by private individuals, of silk, cotton, woollen, leather, glass, gold and silver articles, watches, surgical instruments, paper, snuff and tobacco, sugar, &c. There are others which the government has considered it advisable to carry on upon its own account; such are the great manufactory of tapestry, a large manufactory of aqua-fortis, an assay-office and a mint, a plate-glass manufactory, a porcelain manufactory, a great manufactory of cotton and linen, and a cannon-foundry and powder-mills.

The commerce of St. Petersburgh is very considerable. Cronstadt is the harbour. The exports are hemp, flax, tallow, leather, iron, tobacco, canvas, coarse linen, bees'-wax, linseed, linseed-oil, tar, potash, &c. The imports are colonial produce of all kinds, manufactures of silk, cotton, hardware, French wines, jewellery, and all articles of luxury and fashion. The trade with England is greater than with any other country. A few industrial statistics will be found under RUSSIA.

PETRO'LEUM is a viscid variety of bitumen, found in many parts of Europe and America, but chiefly in Asia, flowing from beds associated with coal strata. It has a dark reddish-brown colour; it is slightly translucent, and its odour is bituminous. When petroleum is heated to nearly 450°, drops of an oily fluid come over, though very slowly; this oily body has a brown colour, and is very liquid. *Petrolene* is the name given by Boussingault to this oil; it has a pale yellow colour, slight taste, and a bituminous smell. *Asphaltene* is the solid portion of petroleum. Its colour is black, and it has a great deal of lustre. It breaks with a conchoidal fracture, and is heavier than water. There is an intimate chemical relation between petroleum and several other inflammable substances. [ASPHALTE; BITUMEN; NAPHTHA.]

PETUNTZE is the Chinese name for a white earth used with kaolin in the manufacture of porcelain. Kaolin is said to be derived from the decomposition of the felspar of granitic rocks. Petuntze is the same mineral which has not suffered decomposition, and on account of its fusibility is employed in glazing the porcelain. The English manufacturers of porcelain have sought for and found certain varieties of stone and clay which greatly resemble petuntze and kaolin.

PEWTER is a compound metal, extensively employed, especially in the manufacture of those drinking vessels called *pewter pots.* The finest pewter is said to consist of 12 parts of tin, 1 part of antimony, and a very little copper; while common pewter consists of about 80 parts of tin and 20 of lead. Pewter was formerly much more employed that at present, especially in the manufacture of plates and dishes.

PHILIPPINES. These islands, among the most important in the Indian seas, are rich both in produce and in commerce. The staple articles for the European market are sugar, indigo, rum, and tobacco; and for the Chinese market, sapan-wood, rice, edible birds' nests, and trepang. A small quantity of coffee, ebony, sulphur, cotton, pearls, mother-of pearl shells, tortoise shells, and cordage, are also exported. Cordage is made from the fibres of a species of banana. The principal food of the inhabitants consists of rice and fish. They also cultivate millet, and several kinds of beans and other pulse. The fruit-trees include the cocoa-nut, bread-fruit, mango, orange, fig, areca-nut, and plantain. Gold, iron, and copper, are said to exist in Luzon and Magindanao, but at present none of these metals are worked. Salt and brimstone are procured in several places.

The Malays use very few manufactured goods exported from other countries, and they have applied themselves to some branches of manufacture with success, including earthenware, cotton stuffs, straw and chip hats, mats, and especially cigars and cheroots.

The commerce of the Philippines was formerly limited to the mother country and the Spanish colonies in America. The most important and lucrative branch was the commerce with Mexico, which was conducted by means of galleons that sailed once a year between Acapulco, in Mexico, and Manila, in the Philippines. They chiefly carried to America silk manufactures, and other goods, obtained from the Chinese, and brought in return the produce of the Mexican silver-mines. But since the Spanish colonies in America have obtained their independence, the port of Manila has been thrown open to all commercial nations, and the increase of the exports has been very rapid. Manila now carries on commerce with a great number of nations. The value of British merchandise exported to the Philippines averages about 100,000*l.* annually.

PHLOGISTON. Before the agency of oxygen in leading to the phenomena of combustion and flame was discovered, the name of *phlogiston* was given to an hypothetical substance, by supposing the existence of which Stahl explained the nature of combustion. He imagined that by combination with phlogiston a body was rendered combustible, and that its disengagement occasioned combustion, and after its evolution there remained either an acid or an earth: thus sulphur was by this theory supposed to be composed of phlogiston and sulphuric acid; and lead, of the calx of lead and phlogiston, &c. The doctrine proposed by Stahl maintained its ground for about half a century. Soon after the discovery of oxygen gas by Dr. Priestley, the experiments which others had made on the calcination of the metals were repeated with great accuracy by Lavoisier; the consequence was, that the phlogistic theory gave way to the antiphlogistic; for the combustion, which had been attributed to the extrication of phlogiston, was known in all common cases to be derived from the absorption of oxygen, and this explained the increase of weight which bodies acquired by combustion, whereas on the phlogistic theory they ought to have suffered a diminution by the process.

PHŒNIX OR DATE TREE. The date tree (*Phœnix dactylifera*) is one of the most valuable among eastern plants. A considerable part of the inhabitants of Egypt, Arabia, and Persia subsist almost entirely on its fruit. They make a conserve of it with sugar, and even grind the hard stones in their hand-mills for their camels. In Barbary they form handsome beads for paternosters of these stones. From the leaves they make couches, baskets, bags, mats, brushes, and fly-traps; the trunk is split and used in small buildings, also for fences to gardens, and the stalks of the leaves for making cages for their poultry. The threads of the web-like integument at the bases of the leaves are twisted into ropes, which are employed in rigging small vessels. The sap is obtained by cutting off the head of the palm and scooping out a hollow in the top of the stem, where, in ascending, it lodges itself. Three or four quarts of sap may be obtained daily from a single palm, for ten days or a fortnight, after which the quantity lessens, until at the end of six weeks or two months, the stem is exhausted, becomes dry, and is used for firewood. This liquor is sweetish when first collected, and may be drunk as a mild beverage, but fermentation soon takes place, and a spirit is produced, which is distilled, and forms one of the kinds of arrack. Such being the importance and various uses of the date-tree, it is not surprising that in an arid and barren country it should form so prominent a subject of allusion and description in the works of Arab authors, and that it should be said to have 300 names in their language. Many of these are, however, applied to different parts of the plant, as well as to plants of different ages.

Another kind, called the *Phœnix sylvestris*, is a species common in the arid parts of India. It yields, by incision, tarri, or palm wine, commonly called toddy. Mats and baskets are made of the leaves. Sugar is made from this species.

PHOSPHORUS. This elementary body was discovered in 1669, by Brandt, an alchemist of Hamburg. It is contained in many substances of animal origin, but it is usually procured from bones. Phosphorus is solid, translucent, and nearly colourless, but sometimes it has a yellow reddish tint; it is so soft that it may be indented by the nail, and it is very readily cut. When heated to about 108° it fuses, and at 550° it is converted into vapour. It has a peculiar smell when exposed to the air, but this is probably derived from the action of the oxygen of the air upon it. Neither water nor alchohol dissolves phosphorus, but it is dissolved by æther and by oils. It emits light when exposed to the air in the dark. It is extremely inflammable, and has been known to take fire spontaneously in the atmosphere when its temperature was not above 60°.

Phosphorus combines with a great many other substances, to form oxides, acids, phosphurets, salts, &c.; several of which are useful in the arts and in medicine.

PHOTOGRAPHY. *Photographic pictures* are facsimile representations of objects, produced by the chemical action of light on a prepared tablet, upon which the images of the objects are thrown by a camera-obscura. Such a process has been named after its inventor the *Daguerreotype;* but other methods have received the names of *Calotype*, *Talbotype*, *Chrysotype*, &c. The process generally may be termed photography (light-drawing), or heliography (sun-drawing). The invention was first formally communicated to the public by M. Arago, who read an account of the Daguerreotype process before the Academy of Sciences, January 7, 1839. From that moment Daguerre (who was afterwards rewarded by a pension by the government) and his invention engrossed general attention. The discovery was spoken of as little short of miraculous; and though it does not realise all the sanguine hopes of its early inventors, the invention is unquestionably highly valuable, because it not only ensures perfect fidelity of likeness where it is most essential, and where it is hardly attainable by the most practised and patient hand and eye, but also gives us the minutest details—those which are imperceptible to the naked eye, and of course cannot possibly be represented upon paper, yet become visible in a photographic drawing when it is examined with a magnifying-glass.

In Daguerre's original process, the photographic drawings were produced upon plates of copper coated over with silver. After being washed with a solution of nitric acid, the plate was put into a well-closed box, where it was exposed to the action of iodine, a small quantity of the latter being placed at the bottom of the box with a thin gauze between it and the plate. A layer of ioduret of silver was thus formed on the surface of the plate, and manifested itself by the yellow hue produced on the silver, which shows that the process of giving the plate the sensitive coating on which the action of light delineates objects is completed. Thus prepared, the plate was next placed within a camera-obscura of particular construction; and the delineation of the object was then effected in a very short space of time, but had to be afterwards brought out and rendered distinct by another operation, namely, submitting the plate to the action of vapour of mercury. Even then the process was not completed, for the plate had to be plunged into a solution of hyposulphate of soda, and afterwards washed in distilled water, which being done, the impression was fixed, and the plate could be exposed to light with perfect safety.

Mr. Fox Talbot, and other experimenters, were engaged upon somewhat similar researches about the same time as M. Daguerre; and within the last twelve years numerous improvements have been introduced by Herschel, Talbot, Hunt, Claudet, Beard, Kilburn, and others.

By the experiments of these individuals much has been done to render Daguerreotype portraits more pleasing, by improved management of the light, and by placing behind the sitters painted screens, to relieve the head, and to form artificial backgrounds. One of the greatest difficulties in the original process arose from the circumstance, that, as the image produced in the camera-obscura was totally invisible until brought out by a subsequent exposure to the vapour of mercury, it was impossible to tell precisely at what moment the action of the light should be stopped, to avoid, on the one hand, an image imperfectly developed, and, on the other, the misty undefined appearance occasioned by the unavoidable motion of the object to be copied (whenever it is an animate object), and the discoloured or burnt appearance of an image which has been exposed too long to the chemical action of light. This inconvenience has been remedied by many ingenious devices. One important class of improvements has reference to the means of fixing and securing from injury by the subsequent action of light or other means, the Daguerreotype image. Considerable progress has been made towards transferring the colours of natural objects to the Daguerreotypes; but in the ordinary coloured Daguerreotypes, some of which make a tolerably near approach to the effect which might be expected if colours could be fixed in the camera obscura, the tinting is produced by the application of finely powdered colours to the surface of the photographic impression, which is previously coated with an alcoholic solution of copal, and nearly dried; so that the colouring, which is so delicately performed as not to impair the distinctness of the impression, is not in any degree the result of the action of light.

Most of the numerous patented or proposed improvements in the art depend chiefly on the mode of producing the pictures. The Chromatype, Chrysotype, Calotype, Cyanotype, Amphitype, and Ferrotype, all are so many modes of producing and fixing the impressions. Some of the improvements, however, relate to the mechanism of the camera-obscura, in which the sensitive surface is placed. See further on this point under AMPHITYPE; CALOTYPE; CHROMATYPE.

Mr. Brunel has lately registered an apparatus called a *Photographotrope*, comprising all the necessary materials for taking and fixing a photographic picture, packed up so as to stand upon a tripod or simple support. There is at the top of the apparatus a camera for producing the focal image of the object; and there are the proper means for impressing this image upon a metal plate. Below this is a spirit lamp in a tube, and a recess in which the plate is to be placed to be acted on by heated mercurial vapour. Below this again, is a small galvanic battery, which expedites the photographic process.

PHOTOMETER is the name given to instruments constructed for the purpose of measuring the relative illuminating powers of different sources of light. Photometers have been constructed by Professor Leslie, and by Mr. Ritchie, late professor of natural philosophy in London University College; but a mode of comparing the illuminating powers of two lights was suggested by Count Rumford, which is remarkable for the facility with which it may be applied, and the simplicity of the requisite apparatus, nothing more being needed than a smooth surface of small extent and of a light uniform colour, and a blackened stick for throwing a shadow. The surface is illuminated by the two lights experimented upon, which are to be so placed, that when the stick is interposed between them and the surface, the two shadows may be nearly in contact, which will enable the eye to decide whether they are of equal depth, and will at the same time ensure the intercepting of rays equally inclined to the surface. So long as the shadows are of unequal depth, one of the lights must be brought nearer to or retired farther from the surface till an equality of depth is obtained, and then the squares of the perpendicular distances of the lights from the surface give the ratio of their intensities. If an equality between the inclinations of the intercepted rays to the surface cannot be obtained, then, when the two shadows are of the same depth, the intensities of the lights will be directly proportional to the squares of their perpendicular distances from the surface, and inversely proportional to the sines of the inclinations of the intercepted rays to the surface. This method is theoretically perfect when applied to lights of the same colour.

PIANO-FORTE. This musical instrument is variously formed, and receives different designations, such as *grand*, *square*, *semi-grand*, *cabinet*, *cottage*, and *piccolo*. The first notion of the square piano forte was taken from the clavichord by a German mechanic of the name of Viator, about a hundred years ago; but, for want of friends or funds, he never became known as a maker. The invention, however, was followed up by other musical instrument makers of the same nation, who all left their clavichords and harpsichords for the new instrument, the piano-forte. The grand piano-forte is supposed to be of earlier date than the square piano-forte, and is said to have been the invention of a German musician of the name of Schröder, or, as others say, of Christofali, a harpsichord-maker of Padua. The first maker at all known in this country was a German of the name of Backers, but we are not aware that success attended his exertions in comparison with the solid advantages which were enjoyed by his contemporary, Zumpe, who realised an ample fortune, and retired.

The grand piano-forte retains the shape of the instrument from which it was taken, the harpsichord. Here we have two instruments alike in form, but unlike in almost every other circumstance; for their action, their tones, and the style in which they are played upon, are all entirely different. The action of the harpsichord was simply a key and what was called a *jack*, which was a piece of pear-tree with a small moveable tongue of holly, through which a cutting of crow-quill was passed to touch the string when the jack was in action; the tone produced by this contrivance was a kind of scratch with a sound at the end of it. The action of a grand piano-forte consisted of a *key*, a *lever*, a *hammer*, a *button*, a *check*, and a *damper*, with rails and sockets to connect them. By this combination of parts, every musical effect known or desired at that time was perfectly attainable, and with admirable results by Mozart, Haydn, Cramer, and others. But modern music requires greater powers in the instruments; and for the last half century, the Broadwoods, Erards, Collards, and other celebrated makers, have introduced a succession of singular and most delicate contrivances, to give all possible perfection to the tones and the means of their production.

The *square* piano-forte was taken from the clavichord, but it retains only its shape, with the same disposition of the strings and keys: their actions have no similarity. It may be necessary to state that the 'action' of a piano-forte is the technical name for the whole of the mechanism which intervenes between the pressure on the key and the striking of the string. The action of the clavichord was simply a piece of brass pin-wire, which was placed vertically at a point where it could be struck or pressed against its proper string, the right-hand division of which was free to vibrate, whilst the left-hand was muffled by a piece of cloth, the object of which was to damp or stop the string, which it did the instant the finger was taken off the key. The touch of the clavichord was peculiar, partaking both of the harpsichord and the organ; in other words, both *struck* and *pressed*, and the pressure could be so varied as to produce a kind of trembiant effect. The tones were feeble, soft, and melancholy, and better suited to the student, the composer, or the solitary, than any purposes of social amusement.

The action of the square piano forte, on its first introduction, consisted of a *key*, a *lifter*, a *hammer*, and a *damper*. The key was the same as that of the clavichord. The lifter was a brass wire, with a piece of hide leather as a head, which was covered with a piece of soft leather as a finish. This lifter, when in motion, struck the hammer against the string, and thus produced the tone of the instrument. The damper followed the performer, and stopped the vibrations as quickly as the finger was removed from the key. The tone of this piano-forte was thin and wiry, the hammer having only one slight covering of sheep-skin leather upon it. The subsequent improvements in the square pianc-forte down to the present day have consisted chiefly in the application of sundry small pieces of mechanism, called the *hopper*, the *under-hammer*, and the *check*, to improve the tone.

Some piano-fortes have seven octaves; but the usual number in the best instruments is six and a-half; in others six, or five and a half. The strings of the early piano-fortes were partly of steel and partly of brass, the treble notes of steel, and the lower notes of brass; a few of which, in the bass, were over-lapped or covered, rather open, with plated copper wire, to give them more gravity, according to the length attainable in the instrument. But modern piano-fortes have steel wire throughout with about an octave in the bass closely lapped with unplated copper wire. The strings which are now used in piano-fortes are considerably larger than those which were formerly used; the advantages of which are durability and firmness. Almost all the wire employed for this purpose in England is made by one firm near Birmingham; it requires especial care in the manufacture. *Stops* and *pedals* are used in various degrees in piano-fortes; the stops are moved by hand, to alter the position of the dampers used against the strings; the pedals are moved by the feet for an analogous purpose.

The upright piano-forte was, doubtless, taken from the upright harpsichord; it was invented by Mr. Hancock. The next novelty was the invention of Mr. Hawkins, who constructed an upright instrument with a detached sound-board in an iron frame, and the whole was so arranged as to be able to meet the atmosphere with compensating powers. In the bass, it had spiral or helical strings, by which length was gained; and, in the treble, three octaves of equal tension were accomplished by a uniform size of wire. The cabinet piano-forte and the piccolo piano-forte were two other forms in which the strings were placed vertically: the minor changes in these two varieties have been very numerous.

A laudable attempt has been made within the last year or two to construct piano-fortes which, while well made and of good tone, shall be comparatively cheap on account of being made of plain materials. No efforts, however, can make this a cheap instrument; the mechanism is too intricate and delicate for us to hope to realise "piano-fortes for the million," so far as price is concerned.

PIAZZA. Although in the Italian language a piazza signifies merely an open place, it is employed by us to denote a covered ambulatory, whether formed by columns or arches, in the lower part of a building; such cloistered walks being very common in the *piazze*, or public squares, of Italian cities, as that of St. Mark's at Venice, &c.

PIER, is the general name for the solid spaces between a series of openings in a wall, whether windows or arches; but in its technical meaning the term is more particularly applied to the pillar-like masses of masonry or brickwork from which arches spring, rising from the impost capping the pier, and which generally consists of a series of mouldings, although sometimes it is merely a plat-band, and occasionally the impost is omitted altogether, especially in rusticated basements. In many instances columns are substituted for piers, placed either singly or in pairs; and the arches spring either immediately from their capitals or from an entablature over them. There are again many examples in which both piers and a lesser order or suborder of columns are employed, the latter being insulated on each side of the pier, and their entablature forming the impost from which the arches spring.

The term pier is also applied to the solid masses supporting the arches of a bridge; with the exception of the extreme ones, which are distinguished by the name of abutments. The term is also applied to a mole or jetty carried out into the sea, whether intended to serve as an embankment to protect vessels from the open sea, or merely as a landing-place; for which latter purpose suspension chain-bridges are now frequently employed.

PIGS. The commercial value of swine is very considerable; for besides the flesh considered as an article of food, the skin, the bristles, and other parts of the animal are applied to many useful purposes. In 'Frazer's Magazine' for October, 1850, is given a lively account of the traffic which these animals occasion in one of the newly-formed cities of the United States; the paper has the usual rattling tone of a Magazine article; but there is internal evidence that the statements are trustworthy respecting the varied purposes to which the slaughtered animals can be applied, in a district where the supply is abundant.

That Ireland depends greatly on pigs 'to pay the rent' is well known. A very large proportion of the pigs reared in Ireland find their way either alive or cured into the English market. This transit has increased to an astonishing extent since the Union. In 1801 there were only 2000 pigs sent from Ireland to England; in 1805 it was 6383; in 1813 it was 14,521; in 1821 it was 104,501. In this last named year steam navigation began to tell in the matter, by lessening the expense of freight. By the year 1837 the number rose to 700,000. It is difficult now to form a judgment of the number, for the trade between the two countries is in most cases assimilated to a coasting trade. The small farmers of Ireland mostly sell their pigs to jobbers or dealers who go round the country, and who either drive the pigs at once to the shipping ports, or sell them to third parties who fatten, slaughter and cure the pigs for the bacon market. The year 1847 was not a good year for taking any averages in Ireland; but in that year it was found there were, living in all the farms of Ireland, 622,459 pigs. Pigs are plentiful in Ireland in good years; and it was well ascertained that the number in the calamitous 1847 was far below the average.

The swine and hogs imported into Great Britain from foreign countries in the last three years were:—

Year.	No. Imported.
1848	2,119
1849	2,653
1850	7,287

In fact, we are almost exclusively dependent on Ireland for such of our pigs, pork, and bacon as is not the produce of our own island.

The pigs sold at Smithfield yearly average about 40,000; the selling price presenting a usual average of about 30*s*. The dead pigs sold in Newgate Market annually give an aggregate weight of about 110,000 to 120,000 stone of 8 lbs., besides 15,000 sucking pigs. At Leadenhall Market the weight amounts to the large quantity of 500,000 stone. The Leadenhall butchers also slaughter about 30,000 pigs annually.

PILE ENGINE is a machine by which a heavy mass of iron is raised to a considerable height in the air; the mass being then allowed to fall by gravity on the head of a pile, the momentum acquired by the descent forces the pile into the ground.

Such an engine is employed in driving piles for the support of the sleepers or horizontal timbers on which are built the piers of bridges, the revetments of the ramparts of fortresses, or any other heavy mass of brick-work or stone-work when the soil is not sufficiently firm to carry the structure. Piles are also thus driven in order to form cofferdams in rivers, preparatory to the construction of piers or the faces of quays, basins, &c.

The most important improvement in pile-engines is the steam-hammer of Mr. Nasmyth. The principle of this most powerful instrument consists in having a small steam engine so connected with the ram or hammer, that after the latter has fallen by its own gravity, it is raised again by the action of steam. The saving of the time by the use of this machine is very great, and the invention is one of singular importance in engineering. It is applicable to the forging of anchors, and other works, where powerful blows are to be given.

A very remarkable principle has been introduced within the last few years in pile-driving: it was invented by Dr. Potts, and has been extensively applied by Stephenson, Brunel, and other engineers. In the ordinary process the power is applied to the pile; but in Potts' method the power is applied to the ground itself. The pile is hollow, and is placed perpendicularly over the spot where it is to be sunk; it is made air-tight on the top by fixing a cast iron plate upon it. A tube passes through this plate or cover, and connects the hollow of the pile with an air-pump. When the air is drawn out of the hollow centre, the sand or gravel is sucked up into it, by atmospheric pressure, and the metallic pile is facilitated in its descent. In some cases this operation has been conducted on an enormous scale. A bridge has lately been built by Messrs. Fox and Henderson over the Shannon for one of the Irish railways. It is supported on Dr. Potts' hollow piles. Each pile is ten feet in diameter; and these enormous masses were sunk into a clay soil with astonishing rapidity, by withdrawing the air from the interior of the pile.

PIMENTO, is the produce of *Eugenia Pimenta*, a tree native of the West Indies, but cultivated almost exclusively in Jamaica, thence called Jamaica Pepper. The unripe two-seeded berries, which are about the size of a pea, are dried by frequent turning in the sun, by which their colour is changed from green to brown or grayish-brown. The shell is very brittle, about the thickness of a card, and encloses two seeds, which are roundish, dark brown, somewhat shining, and having a weak aromatic taste. The shell possesses an agreeable clove-like taste and smell. Two kinds are met with in commerce, English and Spanish, of which the former is the better. About 20,000 cwts. of Pimento are imported yearly.

PIN MANUFACTURE. The first thing to be done in the manufacture of pins by the hand method is to reduce a quantity of brass wire to the requisite size. This is generally done in the pin factory, as the wire is received of larger diameter than necessary. It is performed in the usual manner of wire drawing; and the wire is then made up into coils of six inches diameter, and any dirt or crust which may be attached to the surface is got rid of by first soaking the coils in a diluted solution of sulphuric acid and water, and then beating them on stones. The next process is to straighten the wire; after which it is cut into pieces, each about long enough for six pins. These latter pieces are then pointed at each end, in the following manner—The person so employed sits in front of a small machine, which has two steel wheels or mills turning rapidly; of which the rims are cut somewhat after the manner of a file, one coarse, for the rough formation of the points, and the other fine for finishing them. Several of these pieces are taken in the hand, and by a dexterous movement of the thumb and fore-finger are kept continually presenting a different face to the mill against which they are pressed. The points are then finished off by being applied in the same manner to the fine mill. After both ends of the pieces have been pointed, one pin's length is cut off from each end, when they are repointed, and so on until each length is converted into six pointed pieces. The stems of the pins are then complete. The next step is to form the head, which is effected by a piece of wire called the mould, the same size as that used for the stems, being attached to a small axis or lathe At the end of the wire nearest the axis is a hole, in which is placed the end of a smaller wire, which is to form the heading. While the mould wire is turned round by one hand, the head wire is guided by the other, until it is wound in a spiral coil along the entire length of the former. It is then cut off close to the hole where it was commenced, and the coil taken off the mould. When a quantity of these coils are prepared, a workman takes a dozen or more of them at a time in his left hand, while with a pair of shears in his right he cuts them up into pieces of two coils each. The heads, when cut off, are annealed by being made hot and then thrown into water. When annealed, they are ready to be fixed on the stems. In order to do this, the operator is provided with a small stake, upon which is fixed a steel die, containing a hollow the exact shape of half the head. Above this die, and attached to a lever, is the corresponding die for the other half of the head, which, when at rest, remains suspended about two inches above the lower one. The workmau takes one of the stems between his fingers, and dipping the pointed end into a bowl containing a number of the heads, catches one upon it and slides it to the other end; he then places it in the lower die, and moving a treadle brings down the upper one four or five times upon the head, which fastens it upon the stem, and also gives it the required figure. There is a small channel leading from the outside to the centre of the dies, to allow room for the stem. The pins are now finished as regards shape, and it only remains to tin or whiten them. A quantity of them are boiled in a pickle, either a solution of sulphuric acid or tartar, to remove any dirt or grease, and also to produce a slight roughness upon their surfaces, which facilitates the adhesion of the tin. After being boiled for half an hour, they are washed and then placed in a copper vessel with a quantity of grain tin and a solution of tartar; in about two hours and a half they are taken out, and after being separated from the undissolved tin by sifting are again washed; they are then dried by being well shaken in a bag with a quantity of bran, which is afterwards separated by shaking them up and down in open wooden trays, when the bran flies off and leaves the pins perfectly dry and clean. The pins are then papered for sale.

The drawing and cutting the wire, the cutting of the heads from the coils, and the tinning, are performed by men; the other operations by women and children.

Machines have been invented, and partially employed for some of the processes; but most pins are made by the hand method.

PINE TREE. Under ABIES is given a brief description of some among the many varieties of Fir trees. We will here glance at some of the more prominent uses of the Pine, which has many points of similarity to the fir.

In respect to food the pine and fir do not render much service, at least in European countries. The *pine apple* is a misnomer; it is the fruit of another kind of plant, and has obtained its name from a certain resemblance to the cone of a pine tree. The Romans used the pine cones to flavour their wine; and some modern nations do the same. The Laplanders grind the inner bark of the Scotch pine into a kind of coarse flour, to make bread. Pine meal and oatmeal, mixed into a dough, and baked in a pan or plate, are said to make tolerable cakes. The young shoots are eaten in Siberia. Chips of pine have sometimes been used as a substitute for hops. The kernels of the fruit of the stone pine are pleasant eating, and are dished up in various ways in France and Italy. Of the Cembra pine, the kernels yield an oil, and the shell of the kernel yields a red dye. *Spruce* and *spruce beer* are made in the following way:—Twigs of the spruce fir are fastened into a bundle, and boiled in a copper until the bark separates. While this is doing, a given weight of oats is roasted on a hot plate, with sea biscuits or slices of bread. These ingredients are then boiled with the twigs for some time. Sugar or molasses is added; and the liquid is tunned off, leaving all the solid ingredients behind; a little yeast is added, and spruce beer is the result. In England spruce beer is made from *essence of spruce*, which is prepared in America from the young twigs.

As a timber tree, it is scarcely possible to enumerate all the uses of the pine and fir. Many of them are mentioned under ABIES. One species yields long straight timbers for the masts of ships; another is available for part of the hull; a third for flooring boards in a house. It is of white pine that the three magnificent American bridges are constructed, at Philadelphia, Trenton, and Boston.

It would suffice to take the Norway spruce fir as an example of the numerous uses which these trees subserve, in addition to those in which the timber is employed. When burned it yields valuable fuel and charcoal; the ashes furnish potash; the bark is used in tanning; the buds and young shoots yield spruce beer; the cones, boiled in whey, are used as a remedy against the scurvy; the young shoots are used as fodder for live stock in many countries; the floors of rooms and the pathways to churchyards are strewed with the young green tops in Sweden; the inner bark is made into baskets in Sweden and Norway; the long and slender rootlets are used as cords.

The pine and fir yield many remarkable substances derived from the juice or sap of the tree. Among these are *resin*, *turpentine*, *tar*, *pitch*, *lamp black*, &c. Their relation to each other may be stated as follows:—turpentine is the juice of the living tree; resin is a solid residue obtained from the turpentine; spirit of turpentine is the clear liquid which results when the resin is removed from turpentine; tar is the juice of the dead tree; and lampblack is the soot obtained by burning the above. These substances are described under their proper headings.

PINK. There are many varieties of pink colour employed as pigments by artists and painters; but there are also some which, though bearing this name, have not the tint which is usually known by the name of pink. *Brown pink* is a yellow pigment, prepared from French berries, pearlash, fustic, and alum. *Dutch pink* has a golden yellow colour; it is prepared from French berries, turmeric, alum, and whiting or starch. *Rose pink*, which has a roseate hue, is obtained by mixing whiting with a decoction of Brazil wood and pearlash. *Pink dye*, used as a cosmetic and for tinting silk stockings, is made from safflower, subcarbonate of potash, spirit of wine, and lemon juice. *Pink saucers* used by artists, are small saucers on the interior surface of which a layer of pink colour or paint is deposited; the colour is made from safflower, carbonate of soda, French chalk, and solution of tartaric acid; a red powder is produced, which is applied to the saucer with gum.

PIPES. Pipes, tubes, or cylinders are made in various ways, according to their size and material. The large iron cylinders for steam engines, hydraulic machines, and other engineering works, are cast in sand moulds, in the manner described in FOUNDING. Stone cylinders and pipes are cut by the aid of machinery, as noticed under STONE WORKING. Glass pipes are coming extensively into use for draining and for other purposes; they are produced by a combined process of blowing and drawing, something like that by which barometer tubes are made [BAROMETER]. Lead pipes are made in three or four different ways [LEAD]; and those of copper in two or three [COPPER MANUFACTURE]. Wooden water pipes (now almost superseded by iron) are made by boring out the centre of a tree-trunk; and some other kinds of tubes are bored out of the solid [BORING]. TOBACCO PIPES are described in a later article.

PISTON. [AIR-PUMP; HYDRAULICS; STEAM ENGINE.]

PITCH. [TAR.]

PIX, TRIAL OF THE. As a security for the integrity of the coinage, it is required that, before the master of the mint can receive his 'discharge,' or an admission that his duties have been properly performed, the coins should be submitted to a trial by jury. This final examination is technically called the *Trial of the Pix*, from the box in which the coins, which have been selected for that purpose, are contained. They are secured by three locks, the keys of which are respectively in the custody of the warden, master, and comptroller of the Mint. Newspaper readers may have remarked that there was a trial of the pix in March, 1851. The important operation of coining is briefly described under MINT.

PLANE TREE. This Asiatic tree is most valued for its ornamental appearance; but it is not without its economical uses. Its timber is fine-grained, hard, and well suited to such kinds of joiners' work as do not require strength; for which its brittleness renders it ill suited. The *occidental* or western plane, as distinguished from the *oriental* or eastern plane, is a less beautiful tree, and the timber less valuable.

PLANING MACHINERY. The first attempt to economise labour by means of planing machinery was made by General Bentham, who obtained a patent in 1791 for a contrivance by which large planes, wide enough to take the whole width of a plank at one stroke, and supplied with apparatus for directing their course, regulating the depth to which they could cut, and, generally speaking, for superseding the necessity of skill and judgment on the part of the operator, might be worked either by mechanical power or by manual labour. The improved principle, now generally adopted, was introduced in Bramah's patent of 1802. In a beautiful machine which he constructed for the Woolwich Arsenal, the wood is placed upon a carriage, and drawn by hydraulic power under the lower surface of a rapidly revolving disk or mill, to the face of which a series of planes or cutting instruments are attached, which, acting upon the wood in quick succession, bring it to a very smooth and even surface.

Immense saving of labour, accompanied with a corresponding improvement in accuracy has been effected by the application of planing machinery to the levelling of iron and other metals, in lieu of the cold chisel and the file, worked by hand. In some instances this has been done on the principle of Bramah's machine above referred to; but more generally the planing of iron is effected by a stationary cutter, the iron being brought under it by a rectilinear motion. For this purpose it is not usual to employ wide cutting instruments, as for wood; but a narrow tool, cutting a mere line of the surface at once, is brought into contact with all parts of the surface to be levelled in succession.

PLANISPHERE. A planisphere, as now usually constructed, is an instrument for finding the position of the heavens at any one moment, much more easily used than the celestial globe, and very much less expensive. A circular disk of pasteboard, on which the stars visible in our latitude are laid down, turns on a second disk, round which are the days of the year on one circle, and the hours of the day on another. A third and hollow disk turns upon the same pivot, the hollow part being so cut that the portion of the heavens which it shows is precisely that which is visible at one time in the latitude of the instrument: the points of the compass are marked round the rim of the hollow disk or of the horizon. The effect is that by setting the disk which contains the stars to the day of the year, and the hollow disk to the hour of the day, the part of the heavens visible at that day and hour is distinctly shown. The time at which any star rises, culminates, and sets can be found.

PLANTAIN. The plantain is the fruit of the *musa sapientum*, and is eaten to a most remarkable extent by the inhabitants of the torrid zone. From its nutritious qualities and general use, it may, whether used in a raw or dressed form, be regarded rather as a necessary article of food than as an occasional luxury. In tropical countries the plantain is one of the most interesting objects of cultivation for the subsistence of man. Three dozen fruits will maintain a person, instead of bread, for a week, and appears better suited to him in warm countries than that kind of food. Indeed the plantain is often the whole support of an Indian family. The fruit is produced from among the immense leaves in bunches, weighing 30, 60, and 80 lbs., of various colours, and of great diversity of form. It usually is long and narrow, of a pale yellow or dark red colour, with a yellow farinaceous flesh. But in form it varies to oblong and nearly spherical; and in colour it offers all the shades and variations of tints that the combination of yellow and red, in different proportions, can produce. Some sorts are said always to be of a bright green colour. In general, the character of the fruit to an European palate is that of mild insipidity; some sorts are even so coarse as not to be edible without preparation. The greater number however are used in their raw state, and some varieties acquire by cultivation a very exquisite flavour, even surpassing the finest pear. In the better sorts the flesh has the colour of the finest yellow butter, is of a delicate taste, and melts in the mouth like marmalade. In the West Indies, plantains appear to be even more extensively employed than in the Eastern world. The modes of eating them are various. The best sorts are served up raw at table, as in the East Indies, and have been compared for flavour to an excellent reinette apple after its sweetness has been condensed by keeping through the winter. Sometimes they are baked in their skins, and then they taste like the best stewed pears of Europe. They are also the principal ingredient in a variety of dishes.

The *Banana* of hot countries is a mere variety of the plantain, distinguished by being dwarf, with a spotted stem. Botanists call it *Musa Paradisiaca*, in allusion to an old notion that it was the Forbidden Fruit of Scripture.

PLANTING and PLANTATIONS. Planting is the operation of placing in the soil the roots of a plant which has been previously removed. The manner of performing the operation may be reduced to one general principle; that of placing the roots in the soil so as to imitate as closely as possible the position which they occupy when growing naturally. The excavation for the reception of the roots of a plant should be considerably larger than those roots will traverse when extended at the time of planting. It should be as wide at bottom as at top. The bottom should be more or less convex, and the depth such as to admit of the roots being covered to the extent observed in undisturbed seedling plants of the same species; that is to say, the upper part of the root should only be just covered. The lower roots should be regularly disposed over the convex bottom of the excavation, and carefully strewed with some of the finer portion of soil, over which the other roots may be spread. More soil should then be carefully rather than forcibly introduced. A plentiful watering should be given when the soil is nearly all filled in; and after the water has subsided, so as not to stand above the surface, the latter should be covered with the rest of the soil.

Plantations are generally planted thick in the first instance, and with various species of trees. Larch, Scotch fir or pine, mountain ash, &c., are interspersed amongst the hard wood for shelter, or as nurses. Too close planting produces weak drawn-up timber, in consequence of the tops only receiving a due share of light. If, on the contrary, trees are planted at too great a distance from each other they are inclined to ramify into large limbs and spreading tops, with a stem short but much thicker than where the space admits of less expansion of foliage. If therefore very thick timber of no great length be required, wide planting is proper; but if tall timber be the object, the plantation must be moderately thick. The proper season for felling trees is when the sap is most at rest; the operation ought not to be performed at any other time, unless for firewood. With respect to oaks, the practice of barking in the spring and felling in the succeeding autumn is by no means unobjectionable, and on some accounts is decidedly inferior to felling in autumn or very early in winter without previous disbarking.

PLASTER OF PARIS. [CALCIUM; LIME.]

PLASTERING. The business of the plasterer, besides forming plain plastered ceilings and walls, also embraces the formation and fixing of ornamental cornices, centre pieces, and other similar ornaments.

In plastering a brick wall, the first thing observed is to secure a rough and porous surface to which the composition may adhere readily. In applying the plaster, the surface is first brushed free from dust, then wetted with water, and covered with a first coat of fluid stucco, applied with a coarse bristle brush; after which, before it is quite dry, the first coat of coarse mortar-like composition is applied. In plastering upon quarter partitions or upon the under surface of timber floors to form ceilings, a very different process is adopted. In both of these cases a surface is formed to receive the first coat of plaster by nailing to the timber quarterings, or to the joists in the case of a floor, narrow slips of wood called *laths*. This done, the first coat of plaster, consisting of what is called *coarse stuff*, which is a mortar of lime and sand mixed with ox or horse hair, to give it consistency, is applied with a peculiar kind of trowel, in such a way as to force the mortar through the narrow openings between the laths, behind which in consequence of its soft and wet state, it swells in such a way that, as it sets or hardens, it becomes firmly *keyed* to the laths, so that it could only be broken away in little bits, and by the application of considerable violence. This groundwork serves to receive any kind of plastering that may afterwards be applied.

PLATA, RIO DE LA. This noble South American river has one of the broadest æstuaries in the world. Through this æstuary the commercial produce of about one-fourth of South America is brought to the market of the world. It is therefore a great advantage to the countries from which the æstuary of the Plata receives its waters, that the rivers which flow into it offer less obstruction to navigation than is usual in large streams. These rivers are many of them large; the chief are the Paraná, Uruguay, Paraguay, Pilcomayo, Vermejo, Lavayen, Tarija, and Salado.

The same name of *La Plata* is given to a republic which covers an immense area, and the commerce of which finds an outlet at Buenos Ayres on the south shore of the æstuary. In respect to agricultural produce the republic may be divided into two regions, which are separated from each other by the Gran Salina. On the north of it they partake of the intertropical productions: mandioc, rice, Indian corn, and the cocoa plant are cultivated in most of the lower valleys; while in the more elevated tracts, tobacco and cotton succeed well, and are cultivated on a large scale. South of the Gran Salina the agriculture resembles that of southern Europe, except that no rice is raised; wheat and Indian corn are the principal crops, but barley and lucerne are also extensively grown, especially near Mendoza. The principal exchangeable wealth of the republic is derived from the herds of cattle. The number of heads is above 4,000,000, of which the province of Buenos Ayres alone is said to possess 3,000,000; they wander about in the pampas nearly in a wild state. The largest items in the list of exports consist of hides, hair, horns, tallow, and jerked beef.

Gold and silver occur in the Andes, and also in the Sierra de Cordova. Iron and lead are met with in small quantities. There is little coal; but salt is most abundant.

The most important branch of manufactures is that of *ponchos*, or oblong square pieces of woollen cloth, with a hole in the middle, to pass the head through; they are used by the gauchos and other people as cloaks; the finest are made of vicuna skins, in the town of Santiago del Estero. Some woollen fabrics for men and women's dresses are also made, as well as saddle-cloths. In some parts some coarse cotton-cloth was formerly made by the country-people for their own use, but this branch of domestic industry has been nearly abandoned since the introduction of British manufacture.

The internal commerce of the states is considerable, as most of them have some products which are either not at all or only to a small amount raised in the neighbouring states. The external commerce under Spain was very small; but it has greatly increased within the last few years. Trade is now carried on with all the principal countries of Europe, and with various parts of America. The value of the British and Irish produce and merchandise exported to the Argentine States, between 1836 and 1846, varied from 590,000*l.* to 990,000*l.* annually; and in 1849 it amounted to no less than 1,362,904*l.* The imports from the republic to Great Britain in the same year amounted to 1,392,445*l.*

The exports of the principal articles of produce from January to the end of November, 1850, were as follows, in 402 vessels of 88,762 tons:—Hides, ox and cow, salted, 687,367; ditto, dry, 1,514,965; ditto horse, dry, 47,194; ditto, salted, 127,619; Horns, ox and cow, 1,717,632; Tallow, 11,966 pipes, 24,738 boxes, and 80 serons; Wool, 16,414 bales, 3,262 serons, and 180 arrobas; Beef, jerked, 339,654 quintals.

PLA'TINA, or PLA'TINUM, is an important metal, which was first made known in Europe by Mr. Wood, assay-master in Jamaica, who met with its ore in 1741. Platina is separated from the sand and other matters with which it is mixed, by washing with a great quantity of water, from which the heavier parts of course subside, and these contain the ore in question. The ore of platina is composed of irregular rounded grains, which are sometimes flattened; they are of various sizes, often very small, and occasionally they exhibit traces of crystallisation; but these are probably derived from the presence of some other metal. The ore, which has a specific gravity of 17·33, contains traces of six or seven other metals; and the process of separation is one of great complication. The pure platinum has a grayish white colour, intermediate between silver and tin. When it is free from iridium, it is so very ductile that it may be drawn into very fine wire, not exceeding the 2000th part of an inch in diameter; it is also very malleable, and may be beaten into thin leaves. When perfectly pure, it is softer than silver, and it is susceptible of receiving a fine polish. Of all metals it is the least expansible. Its density varies from 19½ to 21½ times that of water. It suffers no change by exposure to the air, nor is it oxidized when heated in it. It does not under any circumstances decompose water.

It is infusible in the strongest heat of a smith's forge, but it may be melted by voltaic electricity or by the oxyhydrogen blowpipe. Of all metals, except iron and copper, it is the most tenacious: a wire of the diameter of $\frac{1}{15}$th of an inch, is capable of sustaining a weight of 274 pounds. Like iron, platina possesses the very valuable property of welding at a high temperature, and this enables us to form it into chemical vessels of great and daily use.

The uses of platina are numerous and important; but it is especially employed for forming vessels, not merely for chemical operations on a small scale, but for the concentration of sulphuric acid by manufactures. Some years ago as much as 1000*l.* was paid for a platina still for making certain acrid chemicals; the price being about a guinea an ounce; but it is now lower in value.

PLATING. [ELECTRO-METALLURGY; TIN MANUFACTURE.]

PLOUGH. The oldest forms of plough of which we have any description in ancient authors, or which are represented on monuments or coins, are very simple; a mere wedge with a crooked handle to guide it, and a short beam by which it was drawn, form the whole instrument. The light Hindoo plough, now in use in many parts of India, seems to differ little from the old model.

The different essential parts of a plough have certain names usually given to them. The *Body* of a plough is that part to which all the other parts are attached. The bottom of it is called the *Sole* or *Slade*, to the fore part of which is affixed the *Point* or *Share;* the hind part of the sole is called the *Heel.* The *Beam*, which advances forward from the body, serves to keep the plough in its proper direction, and to the end of it are attached the oxen or horses, which are employed to draw it. Fixed in the beam in a vertical position, before the point of the share, with its point a little forward, is the *Coulter*, which serves to cut a vertical section in the ground; while the point of the share, expanding into a *Fin*, separates a slice by the horizontal cut from the subsoil or solid ground under it. The *Mould-Board*, or *TurnFurrow*, is placed obliquely behind the fin, to the right or left, in order to push aside and turn over the slice of earth which the coulter and share have cut off: it thus leaves a regular furrow wherever the plough has passed, which furrow is intended to be filled up by the slice cut off from the land by the side of it, when the plough returns. The *Stilts*, or handles, of which there may be either one or two, as is thought more convenient, direct the plough by keeping it in the line required and at a regular depth in the ground. The single stilt appears to be the most ancient form.

Wheels are a modern invention in comparison with the other parts. They support the end of the beam, and prevent it from going too deep into the ground or rising out of it while the plough is going on. The greatest improvements introduced into modern ploughs are in the shape of the mould-board or turn-furrow, and the contrivances for regulating the line of draught so as to make the plough go at an equal depth, and cut off a regular slice of equal breadth, without any great force being applied by the ploughman who holds the stilts. The mould-board is either fixed on one side, or made so as to be shifted from one side to the other; in the first case half the furrow-slices lie on one side and half on the other, and there is of necessity a double furrow where they join. When it is desirable that the surface should be quite flat, and the furrow-slices all in one direction, the mould-board must be shifted at every turn, and a plough which admits of this is called a *Turn-Wrest Plough.*

Ploughs were formerly made of wood, having those parts covered with iron where the greatest friction takes place, the share and coulter only being of iron; but in consequence of the greater facility of casting iron in modern times, most of the parts are now made of this metal. The beam and stilts are still usually of wood, but even these are now sometimes made of wrought iron. The advantages of iron are, its durability and the smaller friction it occasions when once polished by use. The inconveniences are the additional weight of the instrument, and consequent greater friction of the sole. Recent experiments have proved this to be greater than was generally suspected. A great improvement has been introduced by making the points of the shares of cast-iron, which, by a mode of casting the lower surface on a plate of metal, makes one surface much harder than the other; and as the softer surface wears more rapidly, a sharp edge is always preserved. The different parts of a plough are now usually cast so that if any one fails or wears out, it can be instantly replaced, by moving a few screws or bolts. There is another advantage in having the essential parts of cast-iron. If any particular shape has been once discovered to be the best for any part, that shape is preserved without deviation in every plough made on the same pattern, and with respect to the turn-furrow this is of great importance. The stilts of the plough are mostly of wood; one will suffice for a light soil, but two are required for a heavy soil.

The shape of a plough must vary with the nature of the soil which it is to turn up. A light soil must be shovelled up; a mellow one may be turned over with any kind of mouldboard; a very stiff tenacious soil which adheres to any surface pressed against it, will be more easily turned over by a few points of contact which do not allow of adhesion. Hence the point and turn-furrow have been made of all imaginable shapes, and while one man contends for a very concave form, another will admit of nothing which is not very convex. The lighter the plough is, consistently with sufficient strength, the less draught it requires, all other circumstances remaining the same.

It does not fall within the province of this work to trace the circumstances which call for the varied modes of ploughing. They are numerous, depending both on the crop and on the soil. For some purposes the clod requires to be turned right over; for others, to be turned to a certain angle. Very little attention was formerly paid to the straightness of the furrows; but it is evident that every deviation from parallelism causes a defect in the contact of the slices, and a loss of force by the obliquity of the draught. Hence equal and straight furrows are a sign of good ploughing. One of the most useful operations in ploughing land is to cross the former furrows, by which means the whole soil is much more completely stirred; and if any part has been left solid without being moved by the plough-share, which is called a Balk, it is now necessarily moved.

As a means to enable the farmer to save hands and expedite the tillage of the land, ploughs have been contrived which make two or more furrows at once. When they are well constructed, they are very useful on light soils. If it is not required to go deep, and two horses can draw a double plough, there is a decided saving of power; but if it requires four horses nothing is gained. The double ploughs are therefore not much in use.

Deep ploughing is generally acknowledged to accord with the best husbandry, where the subsoil is dry naturally, or has been artificially drained; but some inconvenience may arise from bringing a barren subsoil to the surface, in trench-ploughing by two ploughs following each other in the same furrow. It has therefore been suggested to take off the turn-furrow from the plough which follows the first, so as to stir the subsoil without bringing it to the surface. This idea has been improved upon by constructing a *Subsoil-plough* of great strength, which will go very deep into the ground and stir the subsoil a foot or more below the bottom of the usual furrow.

The instruments which have been invented to save the time and labour required by repeated ploughings are very numerous. New ones are daily invented, and some are supported by wheels, which render them both lighter and more convenient. One of the most important of these instruments is the *Cultivator*, or *Scarifier*. [CULTIVATOR.]

It would be in vain to enumerate the various ploughs which have been invented and which are exhibited at the annual cattle and agricultural shows. The Essex plough, the Gold hanger plough, the Subsoil plough, the Surface plough; as well as those which are designated by the names of their makers, Ransome, Crosskill, Wedlake, Garratt, &c.—all have their respective points of excellence. There has recently been introduced a *hill-side* plough. Several forms of *steam-plough*, also, have been introduced; in which steam-power takes the place of horse power. A steam plough has been recently patented by Messrs. Calloway and Purkis of Putney. There are two ploughs attached to an endless chain which passes over two wheels; and these wheels are moved whenever the locomotive movement of the steam-engine takes place. The ploughing is effected transversely to the movement of the machine; and this movement is only just rapid enough to enable the plough to act upon new portions of ground when necessary.

PLUMBA'GO—*Graphite*, *Black Lead*. This substance occurs both crystallised and massive; but mostly in irregular nodules. It is found in various parts of the world. That of Borrowdale in Cumberland is of the best quality for what are called *black-lead pencils*; while the commoner sorts are used for making melting-pots, for diminishing the friction of machinery, and for protecting iron from rusting. That which is imported from the East Indies is remarkably soft. Plumbago conducts electricity, is infusible, and very difficult of combustion. It was at one time supposed that plumbago was a carburet of iron, but, in the opinion of Berzelius, it is a peculiar form of carbon, and that the substances which it contains are in a state of mixture merely and not of chemical combination.

Plumbago is found usually in primary or transition rocks. At Borrowdale it occurs in nests in a greenstone rock, which constitutes a bed in clay-slate. In Inverness-shire it occurs in gneiss; at Arendal in Norway, in quartz rock; and in the United states, in felspar and mica-slate, but always in primary rocks.

The Borrowdale mine is interesting, and till lately supplied most of the material for English pencils. It is about six miles from Keswick. It is about half way up a mountain two thousand feet high, somewhat difficult of access. Some of the nodules procured are pure plumbago; while others have particles of iron ore adhering to them. From the small supply of the material, and the high price which it commands in the market, the mining operations are conducted with much precaution and even secrecy. In the last century persons contrived to rob the mine of much treasure with impunity; and this led to a very stringent set of rules for working. The mine is now nearly exhausted.

The manufacture of black-lead pencils from this substance is noticed under PENCILS. The cedar of which the cases are formed is sawed into long planks, and subsequently into smaller rods; grooves are cut out by means of a fly-wheel, of such a size as to receive the black-lead. The pieces of mineral are cut into thin slabs, and then into rods; these rods are inserted in the grooves, and the two halves of the case are glued together.

A material for pencils is very much used, especially in France, made of plumbago mixed up with very fine clay. Any required degree of hardness can be given to the composition by varying the proportion of the ingredients. Wolff's "purified black-lead pencils," sold in London, have thirteen different degrees of hardness. Mr. Brockedon and other persons also manufacture pencils in which the *hardness* and the *blackness* vary in any desired degree.

PLUMBLINE. When a heavy body suspended by a flexible string is at rest, the line passing through the point of suspension and the centre of gravity of the weight is in the direction in which gravity acts. The *Horizon* is a plane perpendicular to this line, and the *Zenith* is that point of the heavens marked out by the continuation of the line upwards. If the string be perfectly flexible, it will coincide with the theoretical line above described.

The plumbline is used in the arts. In levelling and in astronomical instruments, it has in most cases been superseded by the spirit level or observation by reflection.

PLUSH. This is a kind of velvet, having a *nap* or *shag* on one surface. It consists of a double warp and a single weft: one of the warps being so thrown up to the surface as to form the loose nap. Very frequently the upper warp is made of goat's or camel's hair; so that when woven and cut the surface presents something of a fur like appearance. The mode of producing fabrics of this kind, whatever may be the materials employed, is noticed under VELVET.

PLYMOUTH DOCK YARD. Plymouth is one of the most important towns in the west of England, in an engineering and commercial point of view. The Breakwater, the Eddystone lighthouse, and the Royal Dock Yard, all tend to give importance to the place. The first two of these are briefly described in earlier articles. [BREAKWATER; LIGHTHOUSES.]

The dockyard is more properly at Devonport; but the two towns form one for all practical purposes. The dock yard extends about half a mile from north to south, by a quarter of a mile from east to west, and in it are employed about 3000 persons. There are six building slips for vessels of various dimensions; three docks for fitting and repairing first-rate vessels; and two for smaller vessels. The building slips are covered with immense roofs of iron, copper, or zinc. On these slips 27 war ships were built between 1828 and 1848. There have been lately about 6000 loads of timber used annually in the dock yard. A new basin is now being constructed, blasted out of the solid rock, at an estimated expenditure of 345,000*l*. There are two rope houses, 1200 feet long. A chain cable storehouse has lately been built, at a cost of 40,000*l*. About 2000 tons of hemp are annually used in the dock yard, for ropes and other purposes. The rigging-house is an extensive building, 500 feet in length. The Smithery is an extensive building, in which Nasmyth's steam-hammer performs wonders in anchor-forging. In the engineering or mill-wright establishment, the planing, turning, punching, drilling, and cutting of metal is carried on. In the saw-mill timber is cut into various forms and sizes by steam-power. There are mast-houses, boat houses, sail lofts, storehouses, and all the works of a great naval yard.

At Keyham Point, a short distance northward of the dock yard, new steam docks are now being constructed on a magnificent scale. They will comprise large basins and docks for the reception of steamers, and factories for conducting every kind of repair which the steamers may require. There will be three-quarters of a mile of granite quays to the basins. Up to the present time the sum expended in these works has been about 700,000*l*.; and at least half a million more will be required to finish them.

There are many other government establishments at Plymouth and Devonport which give rise to much industrial and commercial activity. But there is also much trade and commerce independent of those establishments. Considerable trade is carried on with the West Indies, the Baltic, and the Mediterranean; and coastwise with London and other places. There is an active fishery of hake and whiting. Granite, limestone, slate, and marble, are quarried in the neighbourhood.

The Plymouth Dock Company are forming basins, docks, and quays, to accommodate the steamers on various mail routes which are proposed to be established there. The Cape mail steamers already start from Plymouth. The dock will be placed in immediate connection with the broad guage railway to London.

POLAND. Whether regarded as a kingdom, or as a mere province of the Russian Empire, Poland demands only a few words respecting its produce and commercial industry.

Though Poland is not distinguished by fertility, it produces more grain, hemp, flax, and tobacco, than are required for its consumption, and it exports these articles to other countries. Wheat is only abundant in the hilly southern region: the principal species of grain which are cultivated in the other parts of the kingdom are rye, oats, and buckwheat; barley is also raised, but less extensively. Leguminous vegetables are much valued and their cultivation attended to. As a considerable part of the country is still covered with forests, timber constitutes an important article of export. The forests consist of oak, ash, lime-trees and birch, but chiefly of pine and fir. Several metals and minerals are abundant in the hilly region. Among the metallic ores are those of silver, iron, copper, lead, and zinc. Rock-salt, marble, and a little coal, are met with.

In the city of *Cracow* there are no manufactures of any importance except a few in cloth and woollens. Cracow is the chief depôt in Poland for Hungarian wines, salt, and wax, and is the central point of commerce between Poland and Hungary; but its trade, which is principally in the hands of Jews, is not extensive. At *Warsaw* the manufactures are of many different kinds, and the trade of the city is considerable, the vicinity of the Vistula being favourable to its developement. It is felt, however, that the mouth of the Vistula being in another country (Prussia), is a circumstance which greatly checks the commerce of Warsaw, owing to the restrictions in international commerce between Russia and Prussia. All the other towns in Poland are less in commercial and trading importance than Cracow and Warsaw.

POLARISCOPE. The phenomena of the Polarization of light are of so refined and delicate a character, that any description of a polariscope would be of little value, without such a notice of the phenomena as would carry us beyond the province of the present work. We will therefore merely state that a polarising apparatus, whether called a polariscope or by any other name, is a contrivance for exposing crystals and other translucent bodies to the action of light, with a power of giving rotatory movement to one or more parts of the apparatus.

POLYCHRO'MY is a modern term used to express the ancient practice of colouring statues and the exteriors of buildings. In Egypt it was at all times a universal custom to have recourse to colours in the decoration of architecture. As to the practice in Greece, it appears, from the remains of colour found upon antient monuments, that the colouring was strictly confined to the ornamental parts —to the friezes, the metopes, and the tympana of the pediments. In later times amongst the Romans, in the times of Vitruvius and Pliny, the practice seems to have degenerated into a mere taste for gaudy colours, and to have been very general, as we see in the ruins of Pompeii, where however, occasionally, the Arabesque decorations upon the walls of the courts in the larger houses are very elegant.

Polychrome sculpture was quite as general amongst the Greeks as polychrome architecture. The *acrolithic* and the *chryselephantine* statues both come under this head. In the latter style were many of the most remarkable productions of ancient art: the *Jupiter* at Olympia, and the *Minerva* at Athens, by Phidias; the *Juno*, at Argos, by Polyclētus, and the *Æsculapius*, at Epidaurus, by Thrasymēdes; and others described by Pausanias. In the flourishing period of Grecian art, custom seems also to have defined limits to this practice, for, except in the rudest ages, the figure itself was never painted, although it appears to have been sometimes covered with an encaustic varnish. The naked marble of the works of the greatest sculptors was not coloured; the colouring was confined to the lips, the eyes, the hair, the drapery, and the ornaments of the dress.

At the present day polychromy in architecture is advocated by many persons of taste. The encaustic painting of some of our interiors and the gorgeous splendour of the new House of Lords, are examples. The much discussed choice of colours by Mr. Owen Jones in the Palace of Industry bears on the subject of polychromic decoration.

POMATUM. The pomatums or *pommades* as they are called by the French, are so named because they were originally made of apples and lard. They are now made of various ingredients, and in various ways. For a considerable number of pomatums hogs' lard and beef suet are brought to a very fine state, melted and scented by causing odoriferous flowers to remain in the mixture for many hours. In another method the pomatum is spread into a layer upon which the leaves of scented flowers are placed, and removed daily until the mass is scented. Another mode is by adding fragrant essences to the pomatum. All these are manufactured on a very large scale in France; and the variety of flowers employed is considerable.

PONTINE MARSHES is the name of a low marshy plain in the Papal State, about 24 miles long by 10 broad. It is remarkable from the attempts made to drain it; somewhat analogous in character to those of the BEDFORD LEVEL. There is every appearance that this district, which is a basin nearly surrounded by hills, was once a gulf of the sea, which has been gradually filled up by alluvium from the mountains. Within the historical period it was a fertile district, containing towns, and a considerable population. Both under the Republic and the Empire great works were undertaken for the draining of these marshes; and the Appian Road traversed part of them to Terracina. Something has been done in modern times by the popes, from Boniface VIII. to Pius VI., and by Napoleon during the French occupation of the Roman States. Since that time all that has been done for the Pontine Marshes has been to maintain the drainage in the state in which Pius VI. left it, by keeping the canals clear and the dykes in repair. The greater part of the plain is covered with rich pastures, in which are fed numerous herds of horned cattle, and other parts of it are sown with rice, wheat and Indian corn, and afford rich crops. In the spring, before the great heat renders the atmosphere unwholesome, it has the appearance of a most delightful region. But, except the post stations along the high road, and some scattered huts here and there, there is no permanent population throughout the whole of the plain.

PONTOONS are vessels used in the formation of floating-bridges for military purposes. General Pasley has constructed pontoons in the form of canoes, with decks, each end being shaped like the head of a boat. They consist of light timber frames, covered, except the deck, with sheet copper; and each vessel is formed in two equal parts by transverse partitions, so that the demi-pontoons may be separated from each other when the bridge is to be conveyed on carriages by land with the army. When in the water, the parts are connected together by a rope, which passes through two perforations in the keel, near the place of junction, and by a rectangular frame of wood, which is laid along the deck, and attached to it by lashings.

Sir James Colleton, some years since, invented pontoons of wood of a cylindrical form, some of which have been occasionally employed in experimental operations; and cylindrical pontoons of tin, which were subsequently invented by Colonel Blanchard, have lately been introduced into the service. These last have hemispherical or conical ends. They possess the advantages of great lightness and buoyancy. The diameter of one of the cylinders is 2 ft. 6 in., and its length 22 ft. A rectangular frame, rather greater in length than the breadth of the intended bridge, is made fast, by ropes, longitudinally, on the surface of each of two cylinders placed parallel to one another at about 10 ft. asunder; and on these frames rest the baulks carrying the chesses, or planks, which form the road. Two pontoons, with their platform, constitute a raft; which, when the bridge is to be formed, are rowed to their stations in a line across the river, the lengths of the pontoons being parallel to the banks, and there anchored; the distances between the nearest pontoons in two rafts being equal to that between the two pontoons in each raft. Then each raft carrying the materials which are to make a platform over the water between itself and the next, such platform is laid down in a manner similar to that which is employed in laying down the platform of the raft; and from each of the extreme pontoons a like platform is extended to the shore of the river.

POPLAR TREE. There are several varieties of poplar tree, which render useful service to man, though not in so great a degree as many other trees. The timber of the *white* poplar is very light coloured, and is used in France and Germany for a variety of minor purposes. It makes excellent packing cases, because nails may be driven into it without causing it to split. It is used extensively by turners and cabinet-makers. The boards and rollers around which pieces of silk are wrapped in merchant's warehouses and in shops are made of this wood, which is adopted on account of its lightness lessening the expense of freight. It is much used for flooring-boards, for large folding-doors for barns, and for other building purposes. It is used as a substitute for lime-tree in musical instruments. Wooden dishes and casks are occasionally made of it. The timber of the *black* poplar is used for much the same purposes as the white. It is yellow, soft, and easy to work; and is preferred by cabinet-makers for many purposes. It is used for clogs, the soles of wooden shoes, bowls and other turner's ware, and in cart building. The *Lombardy poplar* produces wood less serviceable than that from the other varieties; but rafters, small beams, boards, &c., made of this wood and afterwards coated with tar, are found to be durable. The wood of the *Trembling poplar* or *Aspen* is white and tender; and is employed by turners; by coopers for herring casks, milk pails, &c.; by sculptors and engravers; by joiners and cabinet-makers; and by the makers of clogs, wooden shoes, butcher's trays, pack saddles, and a number of other articles.

As fuel, poplar wood is of inferior heating power; but it gives out its heat very quickly; the ovens of nearly all the Paris bakers are heated by this wood. The bark of the black poplar is employed in tanning leather; when pulverised it is eaten by sheep; and being very thick, light, and corky, it is used by fishermen to support their nets, and even as corks for bottles. The bark of the aspen forms the principal food of the beaver; it is also usefully employed in medicine.

In Sweden the leaves of the white poplar are eaten by cattle. The buds of the black poplar, macerated in boiling water, and afterwards bruised in a mortar and pressed, yield a fat substance which burns like wax and exhales a fine odour. The balsamic sap with which the buds are covered forms the basis of an ointment which was much prized in former times. The young shoots may be used in basket-making; and the shoots with the leaves on are sometimes used as brooms. The cottony substance or flock which surrounds the seed has been used in Germany and France as wadding; and it has also been occasionally manufactured into cloths, hats, and paper. The *Balsam poplar* yields a balsam from the buds; it is collected from the trees in spring, at which season it collects into drops on the points of the buds. In Siberia a medicated wine is prepared from the buds.

POPLIN. Among the varieties of woven goods in which silk and worsted or silk and woollen are used in combination, poplin is one of the best and most esteemed. *Tabinet* is one form of this material; and Ireland has been distinguished for the excellence of its poplins and tabinets. The demand is now small, as other kinds of textile fabrics have lately been more in favour; but the rich Irish poplins and tabinets, though employing only a small number of persons in their manufacture, maintain their high character.

POPPY. [Opium.]

PORCELAIN. [Pottery and Porcelain.]

PORCH is a general term for any projection forming a covered space immediately before the entrance to a building, open in front, and more or less inclosed at its sides. The distinction between a porch and a portico is, that, however important it may be as a feature, the former appears only a subordinate part of the building to which it is attached; whereas the other may be the whole of a front. In Norman architecture, the porches or portals are little more than a modification of the similar features in Byzantine and Lombardic architecture. Of porches, strictly so called, there are few instances, either in Norman or Gothic architecture; there are often however spacious portals, which do not advance beyond the general plan of the building in front, but form entrances, deeply recessed and inclosed within the lower part of the structure. In ancient English domestic architecture, porches, properly so called, are frequent.

POROSITY is a property common to all the bodies of nature, at least we know none in which the particles are contiguous to one another. In some, as sponge and cork, the pores are visible to the eye, and in others they may be rendered so by the aid of a microscope. In bodies whose pores are not thus manifest, the existence of the intervals between the molecules is proved by various circumstances. Thus water or mercury being contained in an open vessel of wood over the exhausted receiver of an air-pump will, by the pressure of the atmosphere, be forced through the wood, and fall thence in a shower: liquids also are frequently filtered by being made to pass through the pores of paper; and in the Florentine experiment, for determining whether or not water is compressible, the fluid was by pressure forced through the pores of the vessel of gold in which it was contained. Again, the porosity of bodies is inferred from their elasticity, and the sounds which are heard when the molecules are in a state of vibration: also, in transparent bodies (and the most dense metals are, when rendered sufficiently thin, found to be transparent), it is inferred from the fact that the particles of light pass through them, or that the vibrations of an æthereal fluid take place among the molecules. Finally, the porosity of bodies is proved from the fact that they suffer contraction of volume by being exposed to cold and by mechanical compression, since such contractions can only take place in consequence of the particles being forced closer together than they are in the usual states of the bodies.

PORPHYRY. A large number of rocks of igneous origin, both very ancient and comparatively modern, are thus designated; but properly speaking, a particular structure is indicated by it, and not a definite rock or family of rocks. Felspar of a granular texture, without crystals imbedded, is claystone; with imbedded crystals of felspar it is porphyry. Hornblende, mixed with uncrystallised felspar, makes some greenstones; with imbedded crystals of felspar this becomes greenstone porphyry. Hence, by this mode of designation, we have pitchstone-porphyry, greenstone-porphyry, basaltic-porphyry, felspar-porphyry, and even so vague a term as trap-porphyry; and on the other hand, more correctly, porphyritic pitchstone, porphyritic claystone, porphyritic greenstone, porphyritic basalt, and porphyritic granite.

PORTCULLIS is an assemblage of several large pieces of wood, joined across one another like a harrow, and each pointed with iron at the bottom. They are sometimes hung over the gateways of old fortified towns, ready to let down in case of a surprise, when the gates could not be shut.

PORTFIRE is a composition consisting of saltpetre, sulphur, and mealed gunpowder, in the proportion of 6, 2, and 1, respectively, mixed together, and rammed or driven into a paper case of a cylindrical or conical form, and less than an inch in diameter. Portfire is used for firing artillery or mines; and a piece sixteen inches long will burn from twelve to fifteen minutes.

PORTICO. Originally applied without distinction to colonnades and covered ambulatories, this term is now limited to signify a sheltered space inclosed by columns at the entrance to a building; and unless otherwise expressed, roofed with a pediment, like the end or front of a Grecian temple. The term as now restricted, answers to the *Pronáos* of such a temple. Porticos are described according to the number of columns in front, viz., tetrastyle, hexastyle, octastyle, &c. They are called prostyle when, as generally happens, they project from the main building. Such as are *in antis*, and recessed within the front of the building, are technically called *loggias*.

PORTLAND STONE. [DORSETSHIRE; STONE FOR BUILDING.]

PORTLAND VASE. This beautiful specimen of ancient art is one of the choicest treasures deposited in the British Museum. The time of its production is now unknown; but it is presumed to be the work of a Grecian artist. The first information we have respecting it is that about the middle of the 16th century the vase was found enclosed in a marble sarcóphagus, within a sepulchral chamber, under the eminence called the Monte del Grano, about two miles and a half from Rome on the road to Frascáti. This sepulchral chamber appears to have been the tomb of the Emperor Alexander Sevérus and of his mother Julia Mammæa; and the vase was probably a cinerary urn belonging to the sepulchre. The elegance of form and the admirable workmanship of the vase procured for it a place in the palace of the Barberini family at Rome, where it remained more than two centuries; after which it became the property of Sir William Hamilton, from whom it passed to the Duchess of Portland. In 1810 it was deposited in the British Museum by the Duke of Portland. On Feb. 7, 1845, a young man, a visitor at the museum, wilfully broke the vase into several pieces by throwing a stone at it. The offender was secured, and punished by imprisonment. He seemed to be influenced by no other motive than a morbid desire for notoriety. The fragments of the vase were afterwards joined together, and the work restored far more successfully than might have been anticipated.

This vase was said by Montfaucon to be formed of a precious stone; but subsequent examinations has shown the material to be dark blue glass, relieved by figures and devices in white enamel. It is about ten inches in height.

PORTSMOUTH DOCKYARD. The excellence of Portsmouth Harbour attracted the notice of the Romans, who established a station at Porchester on its northern shore. Portsmouth was a place of importance in the time of Henry I., and there was a naval station there in the reign of John. The dockyard is the largest in the kingdom, covering from 115 to 120 acres. It includes a rope-house, anchor wharfs, an anchor forge, a copper-sheathing foundry and mills; block, mast, sail and rigging, and other store-houses; a grand basin, in which vessels are received with all their standing and running rigging to be repaired; building slips, docks for repairing —in a word, all that is requisite for the construction, equipment, armament, and repair of vessels. There are also residences for the port-admiral, the admiral superintendent, and other officers of the yard, a chapel, a school for naval architecture, and other buildings. The block-machinery, invented by the late Sir M. Isambert Brunel, is an admirable manifestation of mechanical skill; it is impelled by steam. [BLOCK-MACHINERY.] Adjacent to the dockyard is the spacious and well furnished gun wharf and its connected buildings. It is the grand depôt for cannon, shot, and every description of ordnance stores.

The trade of Portsmouth, which is considerable at all times, but especially in time of war, depends much upon the expenditure connected with or caused by the naval station and dockyard, and is of a very miscellaneous character. There is a considerable import of cattle from the Isle of Wight and from the west of England. Corn and provisions are brought in from Ireland, eggs from France, timber from the Baltic, and wine is imported direct from the Continent. Steam communication is kept up with the Isle of Wight, Southampton, Plymouth, and Havre. The number of vessels registered at the port is about 150.

PORTUGAL. The agricultural produce of this country includes corn, Indian corn, rice, hemp, flax, honey, wax, plenty of fruit, especially excellent oranges and lemons, almonds, and abundance of good wine. The sea along the coasts and the rivers abound with fish, which is a great article of food with all classes. Sea-salt is collected in various places, particularly in the lagoon of Setubal. The sheep supply abundance of wool, of which some is equal to that of the Spanish merinos in fineness. Portugal has mines of copper, tin, and iron, of which only some of iron are worked. The manufactured articles are coarse woollen cloths in Alentejo and Beira; linens in Minho, Beira, and Tras os Montes; silks at Campo Grande, near Lisbon, and also at Oporto and Braganza; jewellery at Lisbon and Oporto. There are glass-works at Marinha Grande; paper manufactories at Alemquer, Lisbon, and Guimaraens; potteries at Lisbon, Oporto, Coimbra, Beja, Estremoz, and Caldes; cotton manufactories at Alcobaça and Thomar; and tanneries in various parts.

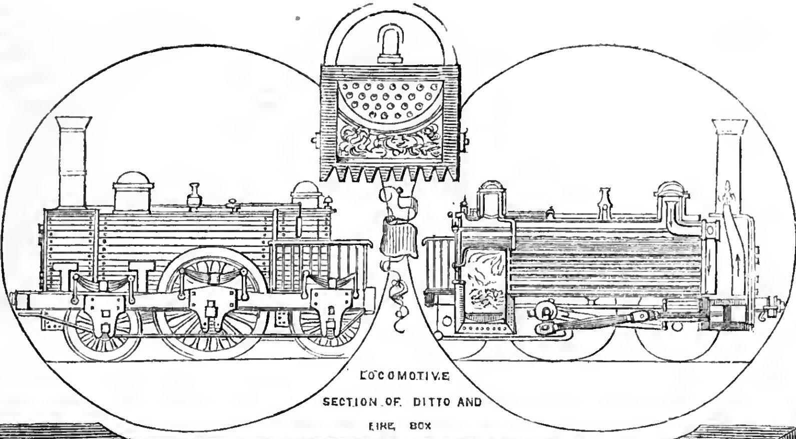
The foreign trade is principally in the hands of English merchants. Most of the Portuguese wines and other produce are consumed in England; especially the wines, of which no less than nine-tenths of the quantity sold to European countries are sent to England; this results from the prevalent taste for Port wine in England. The quantity of wine exported to England in the year 1847 was 2,883,896 gallons. The wine-produce of 1850 has been lately stated to amount to:—

First class wines		34,226	pipes.
Second „	„	18,908	„
Third „	„	19,864	„
Fourth „	„	12,346	„
		85,344	pipes.

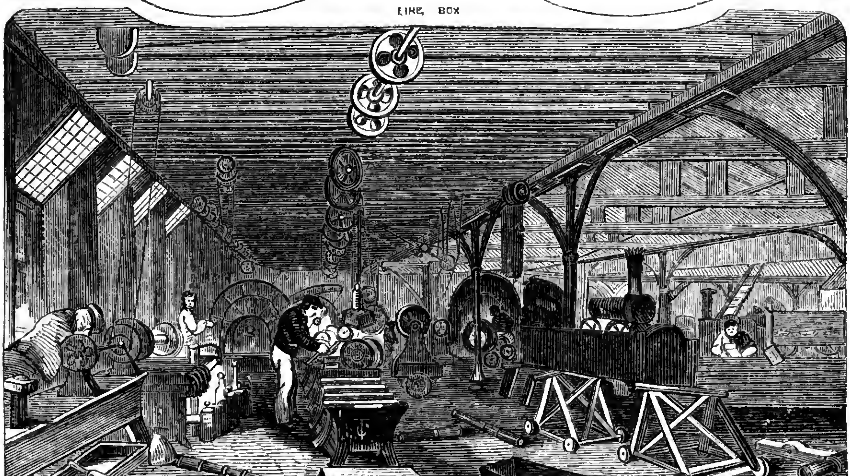
Portugal holds a very humble position in respect to industry and commerce. There are no railways or canals; the roads are bad; and the rivers are navigable only in certain parts of the year. Yet there are not wanting indications of some revival of commercial spirit. The English Industrial Exhibition has called forth the dormant energies of many manufacturers; the articles of Portuguese manufacture were exhibited at Lisbon before being sent to England; the Government voted a sum to defray the expences of transport; and a spirit of fair emulation was excited. A communication from Portugal to one of the London journals, if correct in its statements, will shew that the last ten years have been years of progress in Portuguese industry:—"Oporto, the depôt of our best wines, has likewise become the chief seat of our manufacturing industry. It is now a vast workshop, distinguished not only by the great power of its machinery, but by the humanizing occupation of its people. A district almost wholly industrial adjoins Lisbon on the side next to the entrance of the port. Cavilha, in a few years, has raised twenty new factories. Portaligue thrives admirably in its industry. The credit of our Torres Novas linens improves unquestionably. Wool, both Portuguese and foreign, is woven and dyed in different manners in our factories. The brightness of the colours we use enhances the productions which in this process receive their perfecting finish. Our cotton printing establishments are advancing rapidly to perfection. The expensive and colossal industry of cotton spinning and weaving is already founded in Portugal. Our iron foundries produce machinery capable of presenting in the market solid and well-finished productions. The first steam boilers, of Portuguese manufacture, are constructing in one of the Lisbon workshops. Cabinet-making, cutlery, and other applications of labour to the raw material, are generally improving very greatly, and all this progress has been made within little more than ten years."

POST; MAILS; LETTERS. To trace the influence of the postage system on the industry and commerce of the country is quite beyond our present bounds. Whether as regards the internal machinery of the great establishment in St. Martin's-le-Grand; the wonderful effect of the penny postage rate; the rapid transit of letters by railway; the establishment of ocean mails; or the surprising results of money orders—the subject is indeed a vast one. We can give only a few figures in reference to it.

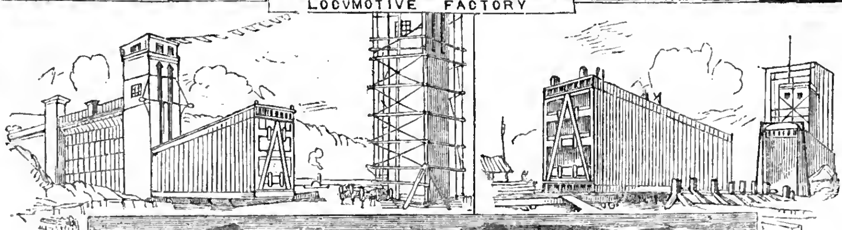
The increase of letters has been at least eight fold since the reduction in the rate of postage. On the 5th of December, 1839, the

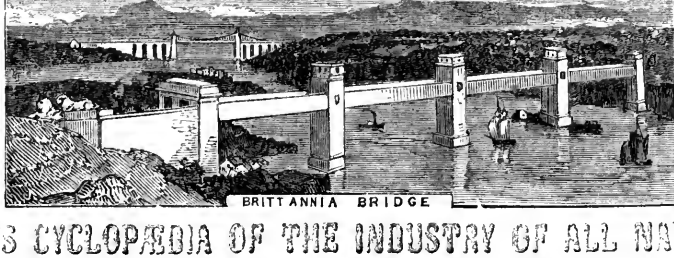


LOCOMOTIVE
SECTION OF DITTO AND
FIRE BOX



LOCVMOTIVE FACTORY





BRITTANNIA BRIDGE

change was made from distance-rates to a fourpenny rate; and on the 10th of December following a further change to the penny-rate was made. The following are the total numbers of letters which passed through the post-offices of the United Kingdom in the last twelve years, beginning with the year when the first partial change was made:—

Year.	Number of Letters.
1839	76,000,000
1840	169,000,000
1841	196,500,000
1842	208,500,000
1843	220,500,000
1844	242,000,000
1845	271,500,000
1846	299,500,000
1847	322,000,000
1848	329,000,000
1849	337,500,000
1850	347,000,000

In the year 1851 we may take one million letters per day, Sundays included, as a very near approximation to the probable number. In the year before the alteration (1838) the gross receipts of the post-office were 2,467,216*l.*; the net receipts were 1,676,522*l.* In 1849, the gross receipts were 2,213,149; and the net receipts 840,787*l.*

The conveyance of the letters from one part of the kingdom to another is effected by contract between the postmaster-general and the coach and railway proprietors. In the year 1839 the number of miles travelled by mail coaches was 7,377,851, at an average speed of about nine miles an hour. At the present time all the mails from London are conveyed by railway, with the aid of branch coaches to convey them beyond the reach of the railways. Contracts are entered into with the various companies and the rates determined partly on the probable number of letters, and partly on the length of line. In 1849, the General Post-Office paid to the Railway Companies for conveying letters and newspapers the sum of 253,586*l.* The mileage performed by the trains which conveyed the letters and newspapers was upwards of 20,000,000 miles.

Among the many admirable contrivances for facilitating the post-office business of railways, is Mr. Dicker's apparatus for giving and receiving the bags at each station. The apparatus is used by many of the great companies, and is about being used by more. The *post* stations are more numerous than the *passenger* stations; or, more correctly, the mail trains do not stop at certain minor stations, which must yet have their regular bags of letters; and as the throwing of the bags to or from the platform during a speed of 30 miles an hour would be very uncertain work, another plan is adopted. The station keeper adjusts the bag which is to go *from* the station; and the mail-guard adjusts that which is to go *to* the station. The station has a *delivery standard*, and the mail-carriage has a *receiving net;* the two bags are hung loosely, respectively, on the standard and on the edge of the net; and while the train is passing rapidly by the station, the edge of the net catches against the station-bag, whisks it off a kind of hook, and deposits it in the net which is spread open at the side of the carriage; at the same instant the carriage-bag is caught against the standard, and thrown down upon the platform, or else enclosed in a net.

In respect to foreign countries, there are contracts in force with steam-packet companies for the conveyance of mails from England to various parts of the world. The amount paid for this service in 1849 was 748,296*l.*

The principle of cheap postage has been applied to the transmission of money through the post-office by means of money-orders. A few years ago the cost of sending 10*s.* to a person 160 miles from London would have been 2*s.* 2*d.*, whereas the expense would now be only 4*d.*, including the postage. In November, 1840, the commission on money-orders was reduced from 1*s.* 6*d.* to 6*d.* for sums above 2*l.* and not exceeding 5*l.*; and from 6*d.* to 3*d.* for sums not exceeding 2*l.* The number of offices empowered to grant money-orders has been increased, and other facilities have been granted. The consequence of these successive changes have been as follows:—

Number and amount of money-orders issued in England and Wales in the quarters ending—

	No.	Amount:
5 April, 1839	28,838	£49,496
5 Jan., 1840	40,763	67,411
5 Jan., 1841	189,984	334,652
5 Jan., 1849	4,203,727	8,151,295
5 Jan., 1850	4,248,891	8,152,643

POTA'SSIUM; POTASH. The remarkable metal *Potassium* was discovered by Sir H. Davy in the year 1807. Its properties are the following:—In colour and lustre it strongly resembles mercury; it is solid at the usual temperature of the air: at 50° it is soft and malleable, and yields like wax to moderate pressure, and at 32° it becomes brittle; at 70° it is somewhat fluid, but not perfectly so till the temperature reaches 150°; if heated to low redness, out of the contact of the air, it sublimes, and condenses on cooling, unchanged. Its texture when brittle is crystalline. Its specific gravity at 60° is only 0·865, thereby presenting a remarkable contrast to mercury. It is opaque, and a good conductor of heat and electricity.

The most remarkable chemical property of potassium is its great affinity for oxygen, which at common temperatures exceeds that of any other body for this elementary substance. It tarnishes rapidly and visibly by mere exposure to the air, and the more rapidly as the air contains moisture, which it decomposes, and by combining with its oxygen becomes oxide of potassium, or potash. On account of its powerful affinity for oxygen, it must be kept either in small glass tubes hermetically sealed, or in a fluid, such as naphtha, which contains no oxygen. When heated in the air it takes fire, burns with a purple flame, the evolution of much heat, and is converted either into potash or peroxide of potash, or a mixture of them. It takes the oxygen from any mixture of gases containing it, and indeed from almost every substance with which that element happens to be combined; so that when thrown upon water it decomposes it, burning vividly.

Oxygen and *Potassium* form two compounds, of which the chief is the well known substance *Potash*. This is white, solid, extremely caustic, and readily attracts moisture and carbonic acid from the air; it fuses when heated, but bears a high temperature without being volatilised or decomposed. The *hydrate of potash* is formed whenever an aqueous solution of potash is evaporated to dryness; it is white, hard, and brittle, extremely caustic, very deliquescent, and very soluble both in water and in alcohol. Potash is most extensively employed in manufactures, and is an extremely valuable alkali. From a combination of cyanogen with potassium *Prussian Blue* is obtained. *Nitrate of Potash, Nitre*, or *Saltpetre*, is colourless, inodorous, has a cooling, sharp saline taste, and is readily soluble both in cold and in hot water. At about 616° of Fahr. nitre fuses, and at a high temperature it suffers decomposition. Nitre possesses powerful antiseptic properties. It is largely employed in the manufacture of gunpowder and of nitric acid, and also in numerous processes in the chemical arts and manufactures. *Chlorate of Potash* is colourless, inodorous, and has a cooling austere taste. When triturated with certain inflammable bodies, as sulphur and phosphorus, combustion or explosion, or both, are produced. This salt is employed in chemical investigations on account of the purity of the oxygen gas which it yields; it is also employed in the manufacture of matches which are fired by means of friction. [MATCHES.]

Carbonate of Potash is known in its impure state by the name of *Pearl Ash*; when pure, it is colourless and inodorous, its taste is strong and disagreeable, it does not readily crystallise, and is never kept in crystals; it is largely employed in the arts, and also in medicine. *Bicarbonate of Potash* is inodorous, colourless, and crystalline; has scarcely any alkaline taste, and is largely employed in medicine and in chemical investigations. *Sulphate of Potash* is colourless, inodorous, bitter, and rather hard; it is employed to a small extent in medicine and manufactures. *Bitartrate of Potash, Cream of Tartar*, or *Tartar*, is colourless, rather hard, inodorous, and has a sour taste. It is very largely employed in the preparation of tartaric acid, in medicine, and some chemical arts. When an equivalent of potash is added to this salt, it becomes *neutral tartrate of potash;* this salt is used in medicine, and being much more soluble in water than the bitartrate, was formerly called Soluble Tartar. *Oxalic Acid* forms three different compounds with potash, the *oxalate, quadroxalate*, and *binoxalate;* this last is a natural product obtained from sorrel, and is commonly known by the name of *salt of sorrel*. It is a colourless crystalline salt, and has a sour bitterish taste. There are many other valuable substances obtained from potassium.

POTATO. The potato was first brought to this country from Virginia by Sir Walter Raleigh, and was first planted in his garden at Youghal, in Ireland. But the potato had been known in Spain and Portugal at an earlier period, and it is from them that we most directly derive the name by which we know it. The inhabitants of Quito called it by some name which the Spaniards corrupted into battata, to which potato is a close approximation. The potato was limited to the garden for at least a century and a half after it was first planted at Youghal, and it was not until 1732 cultivated as a field crop in Scotland.

The farina of the potato, properly granulated and dried, is sold in our shops as *tapioca*, to which it bears the closest resemblance both in appearance and essential properties. For confectionary the flour is so delicately white, and it is so digestible and nutritious, that it ought to be in more general use, among the children of the poor especially, in the winter season, when they so rarely enjoy the luxury of milk; and the cost is not more than a sixth or seventh of the price of tapioca or arrow-root, if it be made at home. Few housewives are ignorant of the method of obtaining it by the use of a common hand-grater and sieve; but for yielding larger supplies some machinery is necessary.

The misery of Ireland, consequent on the failure of the potato crop, is too well known to require notice here. In 1847, the Earl of Clarendon, wishing to know the exact amount of vegetable food grown in the country, caused an accurate enumeration to be made. It was found that there were 284,116 acres of land under potato-crop in 1847; the produce of which was estimated at 2,046,195 tons of potatoes. No means are at hand for determining the ratio which these numbers bear to those of former years; but it is well known that the quantity was greatly diminished during and immediately after the disastrous year 1846

It has been lately estimated that the potatoes sold in Covent Garden market annually amount to about 6,600 tons, or about 14,000,000 lbs.

POTOSI' MINE. Potosi, a town in South America, in the republic of Bolivia, has near it the mountain or Cerro de Potosi, 16,037 feet high. It contains one of the richest silver mines in the world; the mine has yielded since 1556 an amount of silver worth nearly 200,000,000*l*. sterling. Potosi contains about 30,000 inhabitants.

POTTERIES. The name of *The Potteries* is given to a remarkable district in Staffordshire, in which the greater part of the English pottery and porcelain is made. It is a row of seven or eight towns, lying along the same turnpike road, and having the intervals between them every year more and more filled up by more than twenty hamlets and chapelries. It may be characterised as a street eight miles in length, with shorter streets branching out on either side. Over the whole of this space the characteristics of a pottery district are observable; especially the bulky and somewhat ugly *Kilns* which every establishment possesses. The chief towns among the group are Tunstall, Burslem, Longport, Hanley, Shelton, Stoke, Fenton, and Lane End; the smaller places are too numerous for enumeration here. *Etruria*, the celebrated establishment where Wedgewood obtained his fame and his wealth, is not so much a town as a factory, with the mansion of the proprietor and the houses of the workpeople. There are not less than a hundred and twenty pottery and porcelain establishments in the district, some of which employ six or eight hundred persons each. The names of Copeland, Minton, Ridgway, Davenport, and Wood, are among the most celebrated of the manufacturers; and it is among these we are to look for those gradual improvements which will leave us nothing to wish for in emulating the production of China, Sèvres, and Dresden. The Exhibition of 1851 will tell its own tale on this subject.

In the last annual report of the School of Design, the following interesting remarks are made on the progress of the branch Schools in the Pottery district:—'The schools at Stoke and Hanley continue to be conducted in the most satisfactory manner, and are exercising a marked influence on the manufactures of those places. The proportion of the students actually engaged in the manufactories is unusually large, amounting to three fourths of the whole number; and about thirty are established modellers and painters. Several of the young pupils have advanced to the study of colour, but the difficulty of forming or maintaining a class, in the absence of proper examples, is extreme. A life class is established at Hanley. The modelling classes have now assumed their proper importance in the schools, with reference not only to their numbers, but to the quality of the pupils, many of whom are modellors of long standing, established in the manufactories, who come to the schools already skilled in the handicraft of their business. Their practice in the schools is to study the figure, and to model after the finest examples of ornament, and afterwards to exercise their knowledge of form and relief by reproducing specimens of the like character, from the engravings of Albertolli and others. No plan can be better adapted for spreading among the modellers, who are also to a great extent the designers, that in which their previous education has been deficient, that is to say, a knowledge of the best forms, and taste to prefer them. There are also several pupils in the modelling classes who have begun at the beginning, and worked through the elementary studies of the school. One of the principal modellers in the Potteries is stated to have drawn his first line in the Hanley school.'

POTTERY AND PORCELAIN. The pottery art appears to have been practised in the earliest ages, and undoubtedly has been known amongst the rudest nations. The most ancient records allude to the *potter's wheel*, and we have proof that great skill had been acquired in the manufacture of porcelain of a superior quality in China and in Japan at a very remote date. The little figures, covered with a fine deep-blue glaze, which are deposited with Egyptian mummies, and numerous jars, some specimens of which may be seen in the British Museum, show that in Egypt, likewise, the art was anciently practised. Vestiges of considerable Roman potteries have been discovered in many parts of this island. In newly-discovered countries it has been found that the use of earthen vessels is familiar among people otherwise little acquainted with the arts of civilised life.

Although *Earthenware* may be considered as a general term applicable to all utensils composed of earthen materials, it is usual to distinguish such utensils more particularly into three different kinds, namely, *Pottery*, *Earthenware*, and *Porcelain*. Under Pottery are classed the brown stoneware made into jugs, &c., red pans and pots, porous vessels, &c. Earthenware consists of the white, blue and white, and yellow ware, which is so extensively used in this country. Porcelain is distinguished from earthenware as being a semi-vitrified compound, in which one portion remains infusible at the greatest heat to which it can be exposed, while the other portion vitrifies at a certain heat, and thus intimately combines with and envelopes the infusible part, producing a smooth, compact, shining, and semi-transparent substance, well known as the characteristic of true porcelain.

Until the beginning of the 18th century, the manufacture of earthenware in this country was confined to a few objects of the coarsest description, and till nearly the close of the same century, the porcelain of China was still in common use on the tables of the wealthy, the home manufacture being confined to articles of the commonest domestic use. Earthenware was likewise largely imported from Holland, and superior kinds from Germany and France. English earthenware and porcelain are now not only brought into general use in this country, to the exclusion of all foreign goods, but earthenware is also largely exported to almost every part of the known world, and even to those countries where the art was previously prosecuted. England is mainly indebted to Mr. Wedgwood for the extraordinary improvement and rapid extension of this branch of industry. Before his time our potteries produced only inferior fabrics, easily broken or injured, and totally devoid of taste as to form and ornaments. Wedgwood's success was not the result of any fortunate discovery accidentally made, but was due to patient investigation and unremitting efforts. He called upon a higher class of men than had usually been employed in this manufacture to assist in his labours, and in prosecuting his experiments he was guided by sound scientific principles; and signal success,which crowned his first exertions, only served as an additional motive for continuing his pursuit. One of the principal inventions of Mr. Wedgwood was his *table ware*, known at present as *Queen's Ware*. It is characterised as a dense and durable substance, covered with a brilliant glaze, and capable of bearing uninjured sudden alternations of heat and cold. Mr. Wedgwood's more beautiful inventions were—a *terra cotta*, which could be made to resemble porphyry, granite, Egyptian pebble, and other beautiful stones of the silicious or crystalline kind; a black porcelainous biscuit, very much resembling basalt in its properties, and therefore called Basaltes; a white and a cane-coloured porcelain biscuit, both smooth and of a wax-like appearance; and another white porcelainous biscuit, distinguished as jasper, having in general all the properties of the basaltes, with a very important addition, the capability of receiving through its whole substance from the admixture of metallic oxides, the same colours as those oxides communicate to glass or enamel in fusion. This peculiar property renders it applicable to the production of cameos and all subjects required to be shown in bas-relief, as the ground can be made of any colour, while the raised figures are of the purest white. Mr. Wedgwood likewise invented a porcelain biscuit, nearly as hard as agate, which will resist the action of all corrosive substances, and is consequently peculiarly well adapted for mortars in the chemist's laboratory.

Since porcelain is only a finer kind of pottery, the following description, in its earlier portion at least, will comprehend the mode of manufacturing both kinds of ware.

The materials for earthenware are reduced to the consistence of cream, in which state they are called *slip;* this fluidity is necessary to insure the perfect mixture of all the ingredients, and their mutual chemical action in the fire. The basis of the composition is a clay from the plastic clay formation in Devonshire or Dorsetshire, to which is added ground flint, which gives whiteness and solidity to the goods. For the better kinds, a portion of China-clay, or decomposed felspar from Cornwall, is added, together with a small quantity of ground white granite. By this means the density of the ware is increased, greater purity of whiteness is obtained, and also a degree of vitrification which makes the ware sonorous when struck. The flints employed are burned in a kiln, slaked to destroy their coherence, and ground to powder in a mill. The powder is then sifted in water, until reduced to a fit state for combination with the other substances. The clays are thrown into their several vats sunk in the ground, where they are blended with water, and sifted through fine silk lawns into other receptacles, and then diluted with water. The mingled flint and clay, in the state of a creamy liquid, is then pumped into a boiler, or slip-kiln, the bottom of which is formed of large flat fire-bricks, under which four or five parallel flues pass from the fire-place to a high chimney. The water is evaporated, until the boiling mass is brought to a proper consistency for working; but the steam having given it a cellular and porous texture, it requires to be beaten or wedged until the air is driven out, and a section of the mass, when cut, is smooth and compact.

All the various kinds of ware, such as *cream ware, drab ware, drab body, brown body, Egyptian black, blue body, jasper body, turquoise body*, &c., are formed of different kinds and proportions of flint and clay, with small additions of colouring materials. Round articles, which may be turned upon a lathe, have their form given upon the thrower's wheel, which is a lathe with a vertical spindle, having a small round table on the top, at which the thrower sits. He receives the clay prepared to the proper size by a woman, and throws it upon the whirling-table between his knees, which is put in motion by the wheel-woman, whose eye watches every motion of the thrower, and regulates the velocity of the work with perfect accuracy. The thrower first draws the clay up into a pillar, then depresses it into a flat cake, until the whole mass has been drawn into a circular arrangement of all its parts. He then opens the hollow of the vessel with his thumbs, and continues to draw out the clay, or press it inwards, until the desired shape is given to it. It is then cut from the table by a brass wire, and placed on a board, which, when full, is carried into a stove-room to harden.

When a number of vessels of the same size are to be thrown, a gauge is fixed so that its point just touches the top edge of the article when it is revolving; this fixes both the height and diameter of all that are made in that pattern.

When the vessels are sufficiently hardened, they are turned upon a lathe similar to that used by wood-turners. The turner dexterously shaves away the clay to the proper thickness, and works the mouldings, &c., polishing the whole with a steel burnisher. He frequently ornaments bowls, jugs, &c., with a coating of various coloured clays, which are sometimes blended with each other, so as to give a marbled surface; by these earthy pigments he produces an infinite variety of patterns. This kind is called *Dipped Ware*.

Such articles as require handles and spouts are then passed to the handler, who makes those appendages in plaster moulds, and sticks them to the vessels with liquid clay. Plain handles are pressed by a syringe through a hole of the proper size and form, and as the clay comes through in long strings, it is cut off, and bent into the desired shape for the handle.

Thrown and turned goods are sometimes ornamented with figures in relief, which are made out of flat moulds by children, and fixed upon the ware by workmen, who, having carefully adjusted each figure to its place, run a little water under it with a camel-hair pencil, which unites it to the surface of the pot. Goods of an oval or angular shape, which cannot be turned, are made by pressing clay into plaster moulds, which give the outside form to the vessel: this is called *Hollow-Ware Pressing*. Another kind, called *Flat-Ware Pressing*, is performed by giving the shape to the goods by moulds which fit the inside of the vessel; plates, dishes, saucers, cups, and hand-basins are made on this principle.

Casting is resorted to when a mould is so intricate as to be difficult for the workmen to fill by pressing. Slip clay is poured into the mould, which rapidly absorbs the water; and a coating of clay is deposited upon the inside; the remaining fluid is then poured out or drawn with a syringe, and a thicker mixture is put in, and left rather longer than the first before it is withdrawn. The mould is then put into a stove to dry.

When completed by the workman, the goods are placed on boards to dry, before going to the biscuit-oven, in which they receive the first fire. The ware to be thus burnt is placed in *Saggers* made of crucible clay; in shape they resemble hat-boxes, and being piled in columns, each sagger covers the one beneath it, and protects the goods from the immediate contact of smoke and flame. When the baking is finished and the oven cooled, the doorway is opened, the saggers brought out, and their contents submitted to a rigid scrutiny: all cracked and crooked pieces are rejected and thrown away. The ware is now called *Biscuit*, and in this state goes to the printer or biscuit-painter to be ornamented.

The printing of earthenware is effected by transfer-papers from engraved copper-plates. The ink used in printing is made of linseed-oil boiled with litharge, rosin, balsam of sulphur, or Barbadoes tar, and is tinted with any of the usual mineral colours—blue being the principal, and formed of oxide of cobalt. The colour having been ground very fine, the printer blends it with his oil upon a hot stove, and filling the engraved plate with it, takes off the impression by the common rolling-press. The tissue-paper used for this purpose is first prepared with a solution of soap. As soon as the print is taken, a girl cuts out the engraving with scissors, and hands it to the transferer, who carefully places the print upon the biscuit-ware, which being absorbent, holds it with great tenacity. The transferer then passes it to her assistant, who with the end of a cylinder of flannel, tightly rolled and bound with twine, rubs the print with such force as to work the ink into close contact with the biscuit. The goods thus coated with paper are then put into a tub of water, and the paper being wiped off with a sponge, every minute point of the engraving is found accurately transferred to the earthenware. When dry, the goods are packed close in a large muffle, or kiln, round which a fire circulates, and brings the whole to a low red heat. By this means the oil is burned out of the colour, which would be injurious to the process of glazing which follows. Some patterns are executed on biscuit by painters, who lay on the colours in gum-water.

The biscuit-ware, thus ornamented, is carried to the dipper, who dips each piece into the tub containing the finely-ground mixture which, when melted, forms the glassy coating to the ware. This glaze is blended in water, which, being absorbed by the biscuit, leaves a thin cover of glazing-powder upon the surface; a dexterous shake of each piece in a circular motion, as it emerges from the fluid, prevents the glaze from setting unequally, and throws off all that is superflous. The material of the glaze differs according to the kind of ware: white lead is a general ingredient.

When the goods have been dipped in the glazing mixture, they are dried, and placed in saggers, which are washed on the inside with a compound of glaze with lime and clay. Every piece is carefully placed so as not to touch another; otherwise, when the glaze melts, they would stick together. When drawn from the oven, the ware is carried in baskets to the glossed warehouse, where it is again subjected to a close examination.

Porcelain is a finer species of pottery, in which the ingredients are so selected that they act chemically upon each other, and are brought to a state of vitrification; the fracture has a dense or greasy surface, like that of a flint stone, and is therefore not liable to be acted upon by acids. When the porcelain is coloured by metallic matter, it is called stoneware; jasper and some drab-ware are of this description: but when it is perfectly free from colouring matter and is translucent, it is called China; of which there are two species, hard and soft china.

Hard China is formed chiefly of Kaolin or Cornish clay, felspar, sand, and selenite; but Soft China, which is more frequently made in England, has a different composition. Bones calcined and ground are largely used in the manufacture of English china, combined with aluminous and silicious earths in such proportions that they will vitrify together. The mode of mixing the materials, and the general processes of manufacture, are nearly the same as for earthenware.

The decoration of china by enamel colours and gold affords employment to a great number of persons, some of whom attain great excellence in their beautiful art. The colours used are all prepared from metallic oxides, which are ground with fluxes, or fusible glasses of various degrees of softness, suited to the peculiar colours with which they are used. When painted, the goods are placed in the enamel-kiln, where the fluxed colours melt, and fasten to the glazed surface, forming coloured glasses. The gold, which is applied in the form of an amalgam ground in turpentine, is afterwards burnished with steel burnishers.

Pottery, comprising the coarsest and commonest wares, involves the use of clay only, and requires much less careful processes than porcelain or earthenware.

The porcelain manufacture has made great advances within the last few years. The Exhibitions of manufactures in this country have afforded room for the honourable emulation of manufacturers from different districts; while the excellence of Sèvres, Dresden, and other foreign manufactures of porcelain, have shewn our native artists what are the points in which we are still excelled by our neighbours. The production of statuettes in biscuit and parian has lately reached a high degree of beauty; especially in those specimens which, under the name of Art Manufactures, have called forth the inventive skill of Bell, Marshall, and other sculptors, and the practical skill of Minton, Copeland, and other distinguished manufacturers. Slabs of highly decorated porcelain are now much used in fire-places, and in many forms of house-decoration. The mode of pressing dry porcelain powder into various forms has given rise to many new productions [BUTTON MANUFACTURE]; and the combination of parti-coloured clays has enabled the manufacturers to imitate many of the pavements and floors of the Romans [TESSELATED FLOORS.]

In respect to the commerce in these articles, it is the plain, neat, well made, and well glazed *earthenware*, for which the greatest demand exists in foreign countries; for no where are such things so excellently produced as in England. The export in the last three years has been

1848........	53,286,076 pieces.
1849........	61,528,196 „
1850........	76,952,735 „

Two-thirds of these quantities go to the United States. The more costly porcelain, and the rough stone-ware, are not so largely exported as earthenware.

POULTRY. The mechanical arrangements for facilitating the hatching of poultry have been noticed under HATCHING. In respect to the commerce in this variety of farm produce, the only enumeration or estimate which we have met with is that which was made in Ireland in 1847. The poultry then alive in all the farms in Ireland numbered as follows:—

Leinster........	1,674,039
Munster........	1,684,775
Ulster..........	1,567,587
Connaught......	764,654
	5,691,055

In one of the recent valuable papers in the *Morning Chronicle*, it is stated that the average yearly sale of tame birds, or *poultry*, at Newgate Market, is about 900,000; while that of wild birds, or *game*, is about 400,000; making 1,300,000 in all. But Leadenhall Market is said to be the largest poultry and game market in the world; the numbers are given, by the above authority, at 2,700,000 poultry, and 1,300,000 game, making together 4,000,000.

POWER is a term applied to any cause which is capable of producing motion, or of resisting motion; but the word has a merely technical meaning in treatises of mechanics. From among the numerous combinations which occur in machinery, the *Lever*, *Inclined Plane*, *Wheel and Axle*, *Pulley*, *Wedge*, and *Screw*, have been selected, and named *Mechanical Powers*, apparently because they are the simplest objects by which are produced such effects as could not be produced by the unassisted or unadapted operations of a motive agent, as gravitation, muscular strength, &c. The word Power here may be conceived to signify that which produces a mechanical advantage; but the same word may be used to signify a beneficial effect, as when a thing is done quicker or better at an equal expense of labour or time.

The mechanical advantages of simple machines are shown under the words LEVER, WHEEL AND AXLE, &c.; see also MECHANICAL POWERS. Beneficial effect may be produced in various ways without mechanical advantage:—for example, in the division of labour there is not only the moral benefit, namely, the making a human agent fitter for his work by giving him a more limited range of operations, but the actual saving of the labour of laying down one tool and taking up another.

PRAGUE, the capital of Bohemia, is a place of some industrial and commercial importance. The manufactures consist of cotton, hosiery, silk, leather, hats, gloves, earthenware, jewellery, and plated goods, mathematical and musical instruments, glass, buttons, snuff and tobacco, paper and paper-hangings. There are also breweries, saltpetre works, and many other industrial establishments. Prague has a very flourishing commerce: the transit trade is considerable, and there are three great annual fairs.

PRESS. [HYDRAULICS; PRINTING; SCREW-PRESS.]

PRESTON. This is one of our busy Lancashire towns. The staple trade of Preston, till within the last half century, was in linens; but this trade has given place to that of cotton, which is now manufactured very extensively. There are several iron foundries, chiefly for making the machinery used in the cotton manufactures. Leather is extensively made. The Ribble is navigable at spring-tides for vessels of 150 tons; but it is ill adapted for trade. The Lancaster canal passes on the west side of the town, and connects it with the great canal system of the manufacturing districts; while the town is still better connected by railways with the great centres of commerce.

PRINCE'S METAL, or *Prince Rupert's Metal*, is an alloy of copper and zinc, which contains more copper than brass does, and is prepared by adding this metal to the alloy.

PRINCIPAL is the name of a stop or row of metal pipes in an organ, tuned an octave higher than the diapason, an octave lower than the fifteenth, and serving to blend the two, as well as to augment the volume of sound.

PRINTING. The art of printing from blocks has been known in China since the middle of the 10th century, and that mode of printing is still practised there. Even in Europe, although writing, unlike that of the Chinese, is alphabetic, printing from blocks was the method first practised. Some have even supposed that the knowledge of the art was originally obtained from China; but, as far as we can trace, it was not till fully a century after Marco Polo returned from that country that even this simplest kind of printing began to be practised in Europe. It appears to have been first applied to the fabrication of playing cards and manuals of popular devotion. The æra of these block prints and books, as they are called, may be stated to be the first half of the 15th century: one in Lord Spencer's collection bears the date of 1423, and there is reason to believe that other specimens were executed almost as late as 1450. Of the block-books of any considerable magnitude the two most remarkable are—the 'Biblia Pauperum,' a small folio of forty leaves, each containing a picture, with a text of scripture or some other illustrative sentence under it, which is supposed to have been produced some time between 1430 and 1450; and the 'Speculum Humanæ Salvationis,' consisting of sixty-three leaves of the same small folio size, containing in all fifty-eight pictures, with two lines of Latin rhyme under each. With regard however to this last block-book there has been a great deal of disputation, some denying altogether its claim to be reckoned a specimen of block-printing, in so far as the legends are concerned. The probability is that at first the 'Speculum' was entirely a block-book, but that in subsequent editions the block-printing was mixed with printing from moveable types. These block-books are, like the Chinese books at this day, printed only on one side of the leaf; and they all appear to have been produced in the Low Countries.

The art of printing, in its essential principles the same as now practised, had certainly been discovered before the middle of the 15th century; but when, where, and by whom, each successive improvement of the original pigment-printing by means of engraved blocks was discovered and first put in practice, is not so easily settled. The employment of moveable types, the production of such types by the process of casting them in metal, and the cutting of the punch, or stamp of hardened steel, with which the face of the type is impressed in copper to be afterwards used in the matrix, or mould, in casting—these may be considered as the three great mechanical changes, by which block-printing was transformed into the art as it now exists.

Four names have principally figured in the controversy that has been raised about the invention of printing:—John Gutenberg (paternally Gensfleisch), of Strasburg; John Fust (or Faust), of Mainz; Peter Schoeffer (in Latin, Opilio), of Gernsheim; and Lawrence Coster (or Janszoon), of Haarlem. The probability is, that Coster was one of the early block-printers, whose art, there is every reason to believe, was first practised in Holland. The use of separate letters, or types, at first of wood and afterwards of metal, and the various improvements in the manner of casting them, are all to be attributed to Gutenberg, Fust, and Schoeffer. Gutenberg, it is now generally supposed, first began to print at Strasburg with moveable types of wood some time between 1436 and 1442. Having then established himself in Mainz, which was his native town, he there, in 1445, entered into partnership with Fust, who seems to have assisted Gutenberg in devising or carrying into effect his subsequent great improvement of the art, by casting the types of metal. But to Schoeffer, who was in the service of Gutenberg and Fust, and had married Fust's daughter, is assigned the credit of having facilitated and (as far as the principle was concerned) brought to perfection the process of founding by the contrivance of the punch. The knowledge of the art was first made public and carried into other countries by the dispersion of many of the workmen on the storming of Mainz by Adolphus of Nassau, in 1462. Printing was first practised in Italy, in the town of Subiaco, in the Roman territory, in 1465; in France, at Paris, in 1469; in England, at Westminster, in 1474; and in Spain, at Barcelona, in 1475. It is said that by the year 1530 there were already about 200 printing-presses in Europe. The name of William Caxton is indissolubly connected with the introduction of printing into England.

The date of the invention of the *printing-press* is unknown, but some contrivance for this purpose must have been used as soon as printing by blocks or types was introduced. The increased force requisite to make an impression, the size of the surface to be printed from being increased, would soon suggest recourse to some of the simple machines or mechanical powers for the modification of the power requisite to obtain the necessary pressure. The screw, as applied in the common screw-press, would obviously suggest itself; and accordingly, in all the earlier printing-presses, the screw alone is used.

The operations to be performed in the process of printing will point out the essential parts of a printing-press. The types, being set up and arranged in a chase (or iron frame) of suitable dimensions, which is then called a *form*, have to be inked; this is effected by passing across them a cylinder, or roller, covered with an elastic composition of molasses and glue, which has been first rolled in a thick ink made of lamp-black and burnt oil. The paper to be printed has to be laid on the type when inked, and then the requisite pressure for making the impression has to be applied.

Screw Press. The earliest form of printing-press very closely resembled the common screw-press, as the cheese or napkin-press, with some contrivance for running the form of type, when inked, under the pressure, and back again when the impression was made. This rude and inconvenient form of press was superseded by the invention of Blew, a printer of Amsterdam. Other improvements were from time to time introduced; but they were all superseded, about the commencement of the present century, by an invention of Lord Stanhope's.

In the *Stanhope Press*, as in the common wooden screw-press, the form of type is laid upon a table which has a horizontal traversing motion. To the carriage on which the form moves are attached the tympans, which are light frames covered with parchment, so constructed that the inner tympan just lies within the outer tympan. Some blanketing is placed between the tympans, so as to equalise the pressure upon the surface of the types. To the outer tympan is attached a skeleton frame called the frisket. The sheet of paper to be printed being placed on the outer tympan, the frisket is turned down upon it; and then the frisket and tympans are turned down upon the form of type. The frisket is covered with paper, cut out so that the sheet to be printed, when placed between the tympan and frisket, and folded down together on the form, may be in contact with the surface of the type, while the remainder of the frisket-sheet preserves the margin from being soiled. The form of type being inked, and the tympans and frisket, with the sheet of paper between them, folded down on the form, the whole is made to traverse, by means of a crank-handle, until it comes beneath the platten, which is a massive plate of cast-iron, moveable up and down perpendicularly. The principal improvement of the Stanhope Press consists in the manner in which the descending motion is given to the screw. The carriage is then run back, the frisket and tympans unfolded, and the printed sheet being taken out, the same operation is repeated.

The principle of the Stanhope press has been followed out by several subsequent inventors, and improvements of mechanical detail introduced, tending to the economy of time and labour, and to precision of workmanship. In the *Ruthven Press*, the form of type remains stationary, and the platten is removed to permit the type to be inked: and in this, as well as the *Columbian Press*, the pressure is produced by a combination of levers alone, without the use of any portion of a screw or inclined plane.

Copper Plate Press. The press for copper-plate printing consists of two cylinders or rollers of wood, supported in a strong wooden frame, and moveable about their axes, one placed just above and another just below the level of the table upon which the plate to be printed is laid. The upper roller is turned round by the arms of a cross fixed to its axis. The copper-plate being inked, the paper on which the impression is to be taken, and two or three folds of soft material, as blanketing, are placed upon it. The plate so prepared is moved along the table to the junction of the two rollers, and the upper roller being turned by the arms of the cross, the plate, with its furniture, is passed through the press. The rollers may be placed nearer to or farther from each other, according to the amount of pressure requisite for making a good impression, that is, according to the depth of the engraving and the degree of blackness which the impression is required to have.

Printing Machine. The printing-press, though much improved during the last half century by the ingenuity of Lord Stanhope and others, is quite inadequate to a rate of production equal to the present demand. The attention of practical men was consequently directed to some more rapid means of production; and as early as 1790, even before the Stanhope Press was generally known, Mr. W. Nicholson had letters-patent for a machine similar in many respects to those which have now come into use. Subsequently, Mr. König, a German, conceived nearly the same idea, and meeting with the encouragement in this country which he failed to obtain on the Continent, constructed a Printing Machine. On the 28th November, 1814, the readers of the 'Times' were informed that they were then for the first time reading a newspaper printed by machinery driven by steam-power. This printing-machine, though highly ingenious, was very complicated; and the machine of König was superseded by that of Messrs. Applegath and Cowper, the novel features of which were accuracy in the register, an improved method of inking the type, and great simplicity in parts previously very complicated.

Printing-machines are either single or double; the single being that in which only one side of the sheet of paper is printed; the double that in which both sides are printed before the sheet leaves the machine. The single machine is used for most newspapers and that kind of printing in which it is not necessary for the two sides of the sheet to 'register,' that is, for the printing on one side to be exactly at the back of the other; the double machine for books, in which it is essential that the printing on one page should correspond with the printing on the other when the sheets are folded. This important object of the register is effected by causing the parts to move at precisely the same speed. This being the principle of the register, its success will depend on great accuracy of workmanship in the mechanical parts. In the double printing-machines now in use, the sheet of paper is laid on the feeder, which consists of girths of linen tightly stretched by being passed round two cylinders. By the motion of this feeder the sheet is placed between two systems of tapes, which lie two and two over each other on a series of cylinders and rollers. The sheet of paper grasped between them is kept clean at the places in which it is in contact with them, and by the motion of the various parts is conducted under the first printing-cylinder, and receives an impression from the first set of types; thence by means of two other cylinders to the second printing-cylinder, where it receives an impression on the other side from the second set of types. Thus printed on both sides, it is taken out by an attendant. An inking apparatus is placed at each end of the table which carries the types, and which traverses backwards and forwards under the printing-cylinders and inking-rollers. The ink, received from a reservoir by two rollers, is transferred from them to the surface of the inking-table; the surface of the table inks two other rollers, and these, in their turn, ink the types as they pass backwards and forwards for each impression. The excellence of the printing depends in a great measure on the type being properly inked. The machines commonly used for printing books will print from seven hundred to one thousand per hour in perfect register; and for newspapers, printed on one side only, from four thousand to six thousand per hour.

König's machine printed 1,800 copies of the 'Times' per hour. Messrs. Cowper and Applegath's machine of 1827 printed 5000 in an hour. In May, 1848, Mr. Applegath erected a printing-machine for obtaining the enormous number of 10,000 impressions of the 'Times' in an hour. According to a paper on this subject by Mr. Cowper, read before the *Institution of Civil Engineers*, this beautiful machine consists of a vertical cylinder, about 65 inches in diameter, on which the type is fixed, surrounded by eight other cylinders, each about thirteen inches in diameter, covered with cloth, and round which the sheets of paper are conveyed by means of tapes; each paper cylinder being furnished with a feeding apparatus, having one boy to lay on the sheets and another to take them off. The inking rollers are also placed in a vertical position, against the large cylinder, upon a portion of the surface of which they distribute the ink. The ink is held in a vertical reservoir, formed of a ductor-roller, against which rest two 'straight edges,' connected at the back, so as to prevent the ink from running out: it is conveyed from the ductor-roller by one of the inking rollers, against which it is occasionally pushed. The type used is of the ordinary kind, and the form is placed upon a portion of the large cylinder, being fixed to it in a very plain but ingenious manner: a slab of iron is curved on its under side, so as to fit the large cylinder, whilst its upper surface is filed into facets or flat parts, corresponding in width and number to the width and number of the columns of the newspaper. Between each column there is a strip of steel, with a thin edge, to print the 'rule'—the body of it being wedge-shaped, so as to fill up the angular space left between the columns of type, and to press the type together sideways, or in the direction of the lines; the type is pressed together in the other direction by means of screws, and firmly held together. The surface of the type thus forms a portion of a polygon; and the regularity of the impression was obtained by pasting slips of paper on the paper cylinders. The operation of the machine is very simple: the 'layer-on' draws forward a sheet of paper on the feeding-board until its edge is under a roller, furnished with tapes, which drops down and draws the sheet forward and downward, into a vertical position, when other rollers and tapes carry it round the paper cylinder, where it meets the type, which has been inked by passing in contact with the inking rollers; the sheet then continues its progress until it reaches the 'taker-off.'

A few statistics, relative to the printing of the 'Times,' were mentioned by Mr. Cowper, from which it appears, that on the 7th of May, 1850, the 'Times' and 'Supplement' contained 72 columns, or 17,500 lines, made up of upwards of a million pieces of type, of which matter about two-fifths were written, composed, and corrected, after 7 o'clock in the evening. The 'Supplement' was sent to press at 7 50 P.M., the first form of the paper at 4 15 A.M., and the second form at 4 45 A.M.; on this occasion, 7,000 papers were published before 6 15 A.M., 21,000 papers before 7 30 A.M., and 34,000 before 8 45 A.M., or in about four hours. The greatest number of copies ever printed in one day was 54,000, and the greatest quantity of printing in one day's publication was on the 1st of March, 1848, when the paper used weighed 7 tons, the weight usually required being 4½ tons. The surface to be printed every night, including the 'Supplement, is 30 acres; the weight of the fount of type in constant use is 7 tons; and 110 compositors and 25 pressmen are constantly employed. The whole of the printing at the 'Times' office is performed by three of Applegath and Cowper's four-cylinder machines, and two of Applegath's new vertical cylinder machines.

According to recent accounts, it would appear that some of the New York newspapers are now printed with machines still more gigantic and complete than those employed on the 'Times,' and that the rapidity of printing is still greater. There is not the slightest reason to doubt, however, that if the sale of the 'Times' were to largely increase, machines would be invented to increase the rapidity of printing to any required degree. At present, the paper duty, the stamp duty, and the advertisement duty, keep the price of English newspapers much above that of the American, and unquestionably limit the demand.

A few further details illustrative of printing will be found under STEREOTYPE, and TYPE FOUNDING.

PROGNOSTICATOR. This name has been given by Dr. Merryweather to an apparatus recently contrived by him for foretelling probable changes in the weather. It is founded on a curious fact, that *leeches* shew great sensitiveness to approaching changes in the electrical state of the air; and the apparatus is so contrived as to bring these weather-wise animals into use as meteorological instruments. Twelve leeches are placed in a circle, each in a separate glass bottle; every leech tries to get up to the mouth of his bottle when the atmosphere is in such a state as to forewarn an approaching storm; and Dr. Merryweather has contrived sundry small pieces of apparatus, which register any attempts of the leeches to climb through the narrow necks of the bottles. The whole apparatus is contained within a mahogany box. In so novel a contrivance, nothing less than a long course of observation will test the validity of the arrangement.

PROPORTIONAL COMPASS. [COMPASSES.]

PROTEIN is a substance obtained by Mülder from albumen, casein, horn, and animal and vegetable fibrin. When any one of these is dissolved in a solution of potash, and the filtered solution is mixed with a slight excess of acid, a copious grayish-white flocculent precipitate is formed, and a slight smell of hydrosulphuric acid is perceived. This white substance is *protein*, so called from its occupying the first or most important place in relation to the albuminous principles. It is found that all food which sustains animal life, and promotes growth and strength, must contain protein.

PROTRACTOR. Any instrument for laying down angles is thus called; such as the graduated semicircle which is found in cases of instruments, the rectangular ruler with graduated edges, and various other more expensive contrivances. But the truth is, that the easiest and safest protractor is a table of chords, a scale of equal parts, and a pair of compasses. Even the scale of chords laid down on the rulers, used in the usual manner, is a better protractor than the graduated semicircle, which is worthless, except for very rough work.

PRUD'HOMMES. *Prudentes Homines*, experienced men. This name relates to a remarkable kind of commercial or manufacturing council, well known in France, but to which we have nothing exactly parallel in England. In 1452, King René established at Marseille a council of Prud'Hommes, with summary jurisdiction in disputes between the fishermen of that port: this institution has since been frequently confirmed, and still exists. In 1464, Louis XI. granted power to the citizens of Lyon to appoint a Prud'Homme to decide summarily upon disputes that might arise between merchants attending the fair. By a decree of Napoleon, dated March 18, 1806, a council of Prud'Hommes, consisting of nine members (five manufacturers and four master weavers), elected annually, was established in Lyon to settle disputes between manufacturers and their workmen, and between masters and apprentices. The council acted chiefly as a court of conciliation, but was also vested with power to decide, without appeal or expense, cases involving an amount not exceeding 60 francs. This institution has been recognised and confirmed by succeeding governments. Councils of Prud'Hommes with increased numbers, with powers of summons, seizure, and imprisonment not exceeding three days, and with summary jurisdiction to the amount of 100 francs, are now established in all the great manufacturing towns of France, with the exception, we believe, of Paris. If the amount exceeds 100 francs, an appeal lies to the Tribunal of Commerce. The sittings of these councils are held in the evening, when the workmen have given over their labour for the day. Lawyers are not suffered to plead in their courts. The council of Prud'Hommes is perhaps the most extensively-useful institution in France; in Lyon alone, the cases decided annually exceed 5000; appeals are rare, and a reversal of the decree of the council very much rarer still.

PRUSSIA. This important kingdom does not possess a great variety of natural productions; but it has all those the cultivation of which has been gradually introduced into central Europe; and the most indispensable of them in sufficient abundance for its own consumption, and for the obtaining of foreign luxuries and comforts. Agriculture is the chief source of the national wealth, and is carried on with great care in most of the provinces. Wheat, rye, oats, and barley, are raised both for home consumption and exportation; there are likewise peas, beans, vetches, millet, maize, rape-seed, and linseed. Potatoes are cultivated in all the provinces. Flax, hemp, hops, tobacco, succory, beet-root, and garden vegetables of all kinds are raised, but of the first three articles not enough for home consumption. The vineyards of Rhenish Prussia are extensive and valuable. There is abundance of timber. The mineral products are salt from salt-springs, of excellent quality, and in great abundance; amber and coals in large quantities; alum, vitriol, saltpetre, alabaster, basalt, granite, porphyry, marble, slate, freestone, chalk, lime, porcelain-clay, pipe-clay, &c. The metallic products are silver, copper, lead, iron, zinc, cobalt, arsenic, and calamine. The precious stones are the onyx, agate, jasper, and carnelian.

The principal manufactures are:—Linen in all the provinces, but chiefly in Silesia; woollen cloths and cotton goods, especially in the province of the Rhine, at Elberfield, Barmen, Crefeld, &c.; silk, leather, iron, and copper ware, cutlery, articles of gold and silver, succory, paper, china, glass, earthenware, snuff and tobacco, beet-root sugar, gunpowder, &c. The breweries and brandy distilleries are very considerable.

The abundance of products of various kinds, and the active industry of the people, give occasion to an extensive commerce, which is highly favoured by the advantageous position of the country in the centre of Europe, the great extent of coast on the Baltic, and by the great rivers (the Rhine, the Elbe, the Oder, and the Vistula,) which traverse the country, and are connected by navigable tributary streams and numerous canals. In 1831 the Prussian or Commercial League (Zollverein) commenced, and has since been gradually joined by almost all the German states. The object is to establish an entire freedom of trade among the German states, and to subject foreign trade to such restrictions only as the protection of national manufactures or the financial circumstances of the state may render necessary. The Prussian harbours are:—Memel, Pillau, Neufahrwasser near Danzig, Stolpermünde, Rügenwald, Kammin, Schweinemünde, Peenemünde, Griefswald, Stralsund, and Barth. The most considerable commercial towns are:—Berlin, Königsberg, Danzig, Breslau, Stettin, Magdeburg, Cologne, Elberfeld, and Aix-la-Chapelle. The great fairs are those of Breslau, Frankfort-on-the Oder, and Magdeburg. At present there are in Prussia about 1400 miles of railway open for traffic.

In the year 1849 the imports into Great Britain from Prussia were valued at 2,805,649*l.*, and the exports of British and Irish produce and manufactures to Prussia were 428,748*l.* These sums may mislead, unless accompanied by a little explanation. The value of the imports is *official*, that of the exports is *declared*. *Official* value means a certain hypothetical value which was fixed for each kind of commodity by the Custom-house authorities many generations since, and has been retained to this day, without any reference to present prices; whereas *declared* value is the actual marketable value at the time. Another circumstance is, that besides the British and Irish produce, England exports largely of foreign and colonial produce to Prussia.

The contributions of Prussia to the Great Exhibition are very numerous, and of a high degree of importance. They comprise almost every variety of manufactured goods, and natural produce to the extent of the country's resources.

PRUSSIAN BLUE is a pigment of pure dark-blue colour, discovered accidentally by a colour-manufacturer of Berlin, in 1704. It is a prussiate of iron, consisting of 52 parts of red oxide of iron combined with 48 parts of prussic acid, to which is added a certain proportion of alum, in order to give more body and greater brightness to the colour.

PRUSSIC ACID, or *Hydrocyanic Acid.* This powerful acid exists ready-formed in several vegetable products, as the leaves of the cherry-laurel and the peach-tree; but it is generally prepared by the action of hydrochloric acid on bi-cyanide of mercury. It is a colourless liquid, with a strong and peculiar odour; its taste is at first cooling and afterwards burning, and it is extremely poisonous. It boils at about 80°, becomes solid at about 5° Fahr., and then crystallises in fibres. As an acid, its powers are but feeble. It is so very volatile that, when dropped on paper, the sudden evaporation of a portion of it renders the remainder so cold that it solidifies; and this effect is produced even when the temperature of the atmosphere is nearly 70°.

Prussic acid is one of the most deadly of all poisons. In the hands of an experienced practitioner it becomes a valuable medicine in some cases. It is of little direct use in the arts; but its combinations with bases produce many useful substances, of which *Prussian-blue* is an instance.

PSALTERY was an ancient musical instrument of the harp kind, in use among the Jews, and supposed to have been the *nebel* mentioned in several of the Psalms. Whether this instrument was square or triangular, whether played on by the finger or struck by a plectrum, seems doubtful; the probability is that it took many forms, and was played in both ways. According to some authorities this instrument was in shape a trapezium, and similar to, if uot the same as, the dulcimer. [DULCIMER.]

PUERTO RICO. The soil of this Spanish West India island is of the richest and most varied description. The produce of sugar is very abundant, and tropical productions in general are plentiful. The island exported in the first 10 months of 1849—98,000,000 lbs. of sugar, 4,475,000 lbs. of molasses, 6,703,161 lbs. of coffee, and 1,702,000 lbs. of tobacco. The industry and commerce of the inhabitants are exhibited chiefly in connexion with these products.

PUG-MILL. [BRICK.]

PULLEY. The pulley is one of the simple machines or mechanical powers employed in the construction of machinery and in the transmission and modification of force. The kinds of pulley in use are very numerous; but they all consist of combinations of a grooved wheel, moveable on an axis, and a rope lying in the groove; and the manner in which this rope passes over and under a system of these wheels, so as to connect the force with the resistance, or the power with the weight, determines the species or kind of pulley. The following are the combinations by which the principle of the pulley is made available:—

The single fixed pulley possesses no mechanical advantage, the power and the weight being equal to each other. The single moveable pulley consists of one wheel fixed and the other moveable; the power acts at one end of the rope, and the other end is fixed to an immoveable obstacle; the weight or resistance is attached to the sheave, or block, of the moveable wheel. In this the power is one-half the resistance when there is equilibrium. The first system of pulleys consists of an upper and lower set of wheels, called the upper and lower block; the upper being fixed, and the lower, to which the resistance or weight is attached, being moveable. The power is to the weight or resistance as unity to twice the number of wheels in the lower block. A system consisting of one fixed and two moveable pullies is called a Spanish Barton. *Smeaton's Tack*, so called after the celebrated engineer of that name, contains two tiers of wheels, one above the other, in each block. This arrangement is ingenious, but it is attended with great friction and inequality of wear. *White's Pulley* consists of a single wheel in each of the two blocks. The wheel has a conical form, with grooves on its convex surface; and the diameters of the grooves are in arithmetical progression, by which they revolve with velocities equal to that of the line passing over them. The advantage is that the friction is reduced to that of the pivot and the two lateral faces.

There are two systems in which each block contains a single pulley, and has a separate string. In one system the string is made fast at one end to the block next above it, and at the other to an immoveable object. In the other system each string is attached to the weight. These are superior to the other systems, with respect to the ratio of the resistance to the moving power, but they are of no practical use.

PULPIT. Great cost, both of material and workmanship, was frequently bestowed on pulpits in early times; and some of them rank among the most celebrated monuments of art of their period, and for a long time appear to have been treated as an architectural feature of the interior, being constructed, if not of marble, of the same material as the rest of the building. Of stone pulpits we have few early specimens remaining in this country; but there is one in Bristol cathedral, and another in Worcester. The pulpits of the present day are for the most part, in respect to design, mere carpenter's and joiner's work.

PUMICE STONE. This remarkably light and porous stone is a true *lava*. It is vomited forth by the volcanoes which are distributed in different parts of the earth. That which we employ is obtained from Etna and Vesuvius. It is used for many purposes of rubbing and smoothing.

PUMP. [AIR PUMP; HYDRAULIC MACHINES.]

PURBECK STONE. [DORSETSHIRE; STONE FOR BUILDING.]

PUTCHUK is the name by which a fragrant root is designated in the price-currents of Calcutta and Bombay, whence it is exported to Canton, being highly esteemed by the Chinese as an incense. From the places of export this would appear to be a product of India, but neither the plant which yields it nor the place where it grows has been discovered until very recently. The discovery is interesting, as the putchuk is a substance which was known to the ancients. Dr. Royle, while in the north-western provinces of India, obtained a root which formed a considerable article of commerce, and which was said to be brought from Lahore. It was warm and aromatic in taste, fragrant, and frequently called Orris (Iris)-Root by Europeans in India. On comparing specimens of this root, which he obtained in northern India, with what was called putchuk in Calcutta, he found that they were identical, and he was subsequently informed by Mr. Beckett, who had been long settled as a merchant in northern India, that what he purchased from Umritsir under the name of Kooth, he sold in Calcutta by that of putchuk, so that there can be no doubt of the identity of the two substances; but all that has been ascertained with respect to the place where it was produced, was that it seemed to be to the north of the river Sutlege.

PUTTY, the useful cement used by glaziers for fastening the glass in the frames of windows, is composed of linseed oil and whiting. The whiting should be well dried, and then pounded and sifted till it becomes a fine powder and is quite free from grit. The whiting, a little warm, should be gradually added to the oil, and well mixed by means of a piece of stick or a spatula. When it is sufficiently stiff, it should be well worked with the hand on a table, and afterwards beaten on a stone with a wooden mallet, till it becomes a soft, smooth, tenacious mass. Putty by exposure to the air gradually hardens till it becomes almost like stone. A ball of putty, when left some days, becomes somewhat hard, but may be easily softened by beating.

The most extensive employment of this substance for glazing has perhaps been in the recent operations in the Glass Palace.

PYRAMIDS. The pyramids of Egypt, especially the two largest of the pyramids of Jizeh, are the most stupendous masses of building in stone that human labour has ever been known to accomplish. The Egyptian pyramids, of which, large and small, and in different states of preservation, the number is very considerable, are all situated on the west side of the Nile, and they extend, in an irregular line and in groups, at some distance from each other, for a length between 60 and 70 miles. All the pyramids have square bases, and their sides face the cardinal points.

Herodotus was informed by the priests of Memphis that the great pyramid was built by Cheops, king of Egypt, about 900 B.C., or about 450 years before Herodotus visited Egypt. He says that 100,000 men were employed twenty years in building it. Whether this were or not the true origin of the great pyramid, the vast structure, as at present standing, consists of a series of platforms, each of which is smaller than the one on which it rests, and consequently presents the appearance of steps, which diminish in length from the bottom to the top. Of these steps there are 203, and the height of them decreases, but not regularly, from the bottom to the top; the greatest height being about 55 inches, and the least about 20 inches. The horizontal lines of the platforms are perfectly straight, and the stones are cut and fitted to each other with the greatest nicety, and joined by a cement of lime with little or no sand in it. It has been ascertained that a bed, eight inches deep, has been cut in the rock to receive the lowest external course of stones. The vertical height, measured from this base in the rock to the top of the highest platform now remaining, is 456 feet. This platform has an area of about 1067 square feet, each side being 32 feet 8 inches. If to this were added what is necessary to complete the apex of the pyramid, the total height would be about 479 feet. Each side of the base, measured round the stones let into the rock, is rather more than 763 feet, and the perimeter of the base is therefore 3053 feet. The area of the base, measured along the outside of the stones let into the rock, is 64,753 square yards, or about 13¼ acres. This area is about the same as Lincoln's Inn Fields, London, measured by the wall of Lincoln's Inn Garden and the sides of the houses within the court-yards. The surface of each face, not including the base let into the rock, is 25,493 square yards; and that of the four faces is consequently 101,972 square yards, or more than 21 acres. The solid content of the pyramid is about 3,394,307 cubic yards, which (not making any deductions for chambers and passages in it) has been estimated to be six times the mass of stone in the Plymouth breakwater. Reckoning the total height at 479 feet, the pyramid would be 15 feet higher than St. Peter's at Rome, and 119 higher than St. Paul's, London.

These measurements, relating to the Great Pyramid, will serve to convey an idea of all of them; we need not notice them particularly here, nor need the internal cavities and passages be here dwelt upon. The materials of all the pyramids are limestone; and Belzoni is of opinion that part of the stone for the second pyramid was procured immediately on the spot, judging from the manner in which the rock has been cut away round the pyramid. Herodotus certainly understood that all the stone was brought from the mountains near Cairo, where there are indeed ancient quarries of great extent; but it seems probable that the greatest part of the materials came from the west side of the Nile. The blocks of granite were brought from Syene, which is nearly 500 miles higher up the Nile. The rock on which the great pyramid stands has been found to project at least as high as 80 feet into the body of it. The stones of which it is built rarely exceed 9 feet in length and 6½ in breadth; the thickness has been already stated.

At Thebes there are some small pyramids of sun-dried brick, in which the central chambers have vaulted roofs. There are numerous pyramids in Nubia, perhaps eighty or more, but they are generally small. Next to those of Egypt the most extraordinary pyramids now existing are those of Mexico.

PYRENEES. The lofty chain of the Pyrenees gives name to three departments of France. In the mountains themselves iron, copper, and lead mines are worked, and fine statuary and other marble, including some of the most beautiful varieties, is quarried.

In the department of *Basses Pyrenees* the annual produce of wine is about 7,000,000 gallons, the best kinds being those of Jurançon and Gan. The high mountains are to a great extent covered with forests of pine, fir, and oak, which afford good ship timber. The growing of flax and hemp, the trade in hams with Pau and Bayonne, and the traffic in mules and cattle with Spain, are the most important sources of wealth to the agriculturist. Silver, copper, iron, lead, coal, salt, cobalt, and sulphur, are found. Slate, marble of all colours, granite, alabaster, rotten-stone, and marl, are quarried. The manufactures include linen, calico, coloured handkerchiefs, flannel, drugget, capes, hosiery, Bearnese caps, carpets, chocolate, liqueurs and common brandy, paper, leather, pottery, and some iron. Ships are built on the Adour and on the coast. The commerce is composed of the various products already named, and of wine, liquorice, rosin, prepared skins, wool, hides, deal planks, colonial produce, salt, &c.

In the department of *Hautes Pyrenees* about 6,000,000 gallons of good white and red wines are made annually. Horned cattle and sheep are very numerous; good butter and cheese are made; mules, asses, and horses are reared, and also pigs and large numbers of poultry, especially geese, the legs of which are salted for export. Bees are carefully tended, and honey and wax are abundant. Iron, copper, zinc, lead, manganese, nickel, and cobalt, are found, but no mines are worked; marble of different colours, building stone, slate, granite, amianth, kaolin, marl, fullers' earth, and potters' clay, are raised. The commerce of the department is limited to cattle, corn, mules and horses for Spain, timber, oak staves, hoops, the agricultural products before named some linen, cotton and woollen stuffs, cutlery, nails, hides, &c.

In the third of these departments, *Pyrenees Orientales*, about 7,000,000 gallons of wine are made annually. The red wines of Roussillon are in general of excellent quality, agreeable taste, strong body, and well adapted for transport; they are used for giving colour and body to the lighter growths of Cahors and Auvergne. The wines of Collioure and Port-Vendres have the highest repute; they fine themselves and become of a golden hue with age; in this state they take the name of *Rancio de Rousillon*. The sweet wines of Rivesaltes hold the first rank among the dessert wines of France. The mountains of the department are in many parts clothed with fine forests of oak, beech, pine, and fir, and abound with aromatic and medicinal plants. The cork tree grows naturally, and is also an object of careful cultivation. Bees and silkworms are carefully attended. Many iron mines are worked, and the ore is smelted, and converted into malleable iron at about 180 forges and furnaces, by means of charcoal prepared on the spot. Copper, lead, bismuth, and alum, are found. A coal mine is worked near Estavar; marble, alabaster, granite, and steatite, are quarried. Besides wine and iron, the industrial products include coarse woollen cloths, leather, corks, knit stockings and caps, brandy, whip-handles, common pottery, tiles and bricks. The fisheries on the coast are actively plied, and large quantities of sardines and anchovies are preserved. The coasting trade in the leading articles named, and in wool, oil, honey, &c., is active.

PYRMONT WATER. Pyrmont is the name of a small county belonging to the Prince of Waldeck in North Germany. It derives its chief revenue and importance from a mineral spring in the town of Pyrmont. The great bathing house which contains 140 apartments, tastefully fitted up, and handsome spacious baths, is the most important structure in the place. Above 300,000 bottles of the water from the principal chalybeate spring are exported annually.

PYROGRAPHY. This name has been recently proposed for a peculiar kind of painting or rather delineation, in which *heat* is the chief agent employed. The homely phrase of *poker painting* is that by which it is generally known; since a red-hot poker might be the substitute for the painter's brush in producing the pictures; but homely English is often made to give way to learned Greek, in scientific and artistic designations.

These pyrographs are pictures produced on the surface of wood by heated irons. Some curious specimens of this art were produced by Dr. Griffiths, Master of University College, Oxford, about thirty or forty years ago. The altar piece in the college chapel, and one or two heads in the Taylor Gallery, are still existing; they are said to have very much the appearance of mezzo-tinto engravings, or of crayon drawings; but, from their very nature are much more durable than any engravings or drawings, and are considered to be well fitted to ornament panels. The wood is either sycamore or plane-tree; which are not liable to warp, and which present large surfaces. The delineations are produced by solid pieces of thick iron, shaped somewhat like the heater of an Italian iron.

This art has a renewed interest imparted to it, by the circumstance that the Committee of the Great Exhibition has allotted 30 feet of wall space to the productions of a lady, Mrs. Mills, who has lately introduced many improvements in the preparation of the wood and in the form of the iron implements. The specimens to be exhibited are fitted by their general character to adorn collegiate, corporate, or baronial apartments. The effect in Dr. Griffiths' pictures is produced mainly by broad shadows; while the more recent productions have somewhat the character of etchings. Representations of animals, such as those which almost live and breathe on the canvas of Edwin Landseer, are said to be those for which the art shows peculiar aptitude.

By the rules of the committee, no *paintings* are admitted at the Exhibition; but it would appear that these curious specimens partake of the durability and surface quality of *carvings*, and are on that ground admissible.

PYROLIGNEOUS ACID. [Acetic Acid.]

PYRO'METER. This instrument was invented by Musschenbroek for measuring the effects produced in the dimensions of solid bodies by the application of heat; but the signification of the term has since been extended so as to include those instruments the object of which is to measure all gradations of temperature above those which can be indicated by the mercurial thermometer. We will briefly describe five or six varieties.

Musschenbroek's Pyrometer consisted of a metallic bar, about six inches in length, one extremity of which was fixed, while the other was left free to advance as the metal elongated from the effect of several spirit lamps placed beneath, which, at each experiment, were charged with the same quantity of highly rectified spirit of wine. The advance of the moveable extremity gave motion to a pinion and wheel, the latter of which drove an index over a graduated circle, each degree of which corresponded to a linear expansion of some determinate fraction of an inch. Desaguliers afterwards substituted fine cords and friction rollers for the wheel and pinion.

Borda's Pyrometer.—The rods employed by Borda in measuring the base-line of the great French Survey consisted of a rule of brass laid upon a somewhat longer rule of platinum and attached at one extremity. The portion of the platinum rule not covered by the one of brass was divided into millionths of its entire length, and further subdivided by means of a vernier and microscope adjusted to the extremity of the brass rule. The value of each of these divisions having been previously ascertained, by first surrounding the compound rule with melting ice, and then immersing it in boiling water, it was only necessary to observe the indications of the vernier in order to apply the requisite correction for reducing the length of the rod to the standard temperature.

Ramsden's Pyrometer.—For low temperatures, the contrivance of Ramsden was employed by General Roy in determining the expansion of the rods used in measuring the base on Hounslow Heath for the Trigonometrical Survey. The rod was immersed in a trough of water, and over each extremity was placed a microscope, to which a slow motion could be given in the direction of the length of the rod by means of a fine micrometer screw. The temperature of the water was then gradually raised, till a thermometer placed in the trough indicated an advance of 10°, 20°, 30°, or any required number of degrees. The consequent elongation of the rod destroyed the coincidence of its extremities with the lines of collimation of the microscopes, which was re-established by turning the micrometer screws, and carefully noting the number of turns and fractions of a turn necessary for that purpose; when, the value in parts of an inch in each turn being previously known, a direct measure of the expansion was obtained, free from the errors of a system of levers or of a train of wheels and pinions.

Wedgwood's Pyrometer.—The property of alumina whereby it undergoes a diminution of bulk when heated, was employed by Wedgwood as a measure of high temperatures. His pyrometer consisted of cylinders of fine white clay, and an apparatus for accurately measuring their length. This apparatus consisted of a metallic plate, upon which were fixed two brass rules slightly inclined to each other. The rules used by Wedgwood were 24 inches long, and divided into 240 equal parts. The distance between the rules at one extremity was three-tenths and at the other five-tenths of an inch; consequently the difference between their distances at any two consecutive divisions was the 1200th part of an inch. The clay cylinders were first baked at a red heat (about 947° Fahr.), and then reduced to exactly five-tenths of an inch in length, so as to fit the first division of the scale. When afterwards exposed to a greater heat they underwent contraction, and the amount of this contraction was determined by observing the division of the scale corresponding to their diminished length.

Dulong and Petit's Pyrometer was constructed for measuring the *cubical expansions* of various substances. By observing the difference of altitude at which mercury of different temperatures stood in the two arms of an inverted glass siphon, they determined the absolute expansion of the mercury; and by comparing this with the apparent expansion of mercury in a glass tube, they deduced the absolute expansion of the glass. A cylinder of the metal whose expansion was sought was then placed within a glass tube, closed at one extremity and terminating at the other in a capillary opening, and the rest of the tube occupied with mercury. Upon the whole being heated a portion of the mercury was expelled equal to the excess of the absolute expansions of the mercury and metal above that of the glass; and as the expansions of the mercury and glass were previously known, the weight of the expelled mercury determined the expansion of the metal.

Prinsep's Pyrometer.—The unoxidable metals (gold, silver, and platina) present three marked temperatures, from the low melting-point of silver to the high ignition of platina; and many intermediate links may be made by alloying the three metals together in different proportions. When such a series has been once prepared, the heat of any furnace may be expressed by the alloy of least fusibility which it is capable of melting. As the melting points of silver and gold are comparatively near to each other, Mr. Prinsep assumed only ten intermediate gradations of heat, the lowest of which corresponded to the fusing point of pure silver, and the others to the fusing points of silver alloyed with 10, 20, 30, &c., per cent. of gold. From the melting point of gold to that of platina, he assumed one hundred gradations of heat, which were the melting points of pure gold and of gold alloyed with 1, 2, 3, &c., per cent. of platina. Among the advantages of this mode of identifying temperatures are:—the smallness of the requisite apparatus, nothing more being needed than a small cupel, containing in separate cells eight or ten pyrometric alloys, each of the size of a pin's head; the indestructibility of the specimens, since those melted in one experiment need only to be flattened under a hammer, when they will be again ready for use; and the facility of notation, since two letters and the decimal of alloy will express the maximum heat.

Daniell's Pyrometer is a complex apparatus depending on the small expansibility of black lead compared with that of metals. A bar of black lead is bored nearly from end to end like a gun; and into this bore is placed a rod of the metal to be experimented on. When both are exposed to a great heat, the metal expands more than the black lead, and causes a small cylinder of porcelain to protrude from the top of the tube or bore. This cylinder is connected with an index or hand which moves round a graduated arc; and the degrees on this arc are so calculated as to indicate the temperature to which the metal has been exposed.

PYROTECHNY. The art of making fire-works is essentially a chemical one. It takes advantage of the chemical affinity between substances, of the power of ready ignition, of the rapid and slow combustion produced by different proportions of the ingredients, and of the production of exquisite colours by the substances while burning. The revolving of stars, &c., is partly a mechanical arrangement arising out of the resistance or inertia of the air when a burning material is forcing its way out of a tube. The three chief ingredients are nitre, sulphur, and charcoal; the secondary ingredients are filings of iron, steel, copper, zinc, and other materials; while various oxides, acids, alkalies, and salts, tend to produce varied colours by different modes of combination. The coloured fires are the most interesting results, and require much care in the choice and preparation of the materials. One familiar kind of fire-work is noticed under ROCKETS.

PYROXYLIC SPIRIT, or *Pyroligneous Æther*, obtained by distillation from wood, is a colourless liquid, has a peculiar penetrating smell, partaking both of alcohol and æther, and its taste is pungent. It is lighter than water, and boils at about 150° Fahr. It is an extremely inflammable liquid, and burns without residue; and being cheaper than spirit of wine, it is advantageously substituted for it in many manufacturing arts. It is capable of combining with chlorine, iodine, and other elementary bodies; it unites also with acids to form various compounds.

Q

QUADRANT. [SEXTANT.]

QUARANTINE LAWS. Quarantine laws are the result of imperfect knowledge on a subject which is of great importance to commerce. They are regulations chiefly of a restrictive nature, for the purpose of preventing the communication from one country to another of contagious diseases, by means of men, animals, goods, or letters. The term Quarantine originally signified a period of forty days, during which a person was subject to the regulations in question. The regulations consist in the interruption of intercourse with the country in which a contagious disease is supposed to prevail, and in the employment of certain precautionary measures respecting men, animals, goods, and letters, coming from or otherwise communicating with it. Men and animals are subjected to a probationary confinement, and goods and letters to a process of depuration, in order to ascertain that the contagious poison is not latent in the former; and to expel it, if it be present, in the latter. Quarantine lines may either be drawn round a coast, as is the case in France, Italy, and Greece, with respect to the Levant; or they may be drawn along a land frontier, as on the frontier between Austria and Turkey.

Goods carried in ships or by land are subject to quarantine, according as they belong to the class of susceptible or non-susceptible goods. Goods which are supposed to be capable of containing and transmitting the poison of the plague, are called *susceptible.* Goods which are supposed to be incapable of containing and transmitting the poison of the plague, are called *non-susceptible.* All animal substances, such as wool, silk, and leather, and many vegetable substances, such as cotton, linen, and paper, are deemed susceptible. On the other hand, wood, metal, and fruits, are deemed non-susceptible. Every ship is furnished by the consul or other sanitary authority at the last port where it touched, with a document styled a *Bill of Health,* declaring the state of health in that country. If the ship brings a *clean bill* of health, the passengers and goods are not subject to any quarantine. If she brings a *foul bill,* they are subject to quarantines of different durations, according as the plague is known or only suspected to have existed in the country at the ship's departure. On account of the prevalence of plague in the countries on the Levant, they are considered as permanently in a state of suspicion; and no ship sailing from any of them is considered to bring a clean bill. The periods of quarantine vary from two or three to forty days; the usual periods are from ten to twenty days. The building in which passengers usually perform their quarantine, and in which goods are depurated, is called a Lazaretto. The most spacious and best appointed lazarettoes in the Mediterranean are those at Malta and Marseille.

The laws of quarantine depend directly on the contagion or non-contagion of certain diseases; and on the difference between *susceptible* and *non-susceptible* commodities, if the contagion-theory be true. It becomes therefore a medical question; and the opinions of medical men throughout Europe are gradually tending to such a result as will either abolish quarantine altogether, or greatly modify and limit it: a result of very great importance to the commerce and industry of Europe.

QUARRYING is the operation of extracting from the ground, or detaching from the sides of rocks, marble, stone, or other minerals in considerable masses. When the material to be excavated lies vertically below the surface of the ground, the work commences by removing the earth to a depth sufficient to lay that material bare, in order that it may be separated into blocks, and removed; but when the stone, &c., is in the interior, and near the side of a mountain or hill, the workmen proceed as in the operation of mining, running galleries into the ground, and leaving pillars of the material for the support of the mass above them.

A quarry of small extent is opened by sinking vertically in the ground a shaft, into which the men descend by ladders; and the blocks of stone, being separated from the mass, are drawn up by means of cranes, which are worked by a windlass or other machine. In working the larger quarries, the vegetable mould forming the upper surface is removed by the spade; and the beds immediately underneath, generally consisting of rag, or stone of an inferior quality, are broken up by gunpowder or otherwise, and conveyed to a distance. The stones intended for sale, and which are generally in beds much below the surface, are sometimes also detached from the mass by blasting; but as by this process the blocks are broken irregularly and the stone wasted, a different method is generally employed. The large mass of stone, as it exists in the quarry, consists of strata contiguous to one another, and the surfaces in contact form planes of *cleavage;* in lines parallel to which the stones being more easily divided than in any other direction, these lines constitute what is called the *cleaving* grain of the material. In order therefore to separate a large block from the mass, a series of iron wedges, placed in line a few inches asunder, on the natural face of the rock and in the direction of the cleaving grain, are driven into the stone till a part is loosened: a channel is then cut in the direction of the length of the intended block, and at a distance from the natural edge of the stone equal to its required breadth; and wedges being planted in the channel, they are driven by repeated strokes till the stone is split in that direction also. In the hardest stones, the wedges are placed not in the channels, but in what are called *pool* holes sunk in the direction in which the block is to be severed from the mass. A similar operation is then performed in the direction of the breadth of the block; and thus a large portion is detached from the original mass.

The natural strata of the stone in different quarries are in different positions; frequently they are horizontal, but generally they are inclined to that plane, and sometimes they are vertical: occasionally also both the first and last of these positions are assumed by the stone in the same quarry. It is evident that the separation of the blocks from a mass must be most easily effected when the natural strata are in vertical positions; cutting the stone in directions perpendicular to the line of the grain is always a work of difficulty, and the operations are attended with some danger to the quarry-men when the latter are obliged to work in galleries under ground.

After the blocks have been severed from the mass, they are reduced as nearly as possible to a rectangular form; and this is done by means of a tool called a *kevel*, pointed at one end and flat at the other, with which the irregular parts are knocked off. The blocks are then usually, by means of cranes which are capable of being moved from place to place, raised upon trucks or low carriages; and these are drawn, generally on iron railways, to the quays or wharfs where the stone is put on ship-board. At the slate quarries in Caernarvonshire the slabs are placed on sledges, which, by an engine, are drawn up an inclined plane; and, from the summit of this plane, the stone is drawn by horses to the Menai.

QUARTZ, is the mineralogical name of numerous varieties of rock crystal, the native oxide of silicium [SILEX], called also siliceous or flint earth, and silicic acid. Quartz occurs crystallised and massive, and in both states it is widely diffused throughout nature, especially as one of the constituents of granitic and the older rocks. Quartz is hard enough to strike fire with steel; it becomes luminous and electrical by friction; it is of various colours; it is infusible; insoluble in acids, in general. but acted on by hydrofluoric acid. *Hornston*, and *chert* are varieties of compact quartz. Cavernous quartz is termed *spongiform quartz* or *swimming stone*. Among the numerous varieties of quartz are *brown* or *smoky quartz*, *purple quartz*, or *amethyst*, *blue quartz*, *green quartz*, *yellow quartz*, and *red quartz*. Among the minerals in which quartz is the chief ingredient, are *agate*, *avanturine*, *flint*, *flinty slate*, *opal*, *chalcedony*, *heliotrope*, *onyx*, *plasma*, *sard*, *sardonyx*, and *jasper*.

QUA'SSIA, is a genus of plants consisting of trees inhabiting the tropical parts of South America, particularly Surinam and the adjoining countries.

Quassia amara, the true Quassia of modern botanists, is a small tree inhabiting the woods of Surinam, Demerara, and probably the greater part of Central America. The wood of the root of this plant was formerly in great repute as a stomachic and as a remedy for the malignant endemic fevers of Surinam. The flowers also were, and still are, in that country infused in wine or spirits, and form a bitter beverage; but the wood is out of use, in consequence partly of its being less easily procured than that of the next species, and partly from an opinion being entertained of some bad properties existing in connection with the intense bitter. *Quassia excelsa* is a large tree inhabiting Jamaica. The wood is white, and scentless, but most intensely bitter; it is one of the ingredients employed by fraudulent brewers in adulterating beer. *Quassia Simaruba* is the plant which furnishes the bark called Simarouba, which comes from Jamaica in bales, and is used as a tonic, although it also appears to act as an emetic.

Quassia is imported in billets, sometimes a foot in diameter, and several feet long; but before being used for medicinal purposes, they are cut into chips, which are of a light gray colour, or, by long exposure to the air, of a yellow or brownish hue. The active principle of Quassia seems to be *quassite*, a neutral substance, which crystallises in white prisms, and is readily soluble in alcohol.

QUERCITRON BARK. This valuable dye-drug is described under BARK. Chevreul has given the name *Quercitrin* to the colouring principle of the Quercitron Bark. It crystallises in colourless acicular crystals, which have a slightly sweet taste, and subsequently a bitter one. They are very soluble in water, in alcohol, and in æther. On boiling a solution of Quercitrin, it becomes turbid, and deposits a quantity of small acicular crystals of *Quercitrein*, less soluble in water, and which forms with hydrate of lead a beautiful yellow lake of lead.

QUERCUS. [Bark; Cork; Oak.]

QUICKSILVER. [Mercury.]

QUINA or QUINIA, is a very important vegetable alkali, contained in the three well-known varieties of Cinchona, or Bark, but principally in the Yellow Bark. This alkali is colourless, inodorous, and extremely bitter. It fuses at about 300° Fahr., and when cold is yellow, translucent, friable, and somewhat like resin. When subjected to a strong heat, with access of air, it is totally dissipated, with the formation of the vapour of the carbonate of ammonia. The only one of the salts of quina extensively employed is the *Disulphate*, the *Quinæ Disulphas* of the London Pharmacopœia, and the *Quinæ Sulphas* of the Edinburgh. The crystals of this salt are colourless, acicular, have a pearly lustre, a bitter taste, and effloresce when exposed to the air.

R

RADIATION OF HEAT. There are certain experiments on the radiation of heat which possess great practical value, in so far as they show what substances should be employed, and what avoided, when heat is required to be retained in any vessel or other body. In the jackets or envelopes for boilers and steam pipes this matter is always attended to.

Sir John Leslie placed a tin canister filled with hot water in the focus of a parabolic mirror of the same metal, and a differential thermometer in the focus of another such mirror, which was placed opposite to it. The four sides of the canister were covered with the substances whose radiating powers were required. When three of the sides were covered respectively with lamp black, paper, and ground glass, and then turned so as to radiate directly on one speculum, the heat reflected by the other raised the thermometer to 100°, 98° and 90°; but when the fourth side, which was uncovered, was similarly directed, the thermometer fell to 12°. Thus it appears that polished metallic substances are bad radiators, which may be attributed to the internal reflection of the heat from their surfaces. A similar apparatus served to measure the absorptive power of different substances, the bulb of the thermometer being covered with an envelope of the substance to be examined; and this power is thus found to be nearly in proportion to that of radiation. In another experiment Leslie filled a canister with ice or snow, and found that the cold apparently emitted from the varnished side was the greatest, and that from the polished side the least; he observed also that the cold like the radiant heat, varied with changes in the absorbent power of the thermometer and of the surface of the mirror.

Count Rumford laid down, as a rule justified by numerous experiments, that if we would confine heated substances, solid or fluid, in a vessel, the surface of the latter should be highly polished; on the other hand, if the object be to cool the substances, the surface should be painted or varnished, or be covered with a soft coating which is not metallic. Also, in warming apartments by steam, the intention being to promote radiation as much as possible, the tubes conveying the steam should be unpolished or painted.

The colours of bodies have some effect on the velocity of radiation and on the absorption of heat. Dr. Stark of Edinburgh surrounded the bulb of a thermometer successively with equal weights of black, red, and white wool, and placed it in a glass tube, which was heated to the temperature of 180° by immersion in hot water; the tube was then cooled down to 50° by immersion in cold water, and the several times of cooling were respectively 21, 26, and 27 minutes.

Those phenomena of radiation which are still the subject of scientific enquiry, and which are not yet applied in the arts, do not come under our notice here.

RAGS. Paper, it is well known to most persons, is made chiefly from the rags or worn fragments of woven materials—linen being the best adapted. The rags of our country do not constitute a fourth, perhaps not a fifth, of the quantity which we use in making paper. Italy and Germany furnish the principal supplies; and it is a curious illustration of national habits that English rags are known from all others by being *cleaner*, while those of Italy are wretchedly dirty. The rags and other materials imported for making paper in 1848 amounted to 7191 tons.

RAILWAYS. If cotton spinning were the greatest commercial phenomenon of the first quarter of the present century, railways may unquestionably be said to be so for the second. Nothing else has been attended by such vast (and in many respects beneficial) results.

Wooden railways or tramways were introduced in the collieries of the north of England in the early part of the seventeenth century. They were adopted in order to reduce the labour of drawing coals from the pits to the places of shipment in the neighbourhood of Newcastle-upon-Tyne. They consisted, in the first instance, simply of pieces of wood imbedded in the ordinary road, in such a manner as to form wheel-tracks for the carts or waggons employed. An improved form was afterwards adopted, by laying the wooden rails on transverse sleepers. The vehicles used upon these wooden railways were generally waggons, containing from two to three tons of coal, mounted upon small wheels. The wheels were provided with a flange or projecting rim, which, by coming in contact with the side of the rail, retained the waggon upon the railroad.

About the year 1767 iron plates were laid upon the wooden rails on a railway at the Colebrook Dale iron works. Some time after the experiment at Colebrook Dale, cast-iron rails, with an upright flange, were brought into use at the colliery of the Duke of Norfolk, near Sheffield, in 1776. Originally they were fixed upon cross sleepers of wood, like those used to support wooden rails; but about the year 1793 blocks of stone were introduced as supports, instead of the wooden sleepers. Various inconveniences attendant on these *plate-railways* led to the use of *edge-railways*, which have now almost entirely superseded the previous form. The first edge-railway of any considerable extent was completed in 1801 for the conveyance of slate from the quarries of Lord Penrhyn. The decided advantages of edge-rails were so well appreciated by the coal owners of Northumberland and Durham, that they were adopted extensively by them within a few years after the successful experiment at Penrhyn. Many successive varieties have been introduced in the form of the rails; but the greatest improvement was the invention, in 1820, of an efficient and cheap method of rolling iron bars suitable for rails and similar purposes. The fibrous texture of wrought-iron makes it far less likely to break when subjected to concussion than cast-iron, and the sectional form used is such as to render bending improbable.

The application of the steam-engine to the purposes of locomotion was suggested in one of the patents of Watt: but it does not appear that either he or any other inventor carried their ideas into practice until about 1802, when Messrs. Trevithick and Vivian patented a high-pressure engine, which, by its simplicity and compactness, was admirably adapted for locomotive purposes. Within a few years they built several carriages, one of which, at least, was for use on a common road. In 1805 they made some interesting experiments with a locomotive on a tramway near Merthyr Tydvil, and thereby proved the practicability of their plan. Engineers at first thought that the wheels would not hold or *bite* on the rails, without some other contrivances; but those fears have been dissipated.

Shortly before the completion of the Liverpool and Manchester railway, the directors decided that horse traction would be too slow for the requirements of the traffic; and they determined to try locomotives. They offered a premium of 500*l.* for the best to be produced which would fulfil certain conditions, of which some were that it should not emit smoke, should draw three times its own weight at the rate of ten miles per hour, should be supported on springs, not exceed six tons weight, or four tons and a half if on only four wheels, and should not cost more than 550*l.* The trial was fixed for October, 1829, when four steam locomotives were produced, one of which was withdrawn at the commencement of the experiment. Of the other three, the *Novelty*, by Messrs. Braithwaite and Ericson, and the *Sans Pareil*, by Mr. Hackworth, failed in some of the conditions. The remaining engine, the *Rocket*, was constructed by Robert Stephenson and Mr. Booth, of the Liverpool and Manchester Railway, and succeeded in performing more than was stipulated for. The most marked improvement in Stephenson's locomotive was the use of a tubular boiler instead of a large flue.

From the opening of that railway, the success of the great system was at once decided. Nothing could check the spread of so vast an improvement; and we have since seen such a twenty years of commercial energy as the world never saw before.

In the laying down and construction of a railway, the engineer so adjusts his inclinations or *gradients* as to make the nearest practicable approach to a level, avoiding if possible any loss of power from undulations of surface, by making all the inclinations on one side of the summit, or highest point to be passed over, rise towards it, and all on the opposite side descend from it. Curves on a main line of railway being objectionable, the engineer so adjusts his line as to avoid them when possible, and to make those which are inevitable of as large a radius as circumstances will admit. The works of a railway consist chiefly of *tunneling, excavation, embankment, arching, viaducts, bridges;* concerning each of which a few words may be said.

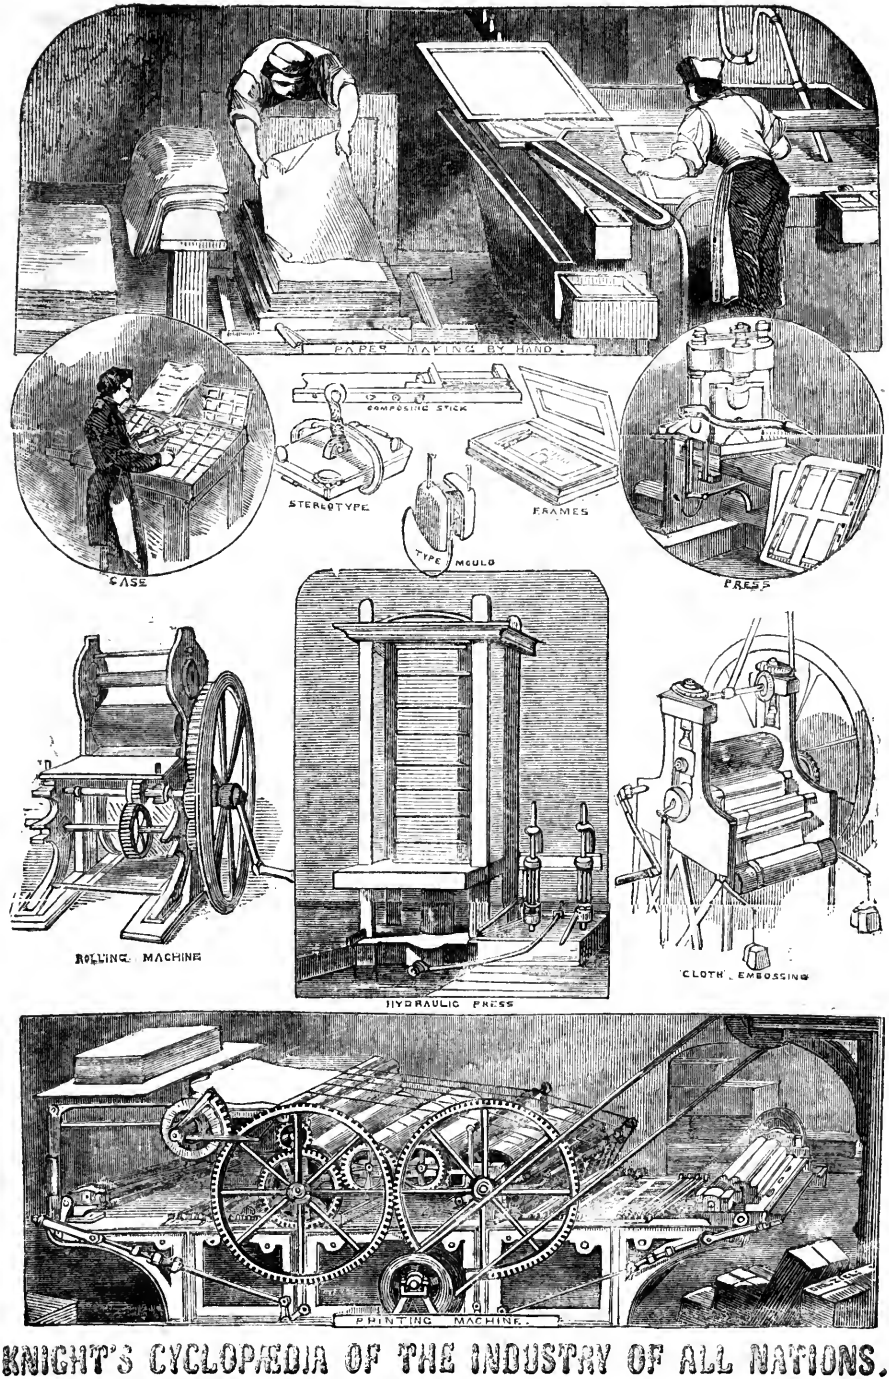
Tunnels are, in general, the most formidable works, and the time and expense of forming them can be least accurately calculated, because unforeseen circumstances often arise to retard their progress. Being objectionable also on other accounts, tunnels are avoided as much as possible in the more recently-designed railways. *Excavations* of great depth and extent are of frequent occurrence where the railway passes through high ground, but not at such a depth from the surface as to require a tunnel. The depth of cuttings is frequently from fifty to a hundred feet; and the slope of the sides depends on the nature of the rock or soil. *Embankments* are the artificial ridges of earth formed to support the railway on a higher level than the natural surface of the ground. Their dimensions are often fully commensurate with those of cuttings, from which their materials are mostly procured. In the ordinary mode of proceeding, an embankment is formed simultaneously with a cutting, the earth waggons proceeding filled from the excavation along a temporary railway to the embankment, where they are tipped up to discharge their contents. *Arching* of almost every kind is more or less required in viaducts, bridges, culverts, and drains; and simpler work in the retaining walls, station buildings, and other necessary erections. *Viaducts* of great magnitude are often executed for the purpose of crossing valleys at an elevation greater than could be conveniently obtained by embankment, and also for entering or passing through towns. They are usually of stone or brick, but sometimes of wood or iron. *Bridges* are required occasionally for crossing rivers, and very frequently at the intersection of roads, and as communications between severed property. They are formed of stone, brick, wood, iron, or combinations of two or more of these.

In order to obtain a firm dry foundation for the blocks or sleepers on which the rails rest, a layer or stratum of broken stone, technically called *ballast*, is spread over the road to the thickness of a foot or more, varying according to the construction adopted and other circumstances. The rails used to be spiked down to stone blocks; but it is found better either to rest them on sleepers placed at intervals, or on continuous timber bearings, as on the Great Western line. Mr. Barlow has recently invented cast iron bearings for the rails, which are found to be a valuable improvement. He has also introduced a very broad wrought iron rail which requires no sleepers, the broad bottom of the rail being laid upon the ballast itself. The rails now used vary from 70 to 90 lbs. per yard. In the old colliery tramways, four feet was not an uncommon width for the *gauge* of the rails, but many lines were less. Some of the colliery railways of Northumberland are four feet eight inches and a half; and from these the Stockton and Darlington, Liverpool and Manchester, and other lines, took their gauge. The advantage of uniformity has led most companies to follow this example. The ordinary width being considered by him inconveniently limited, Mr. Brunel fixed upon seven feet as the gauge of the Great Western and its tributary lines; and hence has arisen the late 'battle of the gauges,' which may be truly said to have cost the respective companies millions of money, in law and legislation.

Wherever there is a uniform gauge, the *clearing-house system* is acted upon by the railway companies, to the obvious advantage of all parties. The principle of the system is, that passengers shall be booked through at all principal stations, and conveyed to their destination without change of carriage; that horses and cattle be in like manner carried through without change of conveyance, and goods without being shifted or re-assorted; that the companies respectively shall pay a fixed rate per mile for such carriages and waggons, not their own property, as they may use, and a further sum per day by way of fine or demurrage for detention, if kept beyond a prescribed length of time; and that all traffic accounts between the several companies shall pass through the Clearing-House.

The carriages used on railways we need not stop to describe; every one has had more or less opportunities of noticing the gradual improvements introduced. The wonder-working *locomotive*, however, must engage a little of our attention.

In a modern locomotive, the tubes through the boiler, for the passage of flame and heated air, are now always made of brass, which is found much more durable than copper. They vary in number in different engines from about ninety to a hundred and fifty or upwards,



KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 34

being frequently less than an inch and a half in diameter. The power of generating steam, which is the measure of efficiency in a locomotive engine, depends much upon judicious tubing. Boilers are frequently tubed to such an extent that from four to six hundred square feet of heated metal is exposed to the water, in addition to the area of the fire box itself. An important feature in a locomotive boiler is its security from bursting, because as the tubes are much weaker than the external casing of the boiler, they are almost certain to give way first; and the bursting of one or two tubes is rarely productive of more serious consequence than extinguishing the fire, and thereby causing a gradual stoppage of the machine. In the old engines the cylinders were placed at the bottom of the smoke-box, and the machinery under the boiler; but there is a growing preference for those in which the cylinders are fixed outside the framing, and the power is conveyed to the wheels by external cranks and connecting-rods. The 'long-boiler' engines of the narrow gauge are very large; but those of the Great Western Company are still more so. One of the engines of this company has about 1750 square feet of heating surface in the boiler; has cylinders of 18 inches diameter and 24 inches stroke; driving-wheels of 8 feet diameter; and two pair of bearing-wheels of 4 feet 6 inches in diameter. The total length is 24 feet; the distance between the supporting wheels 16 feet; the weight of the engine alone, without fuel or water 28½ tons, and of the tender, 10 tons; and the total weight of engine and tender when loaded, about 56 tons. These engines, in the express train between London and Exeter, go at a speed, in some parts, of 60 miles an hour.

Small and light locomotives have been recently introduced, fitted for the traffic of branch lines.

Taking one line of railway with another, main lines with branch lines, and passenger traffic with goods traffic, it is found that one locomotive is required for about every two miles of railway; to work all the traffic effectively, and to have a sufficient reserve store for contingencies. We are thus enabled to form a rough estimate of the number of locomotives in the United Kingdom.

Rope traction on railways is becoming gradually abandoned; and the once highly extolled *Atmospheric traction* is only applied on two miles of the Dublin and Kingstown Railway.

We will next take a rapid glance at the *statistics* of railways. The first railway established in this country as a distinct undertaking, and intended for public use, was the Surrey Iron Railway, the company for which was incorporated in 1801. In the following twenty years only twenty new railway companies were incorporated; but the Stockton and Darlington Railway, the act for which passed, after much opposition, in 1821, gave an impulse to this kind of enterprise. Between 1801 and 1840 there were 299 acts passed relating to railways. These sanctioned the construction of about 3000 miles of railway; but many of the schemes were afterwards abandoned. Down to 1840 about 1100 miles of railway were finished and open, and about 60,000,000*l.* had been expended on them. Between 1840 and 1850, railway legislation presented the following results:—

Year.	Acts.	Length.
1841	19	14 miles.
1842	22	67 „
1843	24	91 „
1844	48	797 „
1845	120	2883 „
1846	270	4790 „
1847	184	1663 „
1848	83	300 „
1849	35	50 ? „
1850	36	50 ? „
	841	10,705

Taking the earlier acts at 299, and mileage at 3000, we have a total of 1140 acts of parliament sanctioning railways, and about 13,700 miles of railway so sanctioned. This includes the lines which have been abandoned.

At the end of 1849 the length of railway open for traffic in the United Kingdom was 5996 miles; at the end of 1850 it was 6621 miles. This last amount is made up as follows:—

England and Wales	5132 miles.
Scotland	951 „
Ireland	538 „
	6621

The average receipts per mile in England and Wales, during 1850, for passengers was 1218*l.*, and for goods 1110*l.*; this shows that the goods traffic has nearly reached the level of the passenger traffic. The passengers conveyed in the year ending June, 1850 were 66,840,175; who paid fares amounting to 6,465,575*l.* It is a curious fact that the average paid by *all* passengers, of *all* classes, for *all* journeys, on *all* the railways, remains every year pretty nearly equal in amount, viz. two shillings per journey; this is much smaller than most persons would have expected, and it shows how much the short or local traffic preponderates over the long or through traffic. The goods traffic in the same twelve months brought 5,942,277*l.*; giving with the passengers' receipts the astonishing sum of 12,407,852*l.*—exceeding one million sterling per month. There is every reason to believe that the year 1851 will show a very notable increase on these numbers.

Among foreign countries, America, Prussia, Germany, Belgium, and France have not been slow to imitate the railway proceedings of England. On the first day of 1851, the United States had 8797 miles of railway, which cost about 60,000,000*l.* On the continent of Europe the system is making rapid strides, but not comparable to that of the United States.

It is satisfactory to know that the Great Exhibition contains specimens of the latest and finest constructions relating to railway machinery.

RAIN-GAUGE, or *Pluviometer*, is a vessel for measuring the quantity of rain which falls on any particular part of the earth's surface, the quantity being indicated by the depth of the precipitated water which would cover the ground about the spot, supposing the ground to be horizontal, and that the water could neither flow off nor penetrate into the soil. The instrument generally consists of a conical funnel, open both at top and bottom, the lower extremity entering into a cylinder below, which thus receives the rain from the funnel. A graduated rod passes through a perforation in a bar fixed in the direction of a diameter of the cone at its upper surface, and is attached, at the lower extremity, to a circular piston, which has nearly the same diameter as the interior of the cylinder: the weight of the piston and rod is such as to allow the former to float with its upper surface on a level with the surface of the water. A rim, of a cylindrical form, rises a little way above the upper extremity of the conical part of the funnel, in order to prevent the rain-water, which would strike the interior of the latter near that extremity, from being thrown out in consequence of the shock.

The diameter of the funnel at the top may be 12 inches, and that of the cylinder 6 inches; in which case the area of the horizontal section on which the rain falls will be to that of the cylinder in the ratio of four to one. Hence a depth of water equal to one inch at the horizontal section will be expressed by a space equal to 4 inches on the length of the rod; and, each of such spaces being divided into 100 parts, the depth of water at the said section will be indicated in hundredths of an inch. The height of the cylindrical vessel below the funnel may be from 25 to 30 inches. For the sake of diminishing the evaporation and of measuring small quantities of rain with greater precision, the diameter of the cylinder is sometimes reduced to 2 inches, and the collected water is, by means of a small pipe, inserted in the bottom of the cylinder, and furnished with a cock made to pass into a glass tube whose interior diameter is half an inch. In this case the diameter of the upper extremity of the funnel being the same, a shower of rain whose depth on the ground might be one-hundredth part of an inch, would be indicated by 5·76 inches in the tube.

RAISINS. The dried fruits of several varieties of the vine are called *raisins.* They are named after the countries where they are produced, or the places whence they are imported; as *Malaga*, *Valencia*, and *Smyrna.* The peculiar small and generally seedless grapes, formerly called *Corinths*, are now better known as the dried or Zante *Currants* of the shops.

There are many modes of preparing the raisins. One is to dry the grapes, after being cut when fully ripe, by exposure to the heat of the sun on a floor of hard earth or of stone. Another method is to cut the stalk half-way through when the grapes are nearly ripe, and leave them suspended till the watery part is evaporated; the flow of sap is in a great measure prevented from entering the fruit, in consequence of the incision, and whilst evaporation continues to go on undiminished, desiccation must take place. The currant-grapes are gathered in the end of August and beginning of September. Rains often spoil the crop when they occur at the time of gathering or drying. The fruit, when sufficiently dry, is separated from the stalks by small rakes, and afterwards stored in magazines, 'scraglie,' constructed somewhat like a lime-kiln, having an opening at top, where the fruit is put in, and a door at bottom, opened only at the time of sale. The fruit is rendered so compact by its own weight, that considerable force is requisite to break it up for the purpose of being packed in the large casks in which it is exported.

The Malaga raisins are esteemed the finest; and the muscatels from thence exceed all others in price. The black Smyrna raisins are those of least value. The white grape of Alexandria furnishes very fine raisins. An oil exists in the seeds of the grape, in the proportion of 12 pounds of oil to 100 pounds of seeds. Though it is not obtained without difficulty, it is extracted in Italy in large quantity. When heat is used it has a harsh taste, and is mostly used for burning; but when cold-drawn, it may be used for food. *Tannin* of the purest kind may be obtained from the seeds of the grape.

Nearly all the raisins imported into this country are from Spain and Turkey. Of the total quantity imported, 99 per cent. is from these countries, namely, 64 per cent. from Spain, and 35 per cent. from Turkey. A small supply is received from Portugal, Italy, and the Cape of Good Hope. The raisins imported in the last three years amounted to—

1848	239,668 cwts.
1849	209,180 „
1850	276,312 „

RAMPART. The ramparts of ancient fortresses were walls of stone or brick, frequently from 60 to 100 feet high and 20 feet broad, including the galleries formed in them; and round or angular towers were constructed at intervals along the walls. A modern rampart is surmounted by a parapet of earth, on the interior side of which, towards the town, is a nearly level space, varying in breadth from 35 to 40 feet, called the terreplein; and on this the artillery is placed. The exterior and interior sides of the rampart are formed with slopes making angles of about 45 degrees with the horizon: or they are retained by revetments, or walls of brick or stone, nearly upright, the exterior face of the rampart constituting the *escarp* of the ditch in front.

RAMSDEN, JESSE, will always occupy a distinguished position in the history of mechanism by his beautiful optical and astronomical instruments. He was born in 1735. At the age of 20 we find him engaged as a clerk in a cloth warehouse in London, in which capacity he continued till 1757-8, when his predilection for other pursuits led him to bind himself for four years to a working mathematical and philosophical instrument maker. He commenced working on his own account, and his skill as an engraver and divider gradnally recommended him to the employ of the leading instrument-makers. Ramsden subsequently married Dollond's daughter, and he received with her part of Mr. Dollond's patent right in achromatic telescopes. His occupation afforded him frequent opportunities of observing the defective construction of the sextants then in use, the indications of which, as had been pointed out by Lalande, could not be relied on within five minutes of a degree, and might therefore leave a doubt in the determination of the longitude amounting to fifty nautical leagues. The improvements introduced by Ramsden are said by Piazzi to have reduced the limits of error to thirty seconds. This circumstance, added to the cheapness of his instruments, which were sold for about two-thirds the price charged by other makers, soon produced a demand which, even with the assistance of numerous hands, he found difficulty in supplying. In his workshops the principle of the division of labour was carried out to a considerable extent, and a proportionate dexterity was acquired by the workmen; but it is asserted that in none of these, even the most subordinate, and least of all in the higher departments did the skill of the workmen surpass that of Ramsden himself. His attention was incessantly directed to new improvements and further simplification, the result of which was the invention of a dividing-machine. From this time his fame was fully established as the first instrument-maker of his day. He died in 1800.

RAPE-SEED. The *Brassica napus*, the plant which produces the rape-seed, and which is of the cabbage tribe, is cultivated like Cole, or Colza (*Brassica napus sativa*), for the sake of its seeds, from which oil is extracted by grinding and pressure. It is also extensively cultivated in England for the succulent food which its thick and fleshy stem and leaves supply to sheep when other fodder is scarce. The mode of cultivation of the colza and rape for seed is nearly the same. The colza takes a longer time to come to maturity, and produces more seed. The rape grows on less fertile soils, and may be sown in spring as well as in autumn. Both are hardy, and resist the winter's frost.

The rape-seed imported in the last three years amounted to:—

1848................	79,970 quarters.
1849................	29,480 „
1850................	107,029 „

RAREFACTION is an augmentation of the intervals between the particles of aeriform fluids, so that the same number of particles are made to occupy a volume greater than that under which they were previously contained. The term is used in opposition to *condensation*, and in the same sense as *dilatation*, which last is applied both to fluids and solids. From the experiments of Gay-Lussac and Dalton it has been ascertained that, under equal external pressures, the rarefactions of all dry gases and of the aëriform substances produced by the evaporation of liquids are equal at equal temperatures, between the points of freezing and boiling water, and that they vary in volume proportionally to the increments of heat expressed by the expansions of mercury in the thermometer. Between the temperatures of freezing and of boiling water, the dilatations of all metals and of the fluids called non-elastic are constantly proportional to the increments of temperature;

but, beyond the temperature of boiling water, the dilatations increase in a higher ratio. A remarkable circumstance is observed in the state of water when near congelation. On being cooled to a temperature within the limits of 33·9° and 34·5° (Fahrenheit), its volume remains stationary, and in this state water seems to have attained its maximum of density; for on continuing the cooling process, the water begins to expand, and it continues to do so until it is converted into ice.

RATAFIA, is a liqueur prepared by flavouring sweetened spirit with various kinds of fruit. There are many varieties, generally named after the fruit which is employed. *Ratafia de Cassio* has cherries, *Ratafia de Curaçoa* has the peels of Portugal oranges; *Ratafia d' Angelique* has Angelica seeds; *Ratafia d' Anis* has aniseed; and so on. There are ratafias not only of fruits but of seeds, berries, flowers, balsams, and other vegetable products. There are ratafias, for instance, of cherries, quinces, raspberry, juniper, walnuts, peach and apricot kernels, coffee, cocoa, clovepinks, Seville orange peel, orange flowers, violets, Tolu balsam, &c. All these ratafias have spice and sugar added to them. The French liqueurists are the most skilled in this as in most other branches of delicate distillation and making of essences.

RAZOR MAKING. [Cutlery.]

READING. The trade of this town is considerable. There was anciently a large manufacture of woollen cloth, but it has become extinct. Silk ribands and galloons are woven, and floor-cloth and sail cloth are made. There are iron foundries, breweries, and yards for boat-building. Trade is carried on in corn, seeds, malt, timber, bark, hoops, wool, cheese, and beer. The Kennet is navigable to the Thames, and the Kennet and Avon Canal affords a water communication with the west of England.

REALEJO, a seaport on the Pacific, in the republic of Nicaragua, is fast rising into commercial importance. The inhabitants are chiefly merchants and persons occupied in ship-building, for which the neighbouring forests supply abundance of timber. Ship-building is a large branch of industry, and there are docks for that purpose. The commerce with the other republics of South America is considerable. The principal articles of trade are cacao, indigo, sugar, timber, mahogany, cedar-wood, tar and pitch, sail-cloth, and hides. The activity along the western coasts of America, consequent upon the discovery of gold in California, and the position of the town at the western terminus of the projected ship-canal between the Atlantic and the Pacific oceans, are likely to render Realejo a place of considerable importance.

REALGER. [Arsenic.]

REAPING. The common *Reaping Hook*, or *Sickle*, with which corn is usually cut, is one of the oldest instruments of husbandry. In reaping with the sickle, a portion of the stems is collected with the left hand, and held fast, while the sickle in the right hand is inserted below the left, taking the stems in its semicircular blade, and cutting them through by drawing the sickle so as to act as a saw, for which purpose the edge is finely serrated in a direction from the point to the handle. The heads of the corn, with the upper part of the straw, are then laid on the ground in quantities which may readily be collected into a sheaf. The division of labour is introduced with advantage amongst a band of reapers. A certain number cut the corn, while others follow to gather the sheaves; some only preparing the bands, and others tying them and setting up the sheaves into stooks or shocks, which usually consist of ten or twelve sheaves. In many places there is a regular measure for the circumference of a sheaf, which should never exceed thirty inches. The bands are made by taking two small handfuls of the cut corn, and crossing them just below the ears into a knot; the sheaf is then pressed with the knee, and the band drawn tightly around it; the ends are twisted together like a rope, and inserted under the band, which effectually fastens it.

Wherever the sickle is used for reaping, the straw is cut at a certain height from the ground, and the remainder forms a stubble, which is sometimes mown at leisure after harvest, and carried into the farm-yard for litter; but in the neighbourhood of large towns, where straw is sold at a good price, or exchanged for stable dung, it is important that as much as possible of it should be cut with the corn. This has introduced the practice called *fagging*, or *bagging*. The instrument used for this purpose partakes of the nature of a scythe, as well as of a reaping-hook. It is shaped like a sickle, but is much larger and broader; and instead of being indented like a saw, it has a sharp edge like a scythe, which is renewed when blunt by means of a stone or bat. The Fagging-Hook cuts the straw close to the ground by a stroke of the hand; and its curved form is only useful in collecting stray stems, and holding a certain quantity of them between it and the left hand of the reaper when he makes up a sheaf. The *Hainault Scythe*, which has been described in most agricultural works, does the work better and with less fatigue; it is in fact a fagging hook, but is not quite so much curved; the handle is longer, and placed at an angle with the plane of the blade. A better instrument however on extensive farms is the *Cradle-Scythe*, which, in the hands of an expert mower, will do more work and more effectually secure all the straw than any other instrument.

Mr. Whitworth, the eminent machinist of Manchester, patented a new reaping machine in 1849. It is a circular disc or scythe (for cutting grass or reaping corn), placed upon the side of a four-wheeled machine: motion being given to the disc by wheel-gearing attached to one of the wheels of the machine.

REBEC was a musical instrument (now disused) of the violin kind, which had three strings tuned in fifths, played on by a bow. It was somewhat smaller than the violin.

RECTIFYING. Under DISTILLATION it is explained that raw spirit, as produced by the distiller, is a very different liquid from those which are retailed in the shops, and consumed in such large quantities. Gin, British brandy, spirits of wine, whiskey, (except the purest Irish and Scotch, and such cordials as aniseed, peppermint, &c.),—are all produced by the *rectifier*, from raw spirit made by the *distiller*. In accordance with the Excise laws of this country, rectifying must not be carried on in the same building, nor at less than a certain defined distance from the same building, as distilling; because the distilled spirit pays duty, the rectified spirit none. Throughout England there are scarcely a dozen distilleries, properly so called; all the others being *rectifying* establishments, where the spirit is redistilled, purified, and flavoured with various vegetable substances. The raw spirit is sold by the distiller to the rectifier in two different strengths, technically known as 25° and 17° 'over proof;' and the transfer from one establishment to the other must be known to and sanctioned by the Excise officers. The spirit is redistilled, by which a certain portion of essential oil is removed from it; and a third distillation then takes place, in which the spirit in the still has the addition of various fruits, herbs, berries, or seeds, according to the liquor to be produced. The distillation is carried on until the spirit becomes very much weaker than crude spirit, (except in the case of spirit of wine), and until it has imbibed the fragrant, the sweetening, and the flavouring properties of the vegetable substances placed in the still.

RED LEAD. Red lead or *minium* is an oxide of the metal; *litharge* being another oxide. Litharge is produced in the process of cupellation, or the separation of the minute quantity of silver which most lead ores contain; it is a refuse, so far as the immediate process is concerned; but it is afterwards used in making flint glass, or as a material whence many of the salts of lead, useful in the arts, are prepared.

Red Lead, however, is purposely manufactured, and the furnaces are adapted expressly for this purpose. It is one of the wonders of chemistry, to see this red powder produced simply by the action of the common air on melted metallic lead: it baffles all our usual conceptions concerning the production of colour. Pigs of lead, to the weight of about 30 cwt., are put into a reverberating furnace, and exposed to a melting heat. A man then stands before the open mouth of the furnace, and keeps the molten lead continually moved by a sort of rake. This movement causes all parts of the metal to come successively in contact with the air, which enters at the open mouth of the furnace. In five or six hours the lead thickens, and acquires the look of a grayish yellow powder; it has become a mixture of oxidized lead with lead which has not yet had sufficient contact of air to have become oxidized. The contents of the furnace are then raked out, and when cold are ground in a mill to a fine state, and steeped in water. The lead particles sink, while particles of yellow oxide remain diffused in the water. The water is poured off, and allowed to settle, and the yellow oxide precipitates. This oxide, when collected and dried, constitutes *Massicot;* and by again exposing it to the heat of a furnace, and allowing it to absorb more oxygen, the oxide changes its colour from yellow to red, and changes from Massicot to Red Lead.

This manufacture is carried on, among other places, at the lead works of Newcastle.

REFINING is a term applied to various processes in the useful arts, and especially in metallurgy, whereby the substances acted upon are purified by the chemical separation of dross and impurities, and of such foreign matters as may be in combination with them. [ASSAYING; IRON MANUFACTURE; LEAD; STEEL MANUFACTURE; SUGAR.] Some of the furnaces employed in these operations are called *refineries* or *refining furnaces*.

REFLECTORS. The reflectors employed for conveying rays of light to a focus, or for throwing them into a different direction, are of varied forms and application. They may be flat, convex, concave, spherical, parabolic or elliptic, according to the purposes required; and they may be made of glass silvered on the back, or of polished silver, or of one among many alloys which yield a bright white surface capable of being beautifully polished.

A few details concerning the reflection from silvered glass, for ornamental purposes, will be found under SILVERING; the aid which a small metallic reflector may render in microscopic observations, is noticed under MICROSCOPE; the larger reflectors for distant view, are noticed under SPECULUM and TELESCOPE; while the reflectors for lighthouses are noticed under LIGHTHOUSE.

REFRIGERATORS. There are many processes in what may be termed chemical manufactures, in which a liquid is required to be cooled with as much rapidity as possible. In the practical modes of effecting this, the caloric of the heated liquid is carried off either by a current of cold water near it, or by a current of air. Exemplifications of these processes will be found under BREWING; DISTILLATION; VINEGAR MANUFACTURE.

REFUGE HARBOURS. A few details on this subject will be found in the articles BREAKWATER, DOVER, HARBOUR, and PORTLAND.

REGA'LIA is the name given to the costly specimens of jewellery belonging to the crown. In England, the regalia properly so called are the crown, the sceptre royal, the virge, or rod with the dove, St. Edward's staff, the orb or mound, the sword of mercy, called Curtana, the two swords of spiritual and temporal justice, the ring of alliance with the kingdom, the armillæ or bracelets, the spurs of chivalry, and sundry royal vestments. The regalia here enumerated, all but the vestments, are preserved in the Jewel-Office in the Tower of London.

REGISTERING MACHINES. Under CALCULATING MACHINES, is given a brief description of many contrivances for registering and numbering by automatic means. Under BANK NOTE MACHINERY, and VOTING MACHINE, also, other similar contrivances are noticed. Some years ago, a machine was invented by Mr. Walker, a cloth manufacturer of Leeds, to which he gave the name of *Opera Meter*, and of which the object was to measure or register the amount of work done by certain machines. The apparatus had a shaft which could be connected with the gig-mill, the shearing machine, or other machines employed in the cloth manufacture. This shaft rotated as fast as the machine to which it was applied; and the shaft gave motion to a train of wheel-work, with a dial face and index hands to denote the number of revolutions made in a given time. The index hands thus became a measure and recorder of the amount of work done.

A piece of mechanism called a *Counter* is often used in cotton factories, to count or reckon how many revolutions the main shaft of the machinery has made in a given time; this number becomes, under certain conditions, a measure of the amount of work which the machinery has effected.

Under OMNIBUS is noticed a recent contrivance for registering the number of persons who enter a vehicle. Whether practically applicable or not, the apparatus is theoretically fitted for supplying a similar register at the entrances of public gardens and places of amusement generally.

REGISTRATION OF INVENTIONS. [DESIGNS, COPYRIGHT AND REGISTRATION; PATENT LAWS.]

REICHENHALL, a town in the circle of the Isar in Bavaria, is a place of great importance, as being the central point of the four great salt-works of Bavaria. The salt springs seem to have been turned to profit ever since the eighth century. As the great consumption of wood for so many years made fuel too scarce to boil all the brine on the spot, a very ingenious system of hydraulic machinery was contrived in 1618 to carry the brine in iron pipes from Reichenhall to Traunstein, over an elevation of 828 feet perpendicular height, and extending 21 miles in length. A similar conduit, 42 miles long, to Rosenheim on the Inn, where there is abundance of wood, was made in 1809; so that now all the springs which formerly ran to waste for want of wood are turned to account. In 1817, the salt springs of Reichenhall, Traunstein, and Rosenheim were connected by hydraulic works of great power and ingenious contrivance with the salt-mines of Berchtesgaden. The salt produced yearly is 16,000 tons.

REIMS, or RHEIMS, a city in the French department of Marne, is noticeable in a commercial point of view, besides the attractions of its famous cathedral. The manufactures are extensive; they consist of woollen cloths, kerseymeres, light stuffs for summer coats and trousers, swanskins, camlets, merinos, cashmere shawls, flannels, blankets, carpets, hosiery, bolting-cloth, cordage, candles, soap, and leather. Wax and wool bleaching, dyeing, wool-combing, brewing, and the making of machinery, are carried on. The spiced bread and biscuits of the town are in great repute. The chief trade is in the above-named articles of manufacture, corn, flour, champagne wines, brandy, spices, colonial produce, wool, cotton-yarn, flax, hemp, raw hides. A railway in course of construction will join Reims to the Paris-Strasbourg line, on which it abuts a little east of Épernay.

RENAISSANCE. The term *Renaissance* indicates the period of the *Revival*, in respect to architectural and decorative matters, when the classic began to be re-introduced after the mediæval styles. It is often used as synonymous with the term *Cinque-Cento*, which literally means five hundred, whereas it is used as equivalent to mille cinque-cento, the *mille* being understood though not expressed, therefore it stands for fifteen hundred. In its technical sense among artists, the term renaissance may be considered to mean the style of architecture and general decoration which prevailed during the 16th century, or rather the earlier part of it; nor is it so restricted, for without exact reference to date, it is also applied to what belongs to the style so denoted though it may happen to be *before* the year 1500, which period may be taken as the line of demarcation laid down by the historians of art.

RENFREWSHIRE. The south-eastern part of this Scottish county is included in the great coal district of the west of Scotland. The chief coal works are at Quarrelton near Johnstone; and at Hurlet and Househill near Paisley: the mines here are very productive. Limestone, sandstone, ironstone, granite, and secondary trap-rocks, are found in considerable abundance. Good freestone for building is quarried; limestone is also wrought for burning; and the mines of coal and ironstone give employment to many persons. The hilly parts of the county on the west and south are chiefly devoted to pasture. Owing to the demand for meat, vegetables, milk, butter, &c., by the large and crowded populations of Greenock, Glasgow, and Paisley, a large part of the cultivated land is meadowland or garden-ground. Dairy farming is very extensively practised.

Renfrewshire possesses a considerable amount of manufacturing and commercial industry in some of the towns. *Greenock* has been already alluded to in connection with the great city of GLASGOW. At the beginning of the last century, the harbour, which was then only fit for the reception of fishing boats, was enlarged: more than ten acres were enclosed between two circular quays; and subsequent improvements have rendered the outer harbour available for ships of large burthen. This has been the means of raising the place to an important position as a seaport. The Newfoundland and Nova Scotia fisheries are carried on extensively. The number of vessels belonging to the port is nearly 500. *Johnstone*, near Paisley, contains cotton mills and some other manufactories. The parish of *Neilston* contains several villages; most of the inhabitants, amounting altogether to about 10,000, are employed in various branches of silk and cotton manufactures, the river Levern affording excellent water power for driving machinery. There is also abundance of clear water suitable for bleaching. PAISLEY industry has been noticed elsewhere. *Pollockshaws* is a tolerably large place, depending almost entirely on the cotton manufacture; spinning, weaving, bleaching, and printing are actively carried on. In *Renfrew* the manufactures are various: muslin weaving is by far the most important. Many females are employed in clipping, tambouring, and flowering. A few small vessels carrying coal, manure, &c., on the Clyde, belong to the burgh; but a considerable number of vessels, chiefly laden with grain from Ireland, or with dye-stuffs for Paisley, discharge their cargoes here.

The following were the factory statistics of Renfrewshire in 1850: Paisley being the chief town to which those statistics relate. There were 51 cotton factories, being a much larger number than in any other Scottish county except Lanark; these factories had about 500,000 spindles: 2000 power looms; water and steam power equal to 2742 horse-power; and 7884 factory operatives, of whom no less than 5717 were females. There were 3 woollen factories, 1 worsted factory, 4 flax factories, and 1 silk factory—the whole nine employing about 1500 persons.

RENNIE, JOHN, is a member of a family well worthy of admiration in all that respects mechanical and engineering skill. He was born in 1761 in Haddingtonshire. He appears to have very early devoted his attention to the subjects of machinery and architecture, and he attended at Edinburgh the lectures given by Dr. Robinson and Dr. Black, on mechanical philosophy and chemistry. About 1780 he left his native place, and shortly afterwards established himself as a mechanist in London, where he obtained immediate employment. From this period he continued to be occupied in the construction of steam-engines, or of the different kinds of machinery to which, as a first mover, steam is applied; and at the same time he was almost constantly engaged in designing or superintending those public works which have given him so just a claim to celebrity. Between 1799 and 1803 he constructed the stone bridge at Kelso, below the junction of the Tweed and Teviot. He also built stone bridges at Musselburgh and other places in Scotland; but his masterpiece of this kind is the Waterloo Bridge over the Thames. The Southwark Bridge, over the same river, is an iron bridge, and was also constructed by him. He superintended the formation of several canals. But his chief work in connection with inland navigation is the Kennet and Avon Canal, which extends from Bath to Newbury. He also gave a plan for draining the fens at Witham in Lincolnshire, which was executed in 1812. The London Docks and the East and West India Docks at Blackwall are among the great works which are executed from the plans and under the direction of Mr. Rennie. He formed the new docks at Hull (where also he constructed the first dredging machine used in this country), the Prince's Dock at Liverpool, and the docks of Dublin, Greenock, and Leith. To these must be added the Plymouth Breakwater. Mr. Rennie also gave plans for improving the harbours of Berwick, Newhaven, and other places, and the dockyards of Portsmouth, Plymouth, Pembroke, and Chatham: he also built the pier at Holyhead. Before his death he had given plans for improving the docks at Sheerness; which have since been executed by his first and second sons, Messrs. George and John (now Sir John) Rennie. To Sir John Rennie was also confided the charge of the construction of the present London Bridge, from the design of his father.

Mr. Rennie died in 1821, and was buried in St. Paul's Cathedral. His sons are worthily following in his steps in engineering works.

REPULSION. Both attraction and repulsion exist in all the particles of material substances, and seem to be properties by which those particles act upon one another when not in contact. The reality of a substance between the particles of bodies, whether solid, fluid, or gaseous, admits of no question; for the difference in the densities of these classes of bodies, as well as the different contractions of the bodies in the process of cooling, can only be conceived to arise from the different extent of the intervals between the particles. It is right however to observe, that the word repulsion is often applied to phenomena which are in reality the results of attraction. For example, a small quantity of quicksilver being laid on a glass plate assumes a spherical form, instead of spreading over it in a thin surface; and this was once supposed to arise from a repulsive power in the glass, whereas it is owing to the attraction of the particles of quicksilver for one another being greater than the attraction of the glass for the quicksilver. The expansions of solids and fluids by heat, and the elastic powers of gas at different temperatures, are consequences of the repulsions residing in the particles of caloric, or induced by the latter in those of the bodies with which they are combined. The repulsive power existing in the air which is condensed in nitre, produces, on being combined with heat, a velocity of expansion equal to about 7000 feet per second; and the force of pressure resulting from it is thought to be equal to 2000 times the pressure of the atmosphere. It is this which gives such force to the explosion of gunpowder.

The scientific theories whereby the phenomena of expulsion are sought to be explained, and the experiments made to test the theories, are beyond our present scope.

RESINS are secretions of plants, which are probably all in a fluid state, but become solid either by the evaporation of their more volatile parts, or by the absorption of oxygen. They are distinguished from true Balsams by the absence of benzoic acid, and from Gum-Resins by the absence of gum, their complete insolubility in water, and their requiring alcohol for perfect solution. Some are soluble in cold alcohol, and these are termed *resins;* others are soluble only in boiling alcohol, and termed *sub-resins;* but the two are often also associated in the same substance. Many volatile oils, by long exposure to the air, or merely by a reduction of temperature, deposit a substance termed *stearopten*, which is analagous to resin. Where a considerable quantity of volatile oil co-exists with a resin, a honey-like consistence is preserved, and the resin is termed *soft resin*. When a very large portion of oil is present, a fluid condition exists, and *turpentine* is the proper designation.

The manufacture of common resin is described under TURPENTINE.

RESISTANCE is a power by which motion, or a tendency to motion, in any body is impeded or prevented. When a weight or pressure acts upon a beam or bar in any direction, the tenacity by which the particles of such material oppose that action constitutes a resistance of one kind. [MATERIALS, STRENGTH OF.] Again, when a body is made to move on another, the inequalities of the surfaces of both create a resistance of a different kind. [FRICTION.] When a body moves in a fluid, the inertia of the fluid particles displaced by it produces a third kind of resistance. It is computed that a 24-pounder ball experiences a resistance equal to 800 lbs. when its velocity is equal to 2000 feet per second. Like effects take place in the movement of boats or ships; when the velocity is great, the water accumulates in front, and flowing off from thence obliquely, it carries away some from the sides, and, causing the surface of that which is near the stern to be rather lower than the general level, it there produces a diminution of pressure, while there is an excess in front on account of the accumulation.

From the experiments of Mr. Telford, the following values of the resistances experienced by loaded carriages on level roads have been determined. On a good pavement the resistance is $\frac{1}{70}$ of the weight of the carriage and load; on a broken surface of old flint, $\frac{1}{35}$; on gravel, $\frac{1}{15}$; and on a well-constructed railway, from $\frac{1}{300}$ to $\frac{1}{250}$. Mr. Barlow has found that, with small velocities, the force of traction on canals is less than on railways; and when the velocity is equal to four miles per hour, the forces are equal. Beyond this velocity the advantage is in favour of the railway.

All these enquiries are of great importance in ship building, railway making, and other engineering works, where *motion* is to be provided for.

RESPIRATOR, or breath-warmer, is a singular instrument invented some years ago for giving warmth to the air drawn into the lungs in breathing, and thereby enabling invalids to whom cold air is injurious to enjoy the benefits of exercise in the open air without injury or inconvenience.

The apparatus usually consists of from eight to twelve frames of sheet-silver or other metal, about three inches and a half long, one inch and a half wide, and $\frac{1}{200}$th part of an inch thick; the metal of which is pierced away by machinery so as to leave merely a narrow frame containing six vertical bars of $\frac{1}{30}$th and five horizontal bars $\frac{1}{80}$th of an inch wide. On both sides of each of these frames a layer of wires an inch and a half long and $\frac{1}{450}$th of an inch thick is soldered, care being taken to connect each wire, not only with the top and bottom bars of the frame, but also with each of the five horizontal bars. The wires are laid about $\frac{1}{200}$th part of an inch apart, and are so numerous that a large respirator of high power contains 2000 feet of wire, divided into about 12,000 pieces, and soldered to the frames at more than 80,000 distinct points. The frames or lattices of wire-work are fixed parallel to each other, and kept a short distance apart by small studs of a substance which is a slow conductor of heat, so that the inner layer is always kept, as nearly as possible, at the temperature of the air expelled from the lungs, and each successive layer diminishes in warmth, till the outer one is nearly as cold as the external air. The curious and philosophical application of a non-conducting medium between the metallic screens is essential to the perfect action of the instrument, as without it the heat would be equally diffused, and no part of the metal-work could retain more than half the temperature of the breath. By this arrangement the air inhaled, finding each layer of wire warmer than the preceding, is gradually raised, in respirators of the highest power, to the greatest attainable temperature. These instruments are more especially useful in diseases of the lungs.

RETINASPHALTUM occurs in irregular opaque masses of a pale brownish-yellow colour, having a glistening lustre and imperfect conchoidal fracture. It is soft and brittle, melts when placed on hot iron, smokes, and afterwards burns with a bright flame, emitting a fragrant odour. Partly soluble in alcohol, leaving an unctuous residue. It consists chiefly of resin and bitumen.

RETORT, is the name of a chemical vessel in which distillation or decomposition is effected by the application of heat. For different purposes retorts are made of glass, earthenware, and metal; and the form varies according to the mode in which the retort is to be used. In general, when the application of the higher temperatures is required for distillation or decomposition, earthen retorts are employed. In preparing hydrofluoric acid, lead is used; and in concentrating sulphuric acid, platina retorts are now largely employed, and would be universally so, were it not for their very high price. In the distillation of coal [GAS LIGHTING] iron retorts are used; and also, on the small scale, for obtaining oxygen from the peroxide of manganese; and in various other chemical operations.

REVETMENT. This name was originally applied to brick and stone walls used in a particular way in fortification; but it is now also used by civil engineers. A revetment, as constructed by the latter, is a kind of retaining wall. The exterior and interior faces of the revetment or retaining wall of a dock, have in a vertical section the form of concentric arcs of circles, with their convexities towards the land; and this form is given them that the stones may be able to resist the hydrostatical pressure of any water which, when the dock is full, may get behind the wall, and which may be prevented from escaping when the dock is made dry.

RHAMNUS, or Buckthorn, is the name of a genus of plants, many species of which are valuable in the arts. The berries of one species, the *Rhamnus catharticus*, have long been known for their medicinal properties, and still continue to hold a place in several Pharmacopœias. This property is participated in by those of other species, as well as by their inner bark. The berries of several species of Rhamnus form articles of commerce from the Mediterranean, under the name of *French, Turkey*, and *Persian Berries, Grains d'Avignon*, &c., being valued on account of the colouring-matter which they yield, and which varies from yellow to green. This M. Brongniart supposes to be owing rather to different degrees of ripeness than to essential differences in nature. *Sap-green* is a mixture of the juice of these berries with those of some others. *Rhamnus infectorius, saxatilis, amygdalinus, catharticus*, and *Clusii* are the species generally employed; some for dyeing morocco leather of a yellow colour, others for dyeing wool, and the bark of some for striking a black with the salts of iron. The *Lycium* of the ancients is supposed to have been a species of Rhamnus; hence also one species has been called *Rhamnus Lycioides:* it has a hard yellow wood.

RHENISH PRUSSIA. This portion of the Prussian dominions, situated near the Rhine, is very important for its produce and manufactures. The natural productions are equally numerous and valuable Some parts of the mountains are crowned with forests, and the declivities are covered with vineyards where the exposure is favourable. The mineral kingdom yields silver, iron, copper, lead, calamine, marble, slate, freestone, millstones, basalt, porphyry, alum, manganese, sulphur, coal, and salt. In the level parts of the north there are productive corn fields and rich pastures; between the mountains there are fertile valleys, where flax, hemp, hops, and tobacco are grown, and fruit and garden produce of every kind are cultivated in great abundance. Game is plentiful, and all the domestic animals are bred in sufficient numbers. The Rhine passes through this province for 180 miles, and is navigated by steamers. The small rivers and streams are applied to turn mills and to work manufacturing machinery of every kind. The trade of the province is very extensive. The province had, at the end of 1846, 41 cotton factories with 109,547 spindles. When we state that the province contains the important towns of *Cologne, Coblentz, Elberfeld, Düsseldorf, Aix-la-Chapelle* and *Treves*, it will be seen how rich a portion it must constitute of the Prussian dominions, in manufactures and commerce.

RHEO'METER, is an instrument by which the force of an electric or magnetic current may be measured. The word was first proposed by M. Peclet as a synonym for galvanometer; and it has since been employed by Professor Wheatstone in a general sense, together with *Rheoscope*, denoting an instrument by which the existence of an electric, &c. current may be ascertained; and *Rheomotor*, expressing any apparatus, as an electrical or galvanic battery, by which a current of that kind is orignated. The Rheometer or Galvanometer employed by Mr. Wheatstone is a glass cylinder resting on a stand, and containing within it a magnetised needle, which is suspended from the cover. A graduated circle serves to show the deviations of the needle from the zero of the graduations, and the amount of deviation is read by means of a microscrope. For forces or resistances which are considerable, there are placed below the circle numerous coils of fine wire; but for small forces a thick plate of wire making but one coil is used.

RHINE. The Rhine is certainly the most commercial river of continental Europe. From Basel to Mainz the Rhine is navigable for barges of 100 tons; from Mainz to Cologne, for vessels of 200 tons; and lower down, for vessels of 300 tons. The river is connected by canals with the Saône and Rhône, the Schelde, the Meuse, and the Danube. A very important trade in colonial produce, manufactured goods, timber, coal, iron, corn, wine, and other agricultural products, is carried on by the Rhine, and its chief navigable feeders, the Moselle, the Main, and the Neckar. This trade has been greatly increased by the policy of Prussia, which has rendered most of the large towns on her part of the river free ports; and the resolution of the government of the Netherlands, in February, 1850, to abolish the Rhine duties altogether, is likely to add a great stimulus to this traffic. The river is now navigated by the steam-vessels of three companies—those of the Cologne Company, plying between Arnheim in Holland and Strasbourg; the Düsseldorf Company, between Rotterdam and Mannheim; and the Dutch Company's boats from Rotterdam to Mainz. From Basel a railroad runs along the right bank of the river to Wiesbaden, and another runs along the left to Strasbourg, whence a line, now nearly completed, passes to Paris. A short line joins Bonn with Cologne, and from Deutz, a suburb of the latter, a line runs through Düsseldorf into the great railway system of North Germany.

This important river gives name to two of the busiest districts of the continent; viz., *Haut Rhin* and *Bas Rhin*, in France, and *Rhein Provinz*, in Prussia; these are described, in respect to their industrial features, under ALSACE, and RHENISH PRUSSIA.

RHODE ISLAND. A few details illustrative of the produce and industry of this portion of the American Union, will be found under UNITED STATES.

RHO'DIUM. This rare metal exists in combination with platinum, and was discovered by Dr. Wollaston. Rhodium is white, has a metallic lustre, is brittle, extremely hard, and its specific gravity is about 11. It suffers no change by exposure to air, either dry or moist. Rhodium forms very hard alloys with other metals, which are sometimes used for the nibs of pens; but neither the metal nor its combinations have yet been very extensively applied in the arts.

RHÔNE. The Rhône is perhaps the most commercial of the rivers of France. The river is navigable *downwards*, from near Seyssel to its mouth, a distance of 330 miles; for some miles higher up it is available for floating timber. Steamers ply between Lyon and the Mediterranean; owing however to the rapidity of the current, the *up* navigation is very slow. The Rhône is a most important highway for the transfer of the produce of this part of France; and it is connected by the Saône, which is navigable for steamers up to Châlon, and by canals with the Bay of Biscay, the Rhine, the Seine, and the Loire. Its basin includes the Swiss cantons of Valais, Vaud, and Geneva, the duchy of Savoy, and fourteen French departments, most of which are famous for their corn, wine, silk, and oil. In the lower part of its course its waters are turned to great advantage in fertilising the land near its banks by irrigation.

The Rhône gives name to one of the departments of France, fruitful and commercially important. In the extreme south of this department are the famous chestnut forests which yield the favourite large chestnuts sold in Paris by the name of *marrons de Lyon*. The valleys, plains, and accessible slopes are carefully cultivated, the products comprising almost everything that grows in France, except the orange and the olive. The mulberry is cultivated for the production of silk. The lower slopes of the hills are almost everywhere planted with vines; this is especially the case with the slopes along the Saône and the Rhône, from the neighbourhood of Belleville to Condrieu. This region, which includes the *Mont-d'Or*, so called from its rich wine products, contains some of the finest vineyards in France. The annual produce is about 17,000,000 gallons; the best sorts are those called Côte-Rôtie, Romanèche, Condrieu, and Sainte-Foy. The department contains important copper-mines and works at St. Bel near Arbresle, and at Chessy, a small place on the Azergue. Coal mines are worked. Lead, gold, manganese, rock-crystal, porphyry, granite, marble, talc, asbestos, gypsum, fuller's earth, potter's-clay, excellent building-stone, and various other minerals are found. The Mont-d'Or contains excellent stone quarries, and is noted for the great number of fossils it contains.

The department is the most famous spot in Europe for all kinds of silk manufactures, including satins, taffeta, lutestrings, velvets, gold and silver brocade, crape, gauze, shawls, ribands, hosiery, &c. This trade centres at LYON. There are also important manufactures of plain and figured muslins, handkerchiefs, silk hats, calicoes, cotton yarn and twist, blankets, gold and silver lace, small wares, straw hats, mineral acids, machinery and mill work, and liqueurs. There are besides several dye houses, bleach-works, type-foundries and printing offices, breweries, paper-mills, glass-works, potteries, and plaster-mills. The various products named or indicated, together with corn, wool, brandy, raw silk, broad cloth, linen, lace, hardware, hides, bar and sheet iron, ironmongery, timber, planks, staves, &c., form items of an extensive commerce, which is still further increased by the important transit trade carried on by means of the navigable waters of the department, and by the railway to St. Étienne.

RHUBARB. Long as this valuable medicine has been known, it is remarkable that the species of *Rheum* yielding it, and of which the stalks and roots consist, is yet unknown; this is in consequence of the best species, *Turkey* Rhubarb, being only obtained by the Russians at Kiachta from the Chinese. The different species of rhubarb are important plants, not only on account of the roots being so extensively employed, and so valuable for their medicinal qualities, but also on account of the stalks of the leaves being now so much employed, from their agreeable acidity, in making tarts, &c. As the species are all indigenous in cold parts of the world, that is, in the southern parts of Russia, Siberia, Tibet, the north of China, and the Himalayas, so they may all be grown in the open air of this country, and several are cultivated on account of their stalks. Some also, both in England and France, are cultivated on account of the root, which is sold as Turkey Rhubarb.

As the particular species which yields the officinal rhubarb, and even the precise place of its growth, are not known, we can only speak of the drug as it is brought to market. There are six well marked varieties, viz. Russian or Turkey, Dutch Trimmed, Chinese, Himalayan, English, and French. Of the first sort the greater portion at present comes from St. Petersburg, and is denominated Muscovite, Bokharian, or Siberian rhubarb; while a part has always formed one of the imports from China into Bokhara, whence passing to Smyrna, it is known in Europe as *Turkey Rhubarb*, which name it commonly bears in the shops. This kind varies much in size and appearance, the pieces being cylindrical, spherical, flat, or irregular, from two to three inches long, one to three broad, and one to three thick. The smaller pieces are picked out, being preferred, while the larger pieces and the dust are employed for powdering. Holes are remarked in many of the pieces, of which one occasionally extends entirely through, the others only partially; the former having been made in order to suspend the piece in drying, the others in examining the quality. This kind, and probably the other sorts, is frequently worm-eaten, owing to the ravages of a small beetle. *Dutch Trimmed Rhubarb*, called also by some writers *Persian Rhubarb*, and *Batavian*, occurs in flat or round pieces, and is not much different in appearance from the preceding, but it reaches Europe through Canton and Singapore. *Chinese* or *East Indian Rhubarb*, termed in commerce *half-trimmed* or *untrimmed* rhubarb, rarely presents an angular character, but occurs in rounds or flats. The best pieces are heavier and more compact than those of the Russian kind, and the odour is much less powerful and less aromatic. *Himalayan Rhubarb* is not known as a commercial article in this country, nor is it even an article of large consumption in India, where it sells for only one tenth of the best rhubarb, resembling in quality the Russian, and which is found in India. *English Rhubarb* occurs in two states, *dressed* or *trimmed* so as to resemble the Russian kind, and *stick* rhubarb. The first is grown at Banbury in Oxfordshire, and is frequently used for the show-bottles in druggists' windows, and often sold in the streets of London for Turkey Rhubarb, by persons dressed up as Turks. Stick Rhubarb is sold in the herb shops, and is in long pieces. *French Rhubarb* is not brought into this country.

About 300,000 lbs. of rhubarb are imported annually.

RIBBON MANUFACTURE. *Ribbon*, or *Riband*, is the well known name for a long narrow web of silk worn for ornament and use. Ribbons of linen, worsted, and gold or silver thread were formerly included in the term, but it is now generally confined to those made of silk. Paris, Tours, Lyon, and Avignon, were originally the chief seats of the ribbon trade; the two last cities were rivals until the year 1723, when, partly owing to the regulations which the jealous Lyonnese had prevailed upon the government to make in their favour, and partly to a plague of two years' continuance, the trade of Avignon was ruined, and in great measure transferred to Lyon. At Paris the master ribbon-weavers were incorporated into a company, under the designation of *tissutiers rubaniers* of the town and suburbs of Paris. Figured ribbons were made chiefly at Paris. The ribbons called *double lisse* (double warp), which were considered the richest and best, were made at Tours. Before the revocation of the Edict of Nantes, the ribbon-looms of Tours amounted to 3000; but this measure, which banished the Protestants, banished with them their trade, and both Tours and Lyon suffered severely from its effects; but the trade of Lyon afterwards revived. In 1831 the number of ribbon manufacturers at St. Étienne and St. Chamond was 200. The number of ribbon looms in these towns and the surrounding district, which in 1812 was 9000, had increased to 23,000. Their daily produce was 350,000 ells. There are three kinds of looms in use in that district; 1st, the old unimproved single-hand loom called *basselisse*, employed for plain satins and sarsenets. 2nd, the single hand loom called *hautelisse*, generally applied to produce large patterns. 3rd, the *à-la-bar*, or *bar loom*, employed in sarsenets, velvets, sarsenet galoons, stout and light satin, and striped gauzes. There are now few ribbons made at Lyon, many of the ribbon-looms being now employed in weaving shawls. The best ribbons made in France are chiefly for the English market; the home consumption being of the less costly kind.

The making of ribbons and small articles in silk long preceded in England that of broad silk. The trade was principally in the hands of women; and, like a sickly plant of foreign growth, it appears to have constantly demanded props and support, which have however been removed by recent reforms of the tariff. Coventry has become the principal seat of the ribbon manufacture in this country.

The weaving is done on several systems. We shall describe these somewhat in detail, as the ribbon trade illustrates the chief points in the silk manufacture generally. The *Undertaking System* applies now only to the single-hand trade in the country districts,—Bedworth, Nuneaton, Hartshill, &c.: it is the same that the French have employed since the days of Colbert. According to this plan, the undertaker, or master-weaver, receives the silk dyed in the hank from the manufacturer, and returns it in finished ribbons to his order;

all the intermediate operations being included in the price of weaving—two-thirds of which are paid to the journey-hand for his labour. Three-fourths of the single-hand weavers are women, and nearly one half of the remainder are youths under 20. Boys and girls are considered competent weavers at 16 or 17. On the *Journey-Work System*, by which the great proportion of the engine-looms in Coventry and its neighbourhood are worked, the manufacturer gives the silk, already wound and warped, to the 'first-hand journeyman,' who is also the owner of the looms. The shoot silk is given in hank, for the winding of which the manufacturer allows 1*d.* per oz., besides the price for weaving, in which is included 'the filling,' or the winding of the shoot on the small revolving pins within the shuttles. About one-fourth of the hands employed on this system are women. On the *Hand-Factory System* the manufacturer is the owner of the looms. The 'journey-hands work them in the 'loom-shop' of the proprietor, who gets the winding and warping done at his own charge, leaving only the filling to the weaver, which is included in the price of his work, and is often done by very young children. A modern innovation, encouraged by the last system, is the employment of two hands to a loom, the one being occupied uninterruptedly in 'shooting-down,' or passing the shuttle and making the ribbon; the other in 'picking up,' or fastening broken threads, picking out knots, &c. On the *Steam-Factory System* the manufacturer gets every preparatory process done; and by the steam-power one half of the weaving process itself —the shooting down; all that is left to the weaver being the picking up and superintendence.

The *Dutch Engine-Loom*, for weaving ribbons, was introduced about eighty years ago. In this loom, instead of one piece of ribbon only, several are woven at once, four of the broadest width, or as many as twenty-four of the narrowest. Each warp has a separate shuttle. The batten extends across the whole width of the loom; the shuttles slide within grooves made in the batten; the driver is worked horizontally backwards and forwards by a handle. At each motion the shuttles are propelled by the cross bars of the driver across their proper warps in the corresponding direction. The loom is worked by the hands, and with treadles for the feet, like the single-hand. The *à-la-bar* or *Bar-Loom*, was invented and introduced into St. Étienne by two Swiss brothers about seventy years ago. It is a hand power-loom worked by means of a long transverse handle or bar, which extends along the front of the loom, and is connected with wheels on each side, which communicate the motion. The shuttles are driven by means of a rack and pinion across the warps. Figures on ribbons, as in other fabrics, are chiefly formed by omitting the regular crossing of the warp and shoot in such a manner that a difference of texture shall occur in the web so as to mark out any pattern. This is effected in the single-hand loom by a multiplication of treadles connected with the lisses by which the different portions of warp are alternately raised. Forty treadles have been sometimes required to form an intricate pattern. Small figures produced in this manner are called *Leys.* To execute more complicated patterns, an intricate arrangement of the loom is necessary.

Ribbons are made according to a fixed standard of widths designated by different numbers of pence, which once no doubt denoted the price of the article, but at present have reference only to its breadth. The French distinguish their widths by simple numbers. All dressed ribbons, as satins, gauzes, &c., are made in the loom one-twelfth of an inch wider than sarsenets, in order to allow for the diminution of breadth which results from the lengthwise stretching which they receive in the operation of dressing. Fine gauzes require an allowance of two-twelfths. French fancy ribbons are generally made and sold in *garnitures*, that is, a broad and narrow piece taken together of the same pattern. *Sarsenet and Lutestring* ribbons are made by the simple and regular alternation of the warp and shoot, as in plain cloth, called technically *ground.* By *Grogram* (French *gros-grains*) is meant a variation in the texture caused by the warp threads passing over two of the shoots at once, taking up one only: this often finishes the edge of a ribbon.

The figures are frequently produced in a different colour from the ground by the mixture of colours in the warp; the colours being warped separately. In the intervals of the figures the coloured threads are carried along the under side of the ribbon; and it is said to have a double or treble figure, according to the number of colours passing through each dent. A change of colour in the shoot is effected by the use of different shuttles. In brocades the figure is made by small additional shuttles, thrown in partially across the ribbon as the pattern may require; the connecting threads of shoot being clipped off. By *Damask* is meant the laying of the warp over the shoot to form the figure in the manner of satin. Some fancy ribbons are of plain texture, but varied in colouring; they are shot or woven in shades, stripes, bars, or cheques, called in the trade *Plaids;* these last, which require the shuttle to be changed very frequently, are still made in the single-hand loom. In *Shot* Ribbons the warp and the shoot are of different colours. *Clouding* is a peculiar management in the dyeing by which a change of hue is produced in the same thread of silk. In *Chiné* ribbons the figures are printed or painted on the warp after it is prepared for the loom, and afterwards woven in by the shuttle. Ribbons are *watered* by passing two pieces together between two cylinders, one of which has a heater within it. *Galloons* and *Doubles* are strong thick ribbons, principally black, used for bindings, shoe-strings &c. The narrow widths are called Galloons; the broader, Doubles. *Ferrets* are coarse narrow ribbons shot with cotton, used for similar purposes. In *gold* and *silver* ribbons a silk thread of similar colour is wound round by a flattened wire of the metal, and afterwards woven. Lyon was particularly celebrated for its fabrics of this kind.

The number of persons employed in ribbon-making in Coventry, including winders and warpers, was estimated, in 1838, at 6000 or 7000; and in the rural parishes, at 10,000 or 11,000. It has since varied considerably, according to the fluctuations of the ribbon-trade.

The ribbons imported into Great Britain in 1850 amounted to the following quantities:—

Silk or Satin Ribbons	282,799 lbs.
Gauze or Crape Ribbons	44,531 lbs.
Velvet Ribbons	16,675 lbs.

Most of these are imported from France. Very few English ribbons are exported.

RICE. The important rice plant is a native of India, whence it has been introduced into various parts of the world. It is extensively cultivated in India, in the south of Europe, and in the southern United States; and less largely in many other countries. It requires so much heat combined with moisture that it cannot be profitably cultivated in northern climates. The cultivation in India and China depends either upon the rainy seasons, or upon irrigation; the tanks for irrigation are in some cases quite enormous, being bounded by embankments many miles in length. The best rice-fields are never manured, and yet they yield 30 to 100 fold. They are usually exensive open plains through which large rivers pass. They more frequently depend on rain for irrigation than on tanks. There are many kinds of rice, which require different modes of cultivation. One of the principal kinds is sown in June or July, and transplanted in about forty days, when the plants are from 9 to 18 inches high. The fields are then kept constantly wet. When the grain is ripe the water is drained off, and the crop is cut down with the sickle; it is either stacked or trodden out by cattle. The grain is preserved in pits dug in high ground and lined with the rice straw. There are usually two crops in a year; but as the produce is very uncertain, the growers look chiefly to the first.

Of the kinds of rice imported into England, the *Carolina* is the best; the grains are shorter, broader, and boil softer than the *Patna* rice, which is the best Indian kind brought to this country.

Rice is no doubt the grain which yields food for the largest portion of the human race, but even in Hindustan great numbers do not eat rice. In fact in all the north-western provinces wheat is the principal crop, and the natives eat wheaten cakes. It abounds however in nourishment, being composed almost entirely of fecula, that is, 96 per cent., and therefore cannot be baked into bread; but it is more easily cooked. It is light and wholesome, and easily digested, and might form a much larger portion of the diet in Europe than it does. Europeans in India eat it at breakfast as well as at other meals, and with fish as frequently as with their curries.

About 976,196 cwts. of rice were imported in 1849, and 785,692 cwts. in 1850.

RICE-MILL. When rice has been cultivated and gathered, some sort of mechanism is requisite for the removal of the husk. The Chinese and Hindoos beat the grain in a kind of rude mortar of stone or earthenware, with a conical stone attached to a lever worked by the hand or foot. Sometimes several such levers are moved by arms projecting from the axis of a water-wheel. This process being uncertain and tedious, the preference has been given of late to a mill in which the stones are placed at such a distance asunder as to detach the shell without crushing the grain; the stones being inclosed in a case which prevents the dispersion of the rice by the rapid rotation of the machine. The rice is thrown out of the case by an opening in its side, and conducted over a sieve that separates the dust; after which it is made to fall in a gentle stream exposed to a current of air produced by revolving fanners, and is thereby separated from the husk. After the removal of the husk, the grain is exposed to the action of a whitening machine, which removes the inner cuticle, or red skin, remaining on the surface of the grain.

One of the English methods consists in breaking the husk by mill-stones, and removing the red cuticle by beating or titurating in mortars; the latter operation being aided by mixing a quantity of the husks, well dried, with the grain, which obviates an inconvenience occasioned by the glutinous character of the red coating. The refuse matter and the broken grains are then separated by a peculiar kind of screen, and the rice is finally cleansed and polished by rotating in a machine. In another method, the first operation is performed between one millstone and a piece of wood of precisely similar shape, and the subsequent removal of the dark pellicle is effected by rubbing between flat wooden surfaces covered with sheepskin. In a third method, the rice is allowed to enter the upper end of an inclined cylinder by a hopper, and the mutual attrition of the grains, as they pass between bars which are revolving in the opposite direction, causes the separation of the husks, which are removed by a current of air as the grain falls into a bin under the lower extremity of the cylinder.

RICK VENTILATOR. The formation of a rick of harvested produce is comparatively an easy matter; but the preservation of the rick from injuries by heating, rotting, and spontaneous combustion, is an important and difficult subject for the farmer's attention. The destruction of ricks by natural heating is, we believe, not covered by fire-insurance; so that the farmer is left to his own resources. In the case of barley ricks, the grain is frequently discoloured and deteriorated in value, by the too great heat of the interior of the rick. In the case of hay ricks, a large portion is frequently cut away and destroyed or injured, to prevent the rest from taking fire.

It has been lately proposed to obviate these evils by *ventilating* the rick; and an instrument has been invented for effecting it, and patented. The instrument makes a ventilating *chimney* or *flue* in the rick in any part where it is suspected of being too much heated. A hole is bored from the top to the middle or the bottom of the rick, forming a clear circular aperture, which tends to carry rapidly off the heat from the surrounding hay or corn. The instrument has a long shaft, with a cross end for working; and at the lower end of the shaft is an apparatus somewhat like a patent corkscrew, or one of the many sorts of boring tools, by which a hole is bored and the loose material cleared away.

RIFLE, or RIFLED, is a term applied to muskets or pieces of ordnance when their bores are furrowed with spiral grooves; the grooves or channels being formed by a machine which scrapes away the substance of the barrel interiorly in parallel and serpentine directions.

The object to be attained by this grooving may be thus explained. A bullet made of lead cast in a spherical form, according to the practice till lately followed, having unavoidably some irregularities on its surface, and frequently, from unequal expansion, a cavity in the interior; it follows that, when such bullet is discharged from a common musket, it deviates continually from the direction which it should take by gravity and the impulse of the fired gunpowder. The intention therefore in forming spiral grooves within the barrel of a musket or piece of ordnance, is, to produce a rotatory motion of the shot about an axis which shall coincide with the line of its path, in order that the unequal pressure of the atmosphere in its front, on account of any irregularity in its form or density, may correct itself at every half-revolution of the shot on such axis. The number of spiral channels in a rifle-musket is, in general, two; and one revolution of the spiral, in the whole length of the barrel (=30 inches) is considered sufficient.

The most general practice of late has been to press the bullets (by means of the ramrod) into the barrel upon a piece of greased cloth or leather (called the *plaster*). But, at present, rifle-bullets are made with a projecting zone which surrounds them on the circumference of what may be called a great circle. The pieces are loaded at the muzzle, and the parts of the zone which are diametrically opposite to one another are those which pass along the two grooves in the barrel.

Bullets for common muskets, as well as for rifle-barrels, are not now cast in their actual forms, but are made from lead which has been previously cast in cylindrical rods. The bullets are then formed by compressing the rods between two revolving cylinders. The pressure, by forcing the particles together, fills up any vacuities which may form themselves in the rods during the cooling process, and probably renders the density of the ball nearly uniform. Bullets and balls have occasionally been made of other than a spherical form, as experimental means of determining the best form for ensuring a direct course.

RIGA is a very important commercial town, one of the principal indeed in Russia. The numerous ships in the river Düna, the bustle in the streets, and the well-stocked warehouses and shops, are indications of the extensive trade of which Riga is the centre; it is in fact, next to St. Petersburg, the greatest emporium of foreign commerce in the empire. The exports consist of the great staple articles of Russian produce, corn, timber, flax, hemp, linseed, tallow, Russian leather, and sail-cloth. The total value of the exports in 1849 was 2,730,000*l.* against 2,120,000*l.* in 1848. In these were included 44,700 tons of flax; 15,250 tons of hemp; 81,703 barrels of sowing, and 255,000 quarters of crushing, linseed; 11,500 quarters of hemp-seed; 274,260 quarters of corn, chiefly barley, oats, and rye; 35 tons of quills; 410 cargoes of timber and staves; and 1700 tons of hempen and flaxen tow. The sale of linseed or flax-seed for sowing in other countries forms a remarkably large item in Riga commerce. Between 1841 and 1850 the quantity so sold varied from 55,000 to 177,000 barrels. The largest sale is to England which took 50,000 barrels in 1850. In the previous year 1849, 1729 vessels arrived, and 1677 left the harbour.

The value of the imports, consisting of colonial produce, woollens, calicos, silks, wine, &c., is not above one-third of the value of the exports. About two-thirds of the ships that enter the port arrive in ballast. Riga has now considerable manufactories of woollens, cotton goods, tobacco, starch, looking-glasses, and iron wares; it has also sugar-refining houses.

RIGGING. This is the name given to the whole of the ropes and cordage of a ship. It is divided into two kinds—the *standing* and the *running* rigging. The standing rigging comprises all the *shrouds*, *stays*, *back-stays*, and other ropes which are employed to maintain the masts and bowsprit in their proper position, and which remain pretty nearly in a constant state, whether the ship is in full sail or all the sails are furled. The running rigging comprises the various ropes called *braces*, *sheets*, *tacks*, *halyards*, *buntlines*, &c., which are attached to different parts of the masts, yards, sails, and shrouds; and are employed principally in furling and unfurling the sails for the purposes of navigation. The ropes are called *cables*, *ropes*, or *lines*, according to their diameter; but every rope in a ship has besides this its own distinctive name.

The occupation of a *Rigger* is intermediate between those of a rope-maker and a ship-builder, and distinct from both; he takes the coils of rope as prepared by the former, and adapts them to the various requirements of a ship. A *rigging-house* (such as may be seen in most large ship yards) is a place provided with tackle for stretching the ropes, and with the necessary instruments for attaching the blocks, rings, &c. The cordage employed for a large East Indiaman weighs several tons, and some of the ropes are four inches in diameter: the bending and fixing of such ropes, therefore, require the aid of powerful implements. Much of the cordage undergoes a process called *serving*, which consists in binding a small rope very tightly round a larger one, to preserve it both from rotting and from any friction to which it may be exposed. The substance thus bound round the rope is not necessarily a made-rope, but is sometimes made of old canvas, mat, plat, hide, or spun-yarn, according to circumstances: all these substances, when thus employed, receive the name of *service*, and the larger rope is said to be *served* with them.

The rigging of the ship is applied in its proper places at the time when each rope is wanted to serve its destined purpose. Each mast, each yard, the bowsprit, and various other parts of the ship, requires its own particular ropes; and the parts—the wood and the hemp—are built up into form simultaneously.

Other matters bearing on this subject are noticed under Rope Making and Ship Building.

RIGIDITY OF ROPES. When a stiff rope is bent over the upper part of a wheel or pulley, in a vertical plane for example, the weights or powers applied at its extremities are not always sufficient to draw the descending portions into the positions of two vertical lines; and the experiments of Coulomb have shown, that, with ropes consisting of 30 threads and 2½ inches in circumference, the weights requisite to overcome the rigidity, when the ropes passed over a pulley 4 inches diameter, and were strained by weights equal to 25 lbs., 125 lbs., and 425 lbs., were 5 lbs., 8½ lbs., and 23 lbs. respectively. White ropes when wet are more stiff than those which are dry, and the rigidity of ropes is greatly increased by tarring them. In general the weights necessary to overcome the resistance of tarred ropes is proportional to the number of the threads of which they are composed. This rigidity has to be allowed for in the use of thick ropes in engineering works.

RIVETS. The rivets which fasten together plates of iron and other parts of mechanism are usually short thick pieces of iron or copper, forged or drawn into the shape of a rod, and then cut off to the proper lengths. These are used either cold or red hot, according to circumstances; and when placed in a hole, the two ends of each rivet are exposed to such powerful blows (or blows on one end with pressure on the other) as to form a burr or head which clasps the plate tightly. The two millions of rivets in the Britannia Bridge present perhaps the most remarkable example of rivetting yet known. [Menai Bridges.]

ROADS. The Romans were distinguished by the vast extent and solid construction of their roads, of which several thousand miles were made in Italy alone; while every country which was brought under their sway was more or less intersected by these excellent highways. The solidity of their construction was fully equal to the boldness of their design, a fact proved by the existence of many that have borne the traffic of nearly two thousand years without material injury. The Romans always gave a firm foundation to their roads, by ramming down a layer of small stones and broken brick; on this layer a pavement of large stones was laid, either squared to fit closely around one another, or cemented into a hard and firm causeway.

In this country very little was done towards a sound and scientific construction of roads until the beginning of the present century. The *Highland* roads have been made under a commission issued in 1803, and have been of incalculable benefit in opening districts which were before placed almost beyond the reach of commercial enterprise. The commissioners have constructed about 1000 miles of excellent road, and much more than that number of bridges. The *Holyhead* road improvements were commenced in 1815, under Mr. Telford; these comprise the establishment between London and Holyhead of the best coach-road in England, in which principles of sound construction have been more attended to than in any other examples. The greatest angle or ascent allowed in this road is 1 in 35: a slope which may be ascended at a good rate of speed, and descended at twelve miles an hour without risk.

The *Macadamised* roads, named from the inventor, exhibit a particular mode of applying small stones to the surface. Under the old method, stones of irregular sizes and shapes were thrown down upon the soft earth of a road, and became mixed up with it in such a way as to form a very irregular road. Mr. M'Adam conceived that if small stones of nearly uniform size were used, they would tend to lock together into a hard and compact mass, forming a sort of crust nearly impervious to water. He objected to any kind of chalk or earth being mixed with the stone; but the quantity of stone must depend on the quality of the ground beneath; in many cases a layer three feet thick has been required. Mr. Telford employed the still more durable system of placing a layer of hand-laid larger stones beneath the smaller, so as to form, in fact, a sort of two-fold paving.

It has been found by experiment, that a layer of hard broken stone on a substratum of stone affords easier draught for horses than where the substratum is of earth; and that a gravel surface is more trying to horses than a broken stone surface. As a general rule, the hardest stone—such as basalt, granite, quartz, sienite, or porphyry—is found to be the best for road-metal, or the broken stones for the surface; but this is not invariably the case, as some hard stones are found to wear more rapidly than softer but tougher stone. Limestone, slaty stone, and sandstone, are all unfitted for roads. On some parts of the Holyhead road small cubes of iron, about an inch square, are placed at intervals of four inches among the stones, and well packed round with small chips of stone; they have been found to produce a remarkably durable road.

Stone tramways have occasionally been applied to common roads with great advantage. They consist of wheel-tracks formed of large blocks of stone, usually granite, over which the wheels roll smoothly, while there is an intermediate broken stone road for the horses. Iron tramways are sometimes used for a similar purpose. The saving of horse-labour by these tramways is remarkable. Sir John Macneill stated in 1839:—"If a tramway were constructed of iron plates the whole way from Leeds to Birmingham, a coach carrying sixteen passengers might be drawn at the rate of ten miles an hour with only two horses; and one horse would be able to draw a post-chaise more easily than two now can."

The pavements of towns require a different mode of construction from the roads of open districts. They must afford the means of sweeping or cleaning, and there must be pavements besides those which are traversed by vehicles. Of the granite paving, the wood paving, the asphaltic paving, the inhabitants of London have had abundant means of forming a judgment within the last few years, for they have been renewed and repaired to a wearisome degree.

It is supposed by many persons, that if stone or iron tramways were laid down, locomotives on common roads would have had much more success than has hitherto attended them. Such locomotives have been constructed in considerable variety within the last thirty years; but although mechanically correct in principle they have not come into use—owing partly to the imperfect state of the roads. The public journals have recently noticed a new road-locomotive at St. Etienne, in France, which excited much attention on its first appearance. It was invented by M. Verpilleux. On its first journey it went through all the streets of the town with the greatest facility, under the most perfect control of the man sitting in front, turning it to the right or left, or sending it backward or forward, as he pleased. Two cabriolets, filled with some of the friends of the inventor, were attached to the carriage, as was afterwards a heavy cart of coals. The carriage weighs two tons, and is of four horse power. It runs on three wheels, and its speed is 10 English miles an hour. Its consumption of coke per hour is from 20 to 25 kilogrammes. It had left the same morning Rive-de-Gier, and arrived at St. Etienne by the old Sorbiers road, which is badly kept and full of ruts. The carriage, however, did not suffer. A new vehicle on the same principle, but of a 12-horse power, is now in course of construction: it will be able, it is said, to move four coal-waggons with a weight of 12,000 kilogrammes. It is intended shortly to employ this mode of locomotion for carrying the coals of Bessège to the Rhône, and those of Firminy to the Lyon Railway. The cost for doing this will not, it is calculated, be more than one-half of that of the ordinary mode of conveyance.

ROASTING. There is a little chemistry in the art of cooking, which, while it has engaged the philosophic mind of a Liebig, cannot be beneath the notice of others. The familiar modes of preparing animal food, for instance, deserve a little study. In the process of broiling meat, the heat is applied immediately and suddenly to the surface, by which it is hardened, so that the juices of the meat are greatly retained, evaporation being thereby prevented; while in roasting, the heat is applied gradually, the watery portion is evaporated, as well as the fat melted out to a considerable extent, till the progressive browning and hardening of the surface prevent the further escape of the juices. The loss of weight in roasting meat is much greater than by boiling, much of the fat being melted out and water evaporated, but the nutritious matter remains condensed in the cooked solid; whereas, in boiling, the gelatine is partly abstracted. Roasted meat is therefore more nutritive than boiled meat, and also more digestible.

ROCKET is a cylindrical vessel or case, of pasteboard or iron, attached to one end of a light rod of wood, and containing a composition which, being fired, the vessel and rod are projected through the air by a force arising from the combustion.

Rockets have long been used as a means of making signals for the purpose of communication when the parties have been invisible from distance or darkness; and they have occasionally served the important purpose of determining the difference of longitude between two places. Rockets have also been constructed for the purpose of being used in warfare, and such missiles were so employed for the first time at the battle of Copenhagen, in 1807. Signal rockets are made to weigh half a pound, one pound, or two pounds; and the one pound rocket is about 16 inches long. The rod is generally attached near the base, on one side of the rocket, and its length is about 8 feet. The composition with which the cylinder is filled consists generally of saltpetre, sulphur, and charcoal or gunpowder, and the composition which produces what are called the stars, consists of saltpetre, sulphur, antimony, mealed powder, and isinglass. The latter is dissolved in one quart of vinegar, after which one pint of spirit of wine is added, and then the mealed composition is mixed with the liquid till the whole becomes like a stiff paste. The burning composition acting at the head, and at the opposite end of the rocket, produces impulsive forces in opposite directions; but sundry perforations at the lower extremity, by allowing the fire to escape there, nearly destroys the pressure against the lower end, and thus the pressure at the head is almost wholly effective in giving a forward motion to the rocket. The rod serves to guide it in its flight, the resistance of the air perpendicularly to its length checking any vibrations which may be caused by inequalities in the action of the burning composition.

Rockets whose diameters vary from 1 to 2 inches have been found to ascend vertically to the height of about 500 yards, and those whose diameters vary from 2 to 3 inches have ascended to the height of 1200 yards. The distances at which rockets can be seen vary from 35 to 40 miles; and the times of ascent, from 7 to 10 seconds. Rockets, to be employed as military projectiles, were invented by Sir William Congreve, and, in the British artillery service, a body of men, called the Rocket Troop, has been organised expressly for their management. From their form they penetrate to a considerable depth when fired against timber or earth: 12-pounder rockets, after a range of 1260 yards, have been found to enter the ground obliquely as far as 22 feet. As used in pyrotechnic exhibitions, rockets always have pasteboard cases.

ROLLERS. Cylindrical rollers are used for very many purposes in the arts, especially where two are employed in contact. If one roller is rotating on its axis, and if another be brought close to it, surface to surface, with the axes parallel, the second roller will be made to rotate in an opposite direction from the first; this property is often made use of in transmitting and reversing motion. In *cylinder printing*, at the cotton print works, the passing of the cloth between two cylinders, one of which is engraved and supplied with colour, suffices to print the cloth. In bookbinding, or rather in pressing the sheets for the book-binders, a roller-press affords an immense power: this consists, in principle, of two rollers rotating nearly in contact, and pressing between them the quire of leaves. In all kinds of metal working the pressure of two rollers is employed to flatten a mass of metal into slabs, sheets, or ribbons. If the surface of one or both rollers be grooved in a direction transverse to the axis, any substance passed between the rollers will assume a form corresponding with those grooves. It is in this way that railway bars are made; the iron is first passed between rollers grooved so as to produce a square bar, and then through other rollers so grooved as to give the contour of a railway bar. All such modes of compression have a tendency to increase the length of bars according as the width and thickness are diminished.

In agricultural matters the roller is often used singly, and generally as a weight. In the common garden and road roller a heavy cylindrical mass is employed to press the earth or gravel of a path smooth or level; it is sometimes made of stone; but sometimes a hollow iron cylinder, weighted, if necessary, with stones. A roller is sometimes used over corn fields, whose surface is covered with teeth. Such is Crosskill's Patent Serrated Roller and Clod Crusher. This roller is very heavy, and requires three horses abreast to work it over a newly ploughed field; the surface of the roller presents angular teeth in every part, and these teeth tend to break up the clods of earth which have been turned up by the plough. It also tends to give solidity to loose soil, one of the advantages ordinarily produced by sheep-treading.

ROOF. In order to cover in a building in which the space to be spanned is greater than can be covered by single blocks of stone extending from one point of support to another, it is necessary either to have recourse to the principle of the arch, as in vaults and domes of stone or brick, or to form a framework of timber to support the covering. [ARCH; DOME.] Roofs formed of one level plane, which are extensively used in eastern countries, are not adapted for our climate; and a single inclined plane carries up the roof to too great a height.

The best figure for a simple roof is that formed of two inclined planes, rising from the two opposite walls that approach nearest to each other, and meeting over the centre of the edifice, so as to form a ridge: this is called a *common* or *gable-ended* roof. Frequently four inclined planes are used, disposed as a *hipped roof*, which takes its name from the hips, or inclined ridges formed by the meeting of the sides and ends. Sometimes the inclined faces are not continued upwards till they meet, but the roof is completed by a horizontal plane. Such a roof is called a *truncated*, *terrace*, or *cut roof*, and may have two, three, or four inclined faces. A similar saving of height is frequently obtained by means of a roof in which each sloping face consists of two planes of different degrees of inclination. This form, which is denominated a *curb roof* (or, from its inventor, a *Mansarde roof)*, is very common in London, because it affords more space for the formation of bed-rooms in the roof than the simpler forms. These various kinds of roof require many modifications to suit irregularities of shape, or combinations of rectangular forms. Thus, in the junction of different roofs or portions of roofing at right angles with each other, there are inclined lines or *valleys*, which, at the junction of two planes, form hollows the reverse of hips. When two faces of a roof join, so as to form an angle similar to a valley, but in an horizontal instead of an inclined position, the term *gutter* is applied instead of valley. A further distinction is that between roofs with dripping eaves, and those in which the water is collected in gutters. In the former case the roof projects several inches, or even feet, beyond the walls, and the water running from the roof either drops at once on the ground, or is collected in troughs fixed under the margin of the eaves, and conducted by them to descending pipes. In gutter roofs the timbers do not extend to the outside of the walls, which are carried up as parapets, of a reduced thickness, to such a height as to conceal the roof either wholly or partially. The gutters, which are troughs of wood, covered with lead or other metal, are laid at the bottom of the slopes, just within the parapets, and have a gentle inclination (usually about an inch in ten feet), to cause water to run freely towards the pipes.

The timbers of a roof have various names to them, according to their position and purpose. Thus, those which join the wall are the *wall-plates;* that at the meeting of two faces, parallel to the wall-plates, is the *ridge-piece;* and the inclined bars extending from the wall-plates to the ridge-piece are *rafters*, those which form the salient angles in hipped roofs being distinguished as *hip-rafters*. In a hipped roof, the rafters near the ends are called *jack-rafters*. Additional support is supplied by horizontal rectangular bars called *purlins*, and these are supported by a series of bars called *principals*. The lower ends of the principals are mortised into the ends of the *tie-beam*, which stretches across the building, and rests upon the wall-plates. The triangular frame formed by the two principals and a tie-beam, with any bars it may comprise for additional strength, is called a *truss*, and such frames being placed at regular intervals, the timber work between any two of them is called a *bay of roofing*. The lower extremities of the common rafters, being elevated by this arrangement above the wall-plates, are supported by *pole-plates*, or pieces of timber parallel to the wall-plates, resting on the ends of the tie-beams. The supporting frame-work altogether is called a *carcass-roof*. The outward thrust against the wall is counteracted by a horizontal *tie-beam*, and the sinking is prevented by a vertical bar called the *king-post*. Sometimes the king-post is dispensed with, and its office performed by two similar posts, called *queen-posts*, at equal distances from the centre of the truss. In order to keep these in their right position, a short horizontal beam, called a *collar-beam*, is inserted between their upper extremities, and another, termed a *straining-sill*, between their lower ends. *Cushion rafters* are pieces occasionally added, in large roofs, to strengthen the principals. In curb roofs the upper rows of rafters are called *curb-rafters*, and the horizontal bars that receive the upper ends of the lower rafters, and the feet of the curb-rafters, are known as *curb-plates*.

In roofs of very large span it is often desirable, in order to avoid running up to a great height, to form two or more ridges. Roofs without ties may be greatly strengthened by the use of parabolic curves of iron, notched into the rafters of each inclined face, and abutting on the wall-plates, which in such a case are firmly bolted together. Wrought iron straps of various forms are very useful, when judiciously applied, in strengthening the joints of a roof. The *Norman roof* is an ingenious contrivance for the construction of roofs of large span with small pieces of wood; in this arrangement all the rafters abut on joggled king-posts, of which there are several, their relative position being maintained by diagonal braces. Domes of wood, of great size, have been made without trussing, simply by forming the timbers into curved ribs abutting on the wall-plates, which then form a circle, and are kept in their proper positions by horizontal circles framed with them at intervals. The wooden dome formerly existing at the Halle aux Blés, at Paris, was a remarkably bold example of this kind, being 200 feet in diameter, and having a large opening in the centre.

All the different kinds of roof-coverings require certain fitting arrangements of the timber beneath, according to weight, angle of slope, &c. Cast iron, wrought iron, yellow fir, thatch, tiles, pantiles, plain tiles, slates, shingles (thin boards shaped like slates), slabs of thin stone, plaster, asphalte and other cements, tarred paper, sheets of lead, copper, iron, tinned iron, and galvanized zinc iron—all are used for roof coverings.

One of the largest roofs in existence is that over the Riding-school at Moscow; it is 235 feet span, with a slope of 19°; and the external dimensions of the building are 1920 feet by 319. But the most remarkable roof, all things considered, is that which Messrs. Fox and Henderson have recently erected over the Exhibition Building in Hyde Park. The slender appearance of the many hundred columns which support it; the elegant lightness of the girders which brace the columns together; the ridge-and-furrow principle by which drainage is secured; the matchless waggon-vaulted transept, upwards of 400 feet long by 72 in diameter; and the acres of glass which form the roofing material—all serve to distinguish this roof from any before constructed.

The same engineers have recently constructed a magnificent iron roof at the Liverpool terminus of the Lancashire and Yorkshire Railway. It covers five lines of rails and three platforms, and a carriage road twelve yards wide, in one span, having no columns nor supports besides the outside walls; the span varies from 136 feet to 128 feet, and the total length is 631 feet. The total area thus covered is 83,457 feet. The material used in the construction of this roof is entirely iron. The framing consists of a series of trussed principals, placed at intervals of eleven feet from centre to centre; and immediately over the principals are fixed wrought iron purlines, which support the covering; this covering is of corrugated sheet iron, galvanized. The roof is both lighted and ventilated along the ridge by four continuous rows of large skylights, and two rows of louvres; half the light is distributed along the ridge, and the remaining half is equally distributed at the eaves; the total area of light admitted being equal to one-fourth of the entire area of the roof.

ROPE-MAKING. The name *Rope* is generally confined to the larger descriptions of cordage, such as exceed an inch in circumference, though the principles of formation are much the same for cordage of every size; the smaller sizes are known by various names.

In rope-making, whether for large or small ropes, the first process consists in twisting the hemp into thick threads, called *Rope-Yarns*.

This process, which resembles ordinary spinning, is performed with various kinds of machinery. The common mode of spinning rope-yarns by hand is performed in the rope-ground or rope-walk, an inclosed slip of level ground, sometimes 600 feet or more in length. At one end of this ground a spinning-wheel is set up, which gives motion by a band to several small rollers or *whirls*. Each whirl had a small hook formed on the end of its axis next the walk. Each of the spinners is provided with a bundle of dressed hemp, laid round his waist, with the bight or double in front, and the ends passing each other at his back, from which he draws out a sufficient number of fibres to form a rope-yarn of the required size; and, after slightly twisting them together with his fingers, he attaches them to the hook of a whirl. The whirl being now set in motion by turning the wheel, the skein is twisted into a rope-yarn, the spinner walking backwards down the rope-walk, supporting the yarn with one hand, which is protected by a wetted piece of coarse cloth or flannel, while with the other he regulates the quantity of fibres drawn from the bundle of hemp by the revolution of the yarn. The degree of twist depends on the velocity with which the wheel is turned, combined with the retrograde pace of the spinner. When the spinner has traversed the whole length of the rope-walk (or sooner, if the yarns are not required to be so long), he calls out, and another spinner detaches the yarn from the whirl, and gives it to a person who carries it aside to a reel, while the second spinner attaches his own hemp to the whirl-hook. The hemp, being dry and elastic, would instantly untwist if the yarn were now set at liberty. The first spinner, therefore, keeps fast hold of it all the while that the reeler winds it up, walking slowly up the walk, so as to keep the yarn equally tight all the way. When it is all wound up, the spinner holds it till another is ready to follow it on the reel. Sometimes, instead of being wound on a reel as they are made, the yarns are laid together in large hooks attached to posts at the side of the walk, until about four hundred are collected together, when they are coiled up in a *haul*, or skein, in which state they are ready for tarring. In some roperies machines have been introduced, especially one invented by Mr. Lang of Greenock, for spinning yarns.

The yarns being thus spun, they are warped or stretched to a given length, in order that they may, when formed into a strand, bear the strain equally. When the rope is to be tarred, that operation is usually performed upon the yarns immediately after their being warped, as the application of tar to the yarns previous to their combination is necessary to the complete penetration of the whole substance of the rope. The most common method of tarring the yarns is to draw them in hauls or skeins through the tar-kettle by a capstan; but sometimes the yarns are passed singly through the tar, being wound off one reel on to another, and the superfluous tar being taken off by passing the yarn through a hole surrounded with spongy oakum.

In making large cordage, from fifteen to twenty yarns are formed into a *strand*, and three or more such strands are afterwards combined into a rope. The twist of the strand is in an opposite direction to that of the yarns. In *closing* or *laying* the rope, three strands are stretched at length along the walk, and attached at one end to separate but contiguous hooks, and at the other to a single hook; and they are twisted together by turning the single hook in a direction contrary to that of the other three; a piece of wood called a *top*, in the form of a truncated cone, being placed between the strands, and kept during the whole operation gently forced into the angle formed by the strands, where they are united by the closing or twisting of the rope. As the rope shortens in closing, one end only of the apparatus is fixed, the other being on a moveable sledge, whose motion up the rope-walk is capable of regulation by suitable tackle attached to it, or by loading it with weights. The top also is mounted on a sledge, for closing large cordage, and its rate of motion may be retarded, in order to give greater firmness to the twist of the rope. Ropes formed in this manner are said to be *shroud-laid*, or *hawser-laid*.

Those large ropes which are said to be *cable-laid* are formed by the combination of smaller ropes twisted round their common axis, just as shroud-laid ropes are composed of strands twisted round their common axis. As cable-laid ropes are harder and more compact than others, this mode of formation is adopted for ropes to be exposed to the action of water, even though their thickness may not be very great. Originally all the yarns (from $\frac{1}{12}$ to $\frac{1}{8}$ of an inch in thickness) composing a strand were of the same length: but Captain Huddart showed that in such an arrangement the outermost yarns must be more strained than the inner: he accordingly, in 1793, patented his *register* cordage, in which the strain is equalised throughout. The same gentleman invented machinery for almost every department of rope-making.

Ropes formed by plaiting instead of twisting are made use of for some purposes in which pliability is especially needed, they being more supple and less liable to entanglement than those of the ordinary make. Such ropes are preferred for sash-lines, clock-lines, &c., and generally where the rope has to pass over pulleys of small diameter. Flat ropes, which are much used for mining purposes, are either formed of two or more small ropes placed side by side, and united by sewing, lapping, or interlacing with thread or smaller ropes, or of a number of strands of shroud-laid rope similarly united. In either case it is necessary that the component ropes or strands be alternately of a right hand and left hand twist, that the rope may remain in a quiescent state.

Many experiments were made by Réaumur, Knowles, and others, to test the loss of strength by the ordinary twist given to ropes. Duhamel prepared the following statement, to show the comparative strength of ropes formed of the same hemp, and the same weight per fathom, but twisted respectively to two-thirds, three-fourths, and four-fifths of the length of their component yarns:—

Degree of twist.	Weight borne in two experiments.	
$\frac{2}{3}$	4098 lbs.	4250 lbs.
$\frac{3}{4}$	4850	6753
$\frac{4}{5}$	6205	7397

The result of these experiments led Duhamel to try the practicability of making ropes without any twist, the yarns being wrapped round to keep them together. These had great strength, but very little durability. In shroud or hawser-laid ropes the usual reduction of length by twisting is one-third; but cable-laid ropes are further shortened, so that 200 fathoms of yarn are required to make 120 fathoms of cable. A hawser-laid rope 6 inches in circumference by 120 fathoms (720 feet) long, weighs about 10 cwts. A cable-laid rope 12 inches in circumference and 120 fathoms long, weighs 36 cwts. A hawser-laid rope 6 inches in circumference will bear a weight of 140 cwts. The tarring of ropes somewhat impairs their strength, but renders them more durable. Oils, fats, and tallow of various kinds have been occasionally used; but tar is found to be the best preservative.

Several other kinds of vegetable fibre besides hemp have been made use of in the manufacture of cordage, and some appear greatly to exceed hemp in strength. The fibres of the aloe, long wool, hemp mixed with threads of caoutchouc, thongs of ox-hide, and several other substances, have been employed; but none are found to combine so many advantages as hemp.

Ropes formed of iron wire have been, within the last few years, introduced to a considerable extent, and have been found to effect a great saving of expense from their durability and superior lightness. Ropes of twisted iron wire were used in the silver mines of the Harz Mountains twenty years ago; they were nearly equal in strength to solid iron bars of equal thickness, and equal to hempen ropes of four times their weight. Wire ropes are now made in England under many patents. They are formed in various ways, according to their intended use. For standing rigging straight untwisted wires are employed, bound round with cloth or small hempen cordage saturated with a solution of caoutchouc, asphaltum, or other preservative from rust. Flat ropes may likewise be made of straight wires, interwoven or wrapped with hempen yarn, or sewed between canvas, &c. Other ropes are formed much in the same way as those of hemp, the wires taking the place of rope-yarns, and being twisted into strands, and combined into ropes, both hawser-laid and cable-laid. The twisting should not be so hard as in hempen cordage; and all the wires must be protected by an anti-corrosive composition, or by coating with tin, zinc, &c. It is sometimes the practice to twist wires round a core, either of wire, hemp-cord, spun yarn, or other material to form a strand, and to lay such strands round a similar core when there are more than three strands in a rope.

The annexed table, showing the comparative size and weight per fathom for equal strength, may serve to show the great superiority of wire ropes over those of hemp, which they surpass even in flexibility:—

Hemp Rope. Size. Inches.	Weight per fathom. lbs.	oz.	Wire Rope. Size. Inches.	Weight per fathom. lbs.	oz.	Equal to a strain of cwts.
3	2	4	$1\frac{1}{4}$	1	4	50
4	3	15	$1\frac{1}{2}$	1	9	70
5	6	0	$1\frac{3}{4}$	1	14	135
6	9	0	2	2	2	160
7	12	3	$2\frac{1}{4}$	2	9	171
8	14	3	$2\frac{1}{2}$	4	1	198
9	19	6	3	5	4	306
10	25	0	$3\frac{1}{2}$	7	1	486
11	30	0	4	11	6	585
12	36	8	$4\frac{1}{2}$	15	12	704

Suspension bridges are now occasionally made of wire rope of enormous dimensions and strength.

ROSCOMMON. In this Irish county some of the mountains are composed of shales and sandstones, with three beds of coal resting on beds of the millstone-grit series, from which good ironstone is obtained. The coal answers well for smelting iron, and is used in the Arigna iron-works in this county. In many places, good limestone is quarried for building. Potter's clay and pipe-clay are found in various parts of the county. The Royal Canal opens

into the Shannon opposite Tarmonbarry in this county; the Grand Canal just below the junction of the Suck. The traffic on the canals consists chiefly of corn and butter sent to Dublin, and English manufactures and general goods sent in return. The navigation of the Suck commences at Ballinasloe (county of Galway) for light flat-bottomed boats; small row-boats ascend higher. But a canal is cut parallel to it on the Galway side of the river, from Ballinasloe to the Shannon. The soil in the limestone district is commonly fertile; there is, however, a large extent of bog or other wastes. The amount of pasture land is considerable: the natural pastures, which are esteemed to be some of the best ground in the county, are in the limestone districts. The extent of the unimproved mountains and bogs has been estimated at above 130,000 acres; several of those on the uplands are comparatively dry, and afford in their natural state coarse pasturage for young and hardy cattle.

Roscommon has little to boast of in respect to manufactures; its towns are small, and very little is produced there beyond a supply for the immediate wants of the inhabitants.

ROSE ESSENCE. The rose is more frequently cultivated as an ornament than for its applications to medicine or the arts. It has, however, astringent and tonic properties which render it useful in medicine. In the East it is extensively grown for the purpose of procuring, in a variety of ways, the volatile oil which gives it its delicious fragrance. For these purposes the species that are mostly cultivated are the *Musk*, the *Damask*, the *Centifolia*, from all of which the attar, otto, essence, or oil of roses may be procured in considerable quantities. The attar of roses forms an object of considerable commercial importance on the coast of Barbary, in Syria, Persia, India, and various parts of the East. [Attar of Roses.] Many other perfumes are made from roses, and are consumed in large quantities, as rose-water, vinegar of roses, spirit of roses, honey of roses, &c.

ROSEMARY. Besides the beauty of this plant from its variegated leaves, it is used in medicine and perfumery. The *Oil of Rosemary* is chiefly prepared in Spain and the south of France, by distillation of the leaves and flowers. At first it is nearly transparent and very limpid, but by time it becomes both yellowish and thicker. It possesses the strong penetrating odour of rosemary, with a camphor-like intermixture, and a burning taste. Rosemary possesses valuable stimulant and carminative properties; but it is chiefly employed as a perfume, entering into the composition of *Hungary Water*, *Eau de Cologne*, and aromatic vinegar. It is also said to promote the growth of hair and prevent baldness.

ROSIN. [Resins.]

ROTATION OF CROPS. As we touch upon Agricultural subjects in this work only so far as relates to the mechanical appliances of the art, and to the economical uses of the crops produced, we will notice the *Rotation of Crops* simply as a means of shewing what the expression means, and how it bears upon practical agriculture. A further developement of the subject must be sought for in other works.

It has been found from experience that a repetition of the same crops in succession has a peculiar effect on the soil, so that if grain of the same nature be sown year after year in the same ground, it will not produce the same return of the seed, even when abundantly manured. It is the formation of the seed which principally causes the deterioration of the soil; for if the crops be fed off in a green state, or mown before the seed is formed, the same may be safely repeated, and no diminution of the plant is apparent. However judiciously the land may be manured, it is not practicable to raise a crop of wheat or clover, or of many other plants, on a soil which has shown that, as the farmers say, it is *tired* of that crop; but clover grows well after wheat, and wheat after clover, so that the same effect is not produced in the soil by these two crops. In all countries where peculiar attention has been paid to agriculture, the most advantageous succession of crops is generally known; and certain general principles are commonly admitted as fully established.

In order to find the crops which may advantageously succeed each other in rotation, many circumstances must be taken into consideration. First of all the quality of the soil, and its fitness for particular crops; next the wants of the farmer and his family, and the maintenance of the stock required to produce a sufficient supply of manure; and next the particular market which lies open to him. That which forms the food of man is always the principal object in the cultivation; and, excepting rice, which only grows in warm climates, there is no food more universally used than that which is made from wheat. Rye, barley, oats, and pulse, are only substitutes where wheat cannot be raised in sufficient quantities. Next to grain comes meat, chiefly beef, mutton, and pork, of which the consumption increases with the wealth of a nation and the advance of its agriculture. Wheat and fat cattle are therefore primary objects with every good farmer; and he who can raise most wheat and fatten most oxen or sheep or pigs will realise the greatest profit. The rotation adopted depends on all these circumstances combined, and the farmer follows different systems according to the balance of advantages, such as the three-year rotation (a year of fallow, a year of wheat, and a year of barley or oats); or the four-year course (turnips, barley, clover, wheat,) &c.

ROTE, was a musical instrument mentioned by the early French and English writers; it seems to have been similar to what the French call a *vielle*, and the English a Hurdy-Gurdy.

ROTTEN STONE, is a mineral, of a grayish, red, or dark brown colour, soft and earthy, consisting chiefly of alumina. It is employed in polishing metals.

ROTTERDAM, the capital of the Dutch province of South Holland, is intersected by numerous canals connected with the river Rotte, on which the largest merchantmen can come up and unload at the very doors of the warehouses. Along the Maas are many fine quays, the handsomest of which is called the Boomtjes, from the rows of trees with which it is planted. Rotterdam is connected by canals and by railway with the principal towns in Holland. The commerce of Rotterdam extends to all parts of the world, and embraces almost every kind of produce and manufacture. The imports and exports are similar to those of Amsterdam, but greater in quantity. The total value of the imports is about 10,000,000*l.* sterling annually; of the exports about 7,000,000*l.* Rotterdam is pre-eminently a commercial town, and is said now far to surpass Amsterdam in trading importance. Steamers ply regularly to Amsterdam, London, Cologne, Antwerp, &c.

ROTUNDA, is a term applied to buildings which are circular in their plan both externally and internally, or else to halls and other apartments of that shape, included within and forming merely a portion of the edifice containing them. The technical application of the term is however restricted to circular buildings whose height does not much exceed their diameter, for we should not describe a lofty cylindrical edifice, such as a round tower, by the term. The Colosseum in the Regent's Park, London, might without any great impropriety be classed among rotundas. The shape is now very seldom adopted, being unsuited to buildings in general, whatever their particular purpose may be, unless it be one for which nothing more than a single spacious hall or area is required internally. In ecclesiastical architecture circular and polygonal structures were by no means uncommon among the early Christians, especially for baptisteries and sepulchral chapels. The rotunda became afterwards in a manner incorporated with or added to the cruciform plan, being raised aloft and placed over that part of it where the transepts intersect the body of the edifice. Nearly all modern cupolas may be described as rotundas elevated above the rest of the building and viewed by looking up into them from below.

ROUEN. This important French city is situated at a point of the Seine where two small islands convert the river into a good harbour for sea-borne vessels of 300 tons. Above the stone bridge on the eastern side of La-Croix islet lie the large river craft and small steamers that ply up the Seine to Paris; between it and the suspension-bridge, and also below the latter, sea-borne vessels load and unload close to spacious well-built quays, extending all along the right bank of the river, and backed by lofty warehouses. The suburbs generally are inhabited by the manufacturing population; they contain numerous cotton factories. But though Rouen resembles many old towns on the continent in presenting a labyrinth of streets, composed of old picturesque timber-framed gable-fronted houses, it is not, like most of them, abandoned by trade, but still swarms with a population engaged in all the bustling activity of commerce and manufacturing industry.

The important manufactures of Rouen comprise striped and checked cottons for women's dresses, called *rouenneries*, calicos, woollen cloth, nankins, muslin, handkerchiefs, shawls, velvet, hosiery, swanskin, flannel, hats, lace, ropes, blankets, combs, preserved meats and confectionary, liqueurs, glue, soap, mineral acids and chemical products of all kinds, porcelain, pottery, room paper, haberdashery and small wares, steam machinery and mill-work, shot and sheet-lead, tin-ware, cotton and woollen yarns, &c. There are numerous cotton-mills, driven by steam and by water power; hand-loom weaving also prevails to a considerable extent. The other industrial establishments include dye-houses, sugar-refineries, bleach-works, tan-yards, breweries, ship-building docks, saw-mills, mills for grinding dye-woods, copper and iron foundries, fulling and pressing-mills.

Advantageously situated for commerce, with a good harbour, in which the influence of the tide is felt, and in rapid communication by railway with Paris, Havre, and Dieppe, Rouen has a very considerable import and export trade in its various industrial products, colonial and foreign produce, corn, flour, wine, brandy, fish, oil, salt provisions, hides, groceries, drugs, raw cotton, hemp, wool, iron, slates, pitch and tar, timber, &c. About 100 vessels, including steamers, belong to the port. The annual value of exports from the city exceeds a million sterling; the imports do not exceed half the amount; this is exclusive of the transit trade. Rouen is a special entrepôt for colonial and foreign produce, and has one of the most important corn-markets in France.

The Rouen journals announce that a good-sized brig, called the Athalie, has lately sailed from that port for Constantinople, and that another is about to follow. They add that it is hoped that a regular service, by means of sailing-vessels, will be established between the two places, and that eventually steamers will be employed; as the improvements recently made in the bed of the river Seine now enables steamers of large burthen to come up to Rouen. Goods from Paris sent to the Levant *viâ* Marseilles cost 130 fr. to 150 fr. the ton, but from Rouen the expense will rarely exceed 60 fr.

ROUGE. The rouge employed as a cosmetic is made in the following way. Safflower is washed in pure water, dried, reduced to powder, and steeped in a weak solution of soda, which thereby assumes a yellow colour. Lemon juice is added; a little cotton wool is steeped in the liquid; and in a short time the yellow colouring matter becomes precipitated upon the cotton. By a curious train of subsequent processes, the yellow precipitate assumes the delicate rose tint which characterises rouge.

The above is said to be the only rouge which does not injure the skin; but many other kinds are occasionally employed. *Rouge Indienne* is the Indian or Persian red imported from Ormuz. *Liquid Rouge* is the red liquid left from the preparation of carmine. *Rouge de Prusse* is burnt yellow ochre. *Vert Rouge d'Athènes* is obtained from Safflower; but by a process different from that above noticed. *Spanish Lady's Rouge* is cotton wool repeatedly wetted with ammoniacal solution of carmine, and dried.

ROXBURGHSHIRE. This Scottish county, though containing no large town, numbers several in which manufactures are carried on. At *Hawick* the manufactures are chiefly of woollen yarns, flannels, and other woollen under-clothing, plaiding, shawls, tartans, druggets, woollen-cloths of various descriptions, blankets, and lamb's-wool hosiery. At *Jedburgh* similar manufactures are carried on; and there are quarries of red and white sandstone in the parish. The manufactures of *Kelso* are not important; they consist of leather, linens, stockings, hats, woollen cloth, and tobacco. The industry of the county, however, is mostly exhibited in grazing operations, the sheep walks being numerous and extensive.

RUDDER. The rudder of a ship is too well known to require detailed description. When it is in a right line with the keel, its movement suffers no resistance from the water, and the direction of the ship's motion is not affected by it; but when the rudder is forced to assume a position oblique to the keel, the surface becomes subjected to a resistance from the water, which affects the position of the stern of the vessel, and gives a new direction to the keel, and to the vessel's movement. Patents are occasionally taken out for improvements in the form or action of rudders; but there is a pretty general adherence to the old kind of rudder. Some rudders are worked by a *tiller* or lever; others by a wheel.

RUE. This useful plant is a native of the south of Europe. Every part of it is marked by transparent dots, filled with volatile oil. The leaves and immature fruits are medicinal, and owe their virtue to the volatile oil and a bitter extractive. The odour is peculiar, strong, and penetrating; the taste intensely bitter, aromatic, and stimulating. Rue possesses powerful stimulant, antispasmodic, and tonic properties. Rue is sometimes called Herb of Grace, and in some parts of England, Ave Grace. This name is said to have been given to it on account of its use in exorcisms. In company with rosemary it has been used from time immemorial as an emblem of remembrance on account of its evergreen foliage.

RULER, PARALLEL. In its usual form, this instrument consists of two rectangular rulers connected by two cross-bars of equal lengths, which move on pivots in the rulers in such manner that the four pivots, two in each ruler, shall be the four points of a parallelogram. One ruler being held fixed, and a line drawn with the edge of the other ruler in any position, then any motion given to the other ruler by the rotation of the cross-bars gives, on the edge of the moving ruler, a line parallel to the first line. To give the instrument more extent, three rulers are sometimes put together, each connected with the next by cross-bars in such manner that the cross-bars connecting the first and second have an opposite revolution to those connecting the second and third.

The rolling parallel ruler consists of an ordinary ruler of rectangular form, both edges of which are bevelled and divided into inches and tenths, or otherwise. Two short rollers of equal diameters, and connected by an axis of nearly the same length as the ruler, are let into perforations made in the latter, so that when the instrument is moved perpendicularly to its length on the paper, lines drawn along either of its bevelled sides are parallel to one another. Perpendiculars to a given line are drawn by adjusting the ruler so that any division on a bevelled edge may travel on the given line.

RUM. This well known spirit is distilled from cane-juice, or the scummings of the juice from the sugar-boiling-house, or from treacle, or molasses, or from *dunder*, the lees of former distillations. As the entire juice of the cane is not necessary for making rum, the distillation is carried on in conjunction with the manufacture of sugar. The best rum is made from the uncrystallised syrup called molasses. [MOLASSES.] The proportion of molasses made in crystallising a cwt. of sugar varies from 50 to 90 gallons, and depends both upon the climate and the season, being lowest in the Leeward Islands, which have a dry climate, and highest in Demerara and Trinidad, and it is in the latter that in fine seasons the proportion reaches 90 gallons per cwt. Nearly one gallon of proof rum may be made from one gallon of molasses. The best rum is from Jamaica; the worst from the Leeward Islands. The consumption of rum in England is diminishing; its place being filled by gin and British brandy. In the finer qualities of Jamaica rum, slices of pine-apple are put into the hogsheads; and the liquor then obtains the name of *pine apple rum*.

A few statistics relating to Rum will be found under SPIRIT TRADE.

RUSH; DUTCH RUSH. This material, which is used to some small extent in the arts, is the *Equisetum hyemale*. The stem is very rough, with from fourteen to twenty slender furrows. It is a native of England, Scotland, and Ireland, as well as the continent of Europe; but is almost unknown in the middle and southern English counties, and is only sparingly distributed anywhere. It appears to possess tannin, and to act as an astringent. It is supposed to be injurious to cows, and is said to cause their teeth to drop out, but horses eat it with impunity. This plant, more than any other species, is used for the purposes of polishing. Lightfoot says, that in Northumberland the milk-maids scour their pails with it. It is also used for the purposes of polishing wood, bone, ivory, and various metals, particularly brass, and is brought into this country from Holland, where it grows abundantly, and is sold in the shops of London under the name of Dutch Rush.

There are several other specimens of rush or Equisetum, but none so usefully applied as the species just noticed.

RUSHES. The well-known *rushes* of country places belong to a different genus of plants from the Dutch rush. They belong to the Genus *Juncus;* of which one species, the common soft rush, is to be found in most moist pastures, by the sides of streams, and under hedges. In some districts these rushes are used by the poor as a substitute for candles. They are gathered in summer and autumn; the largest and longest being deemed the best. They are kept in water until they are to be peeled; which process consists in divesting the rush of its peel or rind, so as to leave one regular narrow rib from top to bottom, to support the pith. The rushes are then bleached on the dewy grass, and dried in the sun. These rush-piths are finally dipped into any kind of fat or grease, until they acquire a coating analogous to that of a candle. In the bacon districts of Hampshire, hog's fat is employed for this purpose. When White wrote his well-known *Natural History of Selbourne*, he strongly recommended this feature in domestic economy; but it is possible that the cheapening of candles has lessened the relative advantage of the more primitive system.

Rushes are, however, more ordinarily used for plaiting into mats and chair-bottoms, and for constructing small toy baskets. The wicks of rushlights are made of the pith.

RUSSIA. This vast Empire ranks low in respect to produce, manufactures, and commerce, relatively to the vast area which it covers; but still it cannot fail to be important and even mighty when we consider at how many points it comes into near approach to fertile and prosperous lands. The 1,700,000 square miles of area in European Russia are far richer and more populous than the 4,800,000 square miles in Asiatic and American Russia, with the exception, perhaps, of the gold region of Siberia. Its great rivers (Volga, Dwina, Dniester, Don, &c.) place the heart of the Empire in communication with the White, the Black, the Caspian, and the Baltic seas; and as Russia is for the most part a level country, the extent of navigable rivers is most remarkable. The energetic Czars of the Empire have striven to make these water communications still more complete, by cutting canals from river to river at certain points. One such canal, for instance, connects the Volga with the Neva; another connects the Volga with Lake Ladoga; a third connects Lake Onega with the Neva; and a fourth connects the Volga with the Moskwa. The result has been that there is now continuous water communication from the Baltic and White seas in the North, to the Caspian and Black seas in the South; and an immense extension of mercantile traffic has taken place, by which the corn produce of the empire is conveyed to whichever sea will lead to the best market.

In respect to agricultural produce, Russia produces much more grain than is required for the home consumption; and considerable quantities are exported, especially rye. Wheat is the principal object of agriculture in the fertile tracts along the rivers in the southern districts, but especially in the Ukraine. Barley, oats, millet, and maize, are all cultivated. Flax and hemp are more extensively grown than perhaps in any other country in Europe; both the climate and the soil being very favourable to their cultivation. Tobacco is much cultivated in the Ukraine, whence it is exported to the neighbouring countries. The climate is not favourable to the cultivation of fruit-trees; but in the most southern districts there are peaches, apricots, quinces, mulberries, and walnuts; and in the numerous and extensive orchards of the Crimea there are also almonds and pomegranates. Grapes are grown in a few spots. Potatoes, cabbages, turnips, and carrots, are extensively grown; and in some places cucumbers, pumpkins, and radishes. Melons, asparagus, hops, and liquorice, are among the vegetable produce.

The forests constitute one of the principal sources of wealth to Russia; and their produce, consisting of timber, fire-wood, tar, pitch, pearl-ash, and potash, is exported to a large amount. About three-fourths of the countries between 65° N. lat., and the course of the Volga as far east as its great bend near Casan, are covered with forests. In all these countries only pine, fir, larch, alder, and birch are found, with a few lime trees; ash-trees are rare. From these countries is derived the greatest part of the produce of the forests which goes to foreign markets. The central provinces have in most cases no more timber than is required for their own use. West of the Dnieper several extensive forests occur on the banks of the Niemen and in the swamps of Pinsk and Ratnor. South of the swamps there are some forests of beech. The oak forests of Casan, Nischnei-Novgorod, Pensa, and Saratov, have engaged the attention of government, on account of their great importance for the navy. The southern provinces of Russia are almost without trees.

Russia contains minerals in great abundance. Gold is found chiefly in the Ural Mountains, partly on the European side, but mostly on the Siberian side. The produce in 1846 was as follows:—

Private Mining	1490 poods.
Public Mining	187 „
	1677 poods.

The total quantity obtained in 1847 was 1779 poods. The produce in the ten years 1837-46 was 8,387 poods of fine gold, which (at 36 lbs. avoirdupois = 1 pood) amounts to 366,931¼ lbs. troy, value nearly 19,000,000*l*. The produce seems, however, to be gradually diminishing; for the gold produce of 1848 was 1726 poods, and that of 1849 was 1587. Platinum was discovered in the Ural in 1823, and has been worked ever since; the produce in 1848 was 213 poods = 7668 lbs. Silver is met with only in the Asiatic governments. The quantity obtained in 1847 was 1190 poods. Copper and iron are extensively worked in the Ural, and in other places. Mercury, arsenic, nickel, cobalt, antimony, and bismuth, are met with, but are not much worked. Salt is found in various lakes, and a salt formation extends along the western declivity of the Ural Mountains, to the source of the Kama, and thence westward on both sides of the Uwalli. In all these districts salt is made from the salt springs, which are numerous. Coal exists in a few places, but not in large quantities. Other minerals are not much worked, with the exception of marble and granite.

The manufactures of Russia commenced, as in other countries, with the beginning of its political importance, but have been chiefly indebted for their encouragement and progress to the efforts of the government. The czars Ivan I. and II., who in the 15th and 16th centuries had restored Russia to independence, invited artisans and workmen from Germany, the Netherlands, and Italy, and established at Moscow, Yaroslaw, Smolensk, and Kiev manufactures of woollen cloth, linen, arms, &c. But the civil wars before the accession of the house of Romanoff, and the interference of Sweden and Poland, which led to the desolation of the country, checked the infant manufactures, so that in fact nothing was done till the reign of Peter the Great, who in this, as in many other respects, was the founder of the prosperity of Russia.

During the reign of the present Emperor the manufactures of Russia have increased to a remarkable extent. Smelting works, engineering works, cotton factories, woollen factories, tallow-melting works, tanneries, soap factories—all have increased most rapidly. The central part of the empire is the chief theatre of manufacturing industry. Moscow has become the focus of it; in the lesser towns of the government of which it is the capital, the number of manufactories continues to increase. Next to Moscow, in industry, are the governments of Vladimir, Nischnei-Novgorod, Saratov, and St. Petersburg.

The inland trade is carried on in a very great measure by means of annual fairs, the most remarkable of which is that of Nischnei-Novgorod. [FAIRS.] The number of these great commercial fairs is somewhat over twenty; but there is a still larger number of minor fairs and markets. The inland trade, as before remarked, is greatly promoted by the extensive system of inland navigation. The vessels which have arrived from the interior at the ports of Archangel, St. Petersburg, and Riga, have frequently amounted in the year from 2,500 to 3,500 barks. Goods destined for Odessa from the interior are carried down the Dniester or the Dnieper, and from the mouths of those rivers to Odessa by coasting vessels. Kherson, Astrakhan, Taganrog, Nakhitschevan, and Rostow, are the other chief ports.

The ships which enter and clear at the various Russian ports annually have an average tonnage of about 2,000,000 tons; of which those to and from Great Britain amount generally to nearly one half. The British trade at Russian ports in 1848 involved the use of —Inwards, 2,562 vessels; outwards, 1,916 vessels; together 969,572 tonnage, 41,613 men. The declared value of the British and Irish produce and manufactures transmitted to Russia in 1847 was 1,844,543*l.*; the following were the chief items:—Coals, 108,378 tons; woven cottons, 1,541,112 yards; cotton twist and yarn, 12,853,754 lbs.; earthenware, 345,421 pieces; hardware and cutlery, 7,676 cwts.; iron and steel goods, 15,732 tons; lead and shot, 1,764 tons; machinery and mill-work, 226,636*l.*; salt, 2,318,584 bushels; tin, 6,268 cwts.; woollens and worsteds, 57,720*l.*; ditto yarn, 1,727,850 lbs., = 189,014*l.* The value in 1849 was somewhat lower. The nature of the trade between Russia and Great Britain is indicated by the chief exports from the former to the latter in 1847, namely—Bristles, 1,278,570 lbs.; corn, 2,000,000 quarters; flax and tow, 681,167 cwts.; hemp, 542,857 cwts.; linseed, 353,900 quarters; tallow, 939,946 cwts; tar, 9,656 casks; timber, 220,000 loads; wool, 2,949,776 lbs.

The St. Petersburgh and Moscow Railway exhibits some remarkable commercial features. It was at first intended to order all the locomotives and machinery from England, as being the cheapest in the end; but an enterprizing American firm made such offers as induced the Emperor to enter into a contract with them. They were to have the use of certain machine works at Alexandroffsky, which were to be adapted for their purposes; they were to employ their own hands, on their own terms; but they were also to employ 500 serfs belonging to the Alexandroffsky Estate, whose services were to be paid for at a certain stipulated rate: they were to construct, at those works, 200 locomotives, 5,800 trucks, 70 passenger carriages, and other rolling stock, for which they were to be paid at stipulated prices; they had the privilege of importing coal and iron duty free; and they were to be paid once a month till all the works were finished. The whole was finished long before the railway itself was finished; and the Emperor expressed his satisfaction by a distribution of some of those orders and medals which form such a remarkable feature in the imperial proceedings. The Alexandroffsky works covered 160 acres, and at some periods employed nearly 3,000 persons—nearly all of whom were semi-serfs, who worked well if well directed. At the same establishment steam-engines have been made for the Siberian mines.

It is fitting that Russia should shew, at the World's Exhibition, to what point her producing and manufacturing skill has now attained.

RUST, in the common acceptation of the term, is the red pulverulent substance which is formed on the surface of iron when exposed to air and moisture. It is an oxide of iron.

RUSTICATED WORK, in Architecture, is a species of decoration for walls, wherein the joints between the courses, and between the separate stones in each course, are strongly defined by sunk channels or grooves. Rustication gives an appearance of solidity to the surface, and was frequently employed by the Romans. Italian architecture presents many examples of rusticated work, and there are several specimens among the public buildings of London.

RYE. This valuable plant bears naked seeds on a flat ear furnished with awns like barley. The straw is solid, the internal part being filled with a pith, which makes it valuable for litter, and still more so for thatching. The value of the straw is often nearly equal to that of the grain. Rye grows on poor light soils which are altogether unfit for wheat. It was formerly raised in considerable quantities in England, either alone or mixed with wheat, and was then called *Meslin*, from the old French word *meslé*, which means *mixed.* The meslin when ground produced a very wholesome and palatable household bread. Rye is at present raised in very small quantities in England.

In England rye is mostly sown as a green crop, and when fed off early in spring with sheep, the land is invigorated, and will bear excellent potatoes or turnips the same year.

The preparation of the land for rye is the same as for wheat, except that in very light soils no more ploughings are required than will clear the ground of weeds. If rye is sown after harvest, one ploughing only is usually given. It will thrive upon rich wheat soils, as well as upon lighter, and, as it throws out numerous stems in rich land, it is the more profitable as fodder, although the crop of grain might not be so abundant when the plants are too much crowded.

The Rye and Rye-Meal imported in the last three years amounted to the following quantities:—

	Rye.	Rye-Meal.
1848	62,635 qrs.	35,984 cwts.
1849	240,556 „	18,468 „
1850	94,078 „	966 „

S

SACBUT, is the name which was formerly given in England to the Trombone.

SACCHAROMETER, is an instrument used principally in the operations of brewing and making sugar. It serves to indicate the density of the liquid extracted from malt, or the degree to which the juice expressed from the sugar-cane is concentrated previously to undergoing the process of crystallisation; in other words it is a measurer of the sweetness of, or the amount of saccharine matter contained in, a liquid.

The saccharometer which is most commonly employed is made of copper, and differs in form from the hydrometer in common use only in its stem, which is six inches long, having four equal faces, each less than a quarter of an inch in breadth. Three of these faces are graduated, and the volume and weight of the whole are such that when the instrument is immersed in water it sinks till the top of the stem is but little above the surface. The line at which the surface of the water cuts the stem is marked as the zero of the scale; and the graduations are such that, when the instrument is immersed and floats upright in a vessel containing the saccharine matter, the number of the division at the surface expresses the density of the liquid by the number of pounds avoirdupois which ought to be added to the weight of a barrel of water, in order to show the weight of an equal volume of the liquid.

For the general purpose of determining the specific gravity of fluids, on the principle of the hydrometer and saccharometer, the best instrument is one which consists of a glass cylinder about seven inches long and three-quarters of an inch in diameter. It has at its lower extremity a stirrup, carrying a small cup in the form of an inverted cone, and its opposite part is drawn out so as to form a slender stem or tube, which is terminated at the upper extremity by a small cup. About the middle of the stem a mark is made, and, in order that the instrument may be enabled to float vertically in a vessel containing the liquid whose specific gravity is to be determined, a constant weight, which may be a ball of glass containing mercury, is placed in the lower cup.

SACK, is a Spanish wine of the dry kind; in French, *Vin sec;* and in some old English works it is called *seck*. There is a general opinion that sack was the same wine which is now named Sherry.

SAFETY LAMP. [Lamp, Safety.]

SAFFLOWER, or *Bastard Saffron*, is obtained from the *Carthamus tinctorius*. This plant has been cultivated in eastern countries from the earliest times, both on account of the oil expressed from its seed and for the colouring matter procurable from its flowers, which in their dry state form the Safflower of commerce. It is largely used to adulterate saffron. The oil of the seeds of *Carthamus* was valued by the ancients as a laxative medicine, and is still employed by the Asiatics for the same purpose, as well as for external application. It is most extensively used as a lamp-oil. The plant is however chiefly cultivated on account of its flowers, not only in China, India, and Egypt, but also in the south of Europe. The Safflower brought from China is the most valued, and fetches a much higher price than that from Bengal. The quantity imported into Great Britain in 1847 was 1,128 cwts.

SAFFRON consists of the dried stigmas of the *Crocus sativus*, a plant native of Greece and Asia Minor, but extensively cultivated in Austria, France, Spain, and also formerly in England. The Sicilian saffron is said to be the produce of the *Crocus odorus*, but both in ancient and modern times this sort has been little esteemed. England is chiefly supplied from France and Spain; that of Spain being preferred. In Germany however Spanish saffron is not in such repute as the Austrian, great pains being taken in the cultivation of the plant in that country. When the flowers expand, and are thoroughly open under the influence of the sun, the stigmas, of which there are three, are plucked out, a portion of one style remaining attached to them, and spread upon paper, to be dried either by means of portable kilns over which a hair-cloth or fine sieve is stretched, or in a room by the sun. The stigmas have a penetrating, aromatic, and, when in large quantity, stupifying odour, and a bitter aromatic taste; by mastication the mouth and saliva are rendered yellow. By long internal use of them many of the secretions acquire a yellow colour. According to Mr. Pereira, one grain of good saffron contains the stigmata and styles of nine flowers; hence 4320 flowers are required to yield one ounce of saffron. Saffron was formerly met with in two forms, Hay Saffron and Cake Saffron; the former is now alone in demand, the latter being entirely an artificial compound of the florets of the safflower, gum, and some other materials. About 10,000 lbs. of saffron were imported from France in 1847.

SAGAPE'NUM, is a medicinal substance yielded by *Ferula Persica*, which grows in Persia and other regions of the East. It is procured in the same way as assafœtida. It occurs either in tears or irregular masses, of a dirty brownish colour, containing in the interior white or yellowish grains. It is difficult to break (unless when very old), is tenacious, and not easily powdered, except in winter. It has a similar odour to assafœtida, but less powerful, with a nauseously bitter and acrid taste. It consists chiefly of resin, gum, and volatile oil. Its action on the human system is the same as that of assafœtida and other fetid gum-resins.

SAGO. This word signifies, in the language of the Papuas, *bread*, since it constitutes the staple article of food of the inhabitants of the Eastern Archipelago and other parts where the plants which yield it grow. It is not a seed, but the farina from the stem of several palms and palm-like vegetables. Sago is a variety of starch, prepared by the plant for the use of the flowers and fruit, and is most abundant just before the evolution or appearance of the flower-bud, which is known by a whitish dust transuding through and covering the leaves. At this time the stem is cut down near the base, and then divided into pieces of five or six feet in length. A part of the outer hard wood is then sliced off, and the workman, coming to the pith, cuts across the longitudinal fibres and the pith together, leaving a part at each end uncut, so that when it is excavated there remains a trough, into which the pulp is again put, mixed with water, and beaten with a piece of wood; the fibres, being then separated from the pulp, float at the top, and the flour subsides. After being cleared in this manner by several waters, the pulp is put into cylindrical baskets made of the leaves of the tree; and, if it is to be kept some time, those baskets are generally sunk in fresh water to keep it moist, for the pulp will keep long if preserved from the air, but if exposed it presently turns sour.

The quantity yielded by one tree is prodigious. Five or six hundred pounds are not an unusual produce for one tree; and as the vegetation still remains after being felled, a stem again springs up, which goes through the different stages of growth till it is fit for the axe.

The flour or powder is rarely imported, granulated sago being the state in which it is commonly brought to Europe. To bring it into this state from the flour, it must be moistened and passed through a sieve into an iron pot (very shallow) held over a fire, which enables it to assume a globular form. Thus all our grained sago is half baked, and will keep long. Of this granulated sago there are two varieties, the common or *brown* sago, and *pearl* sago. The latter is in small hard horny or semi-transparent grains, about the size of a pin's head; the former are in larger grains, about the size of the grains of pearl barley. Both are inodorous, and with an insipid taste. They swell in cold water, and are almost entirely soluble in boiling water, so as to form a thick starch-like solution, which may be used as a pudding, or prepared in other ways as an article of diet for children and invalids, if a farinaceous diet is required. 65,000 cwts. of sago were imported in 1848.

SAILS; SAIL MAKING. The principal sails of large vessels can be placed at right angles to the direction of the keel of the ship, and this position is given to them when the vessel goes before the wind; in other cases the same sails may, by means of the braces, be placed obliquely to the keel. The sails which are attached to the ship's stays, and the sails of boats or small vessels, are when supine in a vertical plane passing through the keel; a certain degree of obliquity to that plane may, however, be given to them at their lower extremities, if necessary.

When a vessel is in still water, the pressure of the wind against the sails overcomes its inertia, and motion takes place in some direction. The motion goes on increasing by the accelerative power of the wind, as the motion of a descending body is accelerated by the force of gravity; but at the end of a certain time the resistance in an opposite direction, both of the air against the sails and hull of the ship, and of the water against the latter, becoming equal to the accelerative power of the wind, the ship acquires a terminal or uniform velocity, and in this state (neglecting the resistance of the air) there may be said to be an equilibrium between the pressure of the wind against the sails and of the water against the vessel.

The management of a sail in a ship belongs to seamanship; but the manufacture of the sail itself is simply an industrial employment. The canvas used for sails is a very stout material, woven in England or Scotland from Russian hemp, and purchased in the form of rolls called *bolts*, each bolt containing about 40 yards of canvas 24 inches wide. There are six or seven different qualities of this canvas, according to the size and position of the sail to be made; and each quality has a particular number attached to it, and must have a certain weight per square foot. Thus, in the Royal Navy, a bolt of No. 1 canvas, containing 38 yards, must weigh 44 lbs.; whereas No. 7 weighs only about half as much: the intermediate numbers having intermediate weights.

As the canvas is only two feet wide, many breadths are required to form a large sail. The mainsail of an East Indiaman contains nearly 700 yards of canvas: while the whole suit of sails for such a ship requires as much as 9000 yards. As the sails vary much in shape, considerable tact is required in cutting up the canvas so as to avoid waste. The art of the sail maker consists not only in seaming up the numerous breadths, so as to give the requisite dimensions to the sail, but also in strengthening the sail by sewing rope to its edges. The seaming and sewing are effected with large three-sided needles, of seven or eight different kinds, which are threaded with sewing twine having from 200 to 400 fathoms to the lb. The skeins of twine previous to being used are dipped into a trough, containing melted tar, grease, and oil, which is afterwards dried. The sail-maker has a thumb-stall and a palm-thimble, for protecting his right hand. His stitches have a regulated degree of closeness, on which his rate of payment in part depends; there are usually about 100 stitches in a yard. The overlapping of the breadths is an inch or an inch and a half. Besides the seaming, sundry small pieces of canvas are stitched to the sail to strengthen it in various directions; and the edge rope or bolt rope is sewn on with great firmness. So skilfully is the canvas marked out and cut up by a master sail-maker, that in the 9000 yards for the forty sails of a large ship, there will not be more than three or four yards actually wasted.

The *Storm Sails* patented in 1844 by Mr. Archibald Trail are made in the usual manner, but are subsequently strengthened by sewing to their surface a number of canvas bands about an inch broad, with cords woven in them, such bands being secured at their ends into the bolt-ropes, or cords forming the boundaries of the sail, and carried diagonally across the surface of the sail at an angle of 45° with the seams, and at a distance of about three feet from each other. Two sets of bands are used, crossing the sail in opposite directions, one set being attached on each side of the canvas. By this simple contrivance the strain is so equalised as to render tearing less probable than with an ordinary sail; while, if any injury be inflicted, the rent is confined within the narrow limits of one of the diamond-shaped compartments into which the sail is divided by the protecting bands.

SAL AMMONIAC. [Ammonia.]

SALEP, *Salap*, or *Saloop*, is a nutritious article of diet, much valued in the East for its supposed general stimulant properties, but which is justly esteemed bland and nutritious, and well suited to children and convalescents. Salep consists of the tubers of different species of *Orchideæ*, which have been known in medicine from very early times by the name *Orchis*. All these plants have two tubers, charged with nutritious matter, and while one is nourishing the flower-stem and seeds of the current year, by which it is robbed of its store, the other serves as a reservoir for th flower-stem of the succeeding year. This last alone is fit for use. Both are dug up together, but the solid one only is retained. It is dipped in warm water, after which the fine brown skin is easily removed by means of a coarse cloth or brush. The tubers, being thus cleaned and peeled, are to be arranged on a tin plate, and then placed within an oven heated to the same degree as is necessary for baking bread; here they are to remain for seven or ten minutes, in which time they will exchange their opaque and milky whiteness for a semi-transparent horn-like appearance, and a yellowish colour, retaining their original bulk. Being then withdrawn from the oven, they are exposed during some days to dry and harden in the air; or by the employment of a very gentle heat, they may be brought to the same state in the course of a few hours: all that is then required to adapt the salep for food is to boil it in water (or milk) to the required consistency.

SALINOMETER. An instrument has been patented by Mr. How under this name, for measuring the degree of saltness in the water contained in the boilers of marine steam engines. When this saltness gets beyond a certain limit, it impedes the proper action of the boiler, and the salt water requires to be removed. Mr. How's apparatus consists of a small cylinder, open at the top, and having a stop-cock at the bottom. By means of this stop-cock water from the boiler can be admitted into the cylinder. An instrument on the principle of the hydrometer and saccharometer, but adapted to this especial purpose, is immersed in the saline water; and the degree to which its graduated stem will sink suffices to measure the saltness.

SALMON FISHERY AND TRADE. A few commercial statistics concerning salmon will be found under FISHERIES; and we will here append one or two more.

The London market receives its supply of salmon chiefly from Scotland—three-fourths from the river Tay. The Tay salmon sold at Billingsgate in recent years has been about 15,000*l.* annual value. A small quantity of Irish salmon reaches Billingsgate from Limerick and Cork; and a much smaller quantity of Severn and Wye salmon. A small quantity is also brought over from Holland. There seem to be indications that the salmon fisheries generally are declining, and the supply less than it was formerly—owing, as some persons think, to a somewhat reckless mode of fishing, by which the fish are not allowed time to arrive at maturity. Salmon is brought to Billingsgate in boxes. Of late years there have been sold annually at Billingsgate about 30,000 boxes, each containing seven salmon; or about 200,000 salmon. This is independent of the *pickled* salmon, brought to London in kits.

SALT; SALT TRADE. The chemical nature of this invaluable substance is noticed under SODIUM. We will here speak of its extraction and trade.

The principal part of the salt of England is made in the valley of the Weaver in Cheshire. When the salt duty was repealed in 1824, there were 75 works where salt was raised in a fossil state: 34 were at Northwich, 26 at Winsford, 3 at Middlewich, and 2 at Nantwich, all in Cheshire; 2 were at Shirley Wich in Staffordshire; 6 at Droitwich in Gloucestershire; and 3 in Durham. There were at the same time 35 works at which salt was made by evaporation from sea-water, 29 of which were in Hampshire and the Isle of Wight. In Scotland, at the same time, there were 15 salt works, and in all of them salt was made from sea water. At Droitwich alone 260,000 tons of salt are made annually from the brine springs of that town. A singular feud has recently existed in the town, owing to attempts made to prevent the brine from flowing to certain salt works. Nearly the whole of the salt exported is made in Cheshire, and is sent down the river Weaver, which communicates with the Mersey, to Liverpool. The Staffordshire rock-salt is chiefly exported from Hull, and that of Gloucestershire from the port of Gloucester.

The rock-salt of Cheshire was first discovered near Northwich, while searching for coal. It is found from 28 to 48 yards beneath the surface; the first stratum is from 15 to 25 yards in thickness, extremely solid and hard, and resembling brown sugar candy. Many tons at a time are loosened by blasting with gunpowder. Beneath this comes a stratum of hard stone, 25 to 35 yards in thickness; and then is encountered a bed of perfectly white and pure salt, 40 yards thick. There are also brine springs, which appear to have been formed by springs flowing over the beds of rock-salt, and becoming saturated with the saline particles; this brine is pumped up to the surface. The brine springs are from 20 to 40 yards in depth. The English table salt is almost entirely produced by evaporating this brine; but a considerable portion of that which is exported is rock salt. The evaporation was in former times effected by the heat of the sun, but artificial heat is now employed. So far as observation has yet gone, the English supply is practically inexhaustible; no limit is known to the extent of the beds or the springs; and it ought to be regarded as one of the blessings which we owe to the mineral wealth of our country that the beautiful table salt of England may be obtained at such an extremely low price as that now charged for it. One specimen of Northwich rock salt, weighing two tons, has been forwarded to the Great Exhibition.

About 70,000 tons of Cheshire salt are annually used by the alkali makers on the banks of the Tyne. It used to be conveyed round the Land's End and the south coast by ships; but it is now sent by canal and river to Liverpool, from thence to Maryport by sea, and from thence to Newcastle by railway.

A duty of 10*s.* per bushel was laid on salt in 1798, which in 1805 was increased to 15*s.* In 1823 this duty was reduced to 2*s.*; and in 1825 was wholly repealed. Salt used in the fisheries, in bleaching, or in agriculture, was nearly duty-free. The salt exported in 1849 amounted to 18,539,865 bushels.

The British government in India monopolises both the manufacture and sale of salt. In the ten years 1836-45, the net receipts from this monopoly of home salt, and duty on imported salt, varied from 989,389*l.* to 1,707,287*l.* annually. It is believed that a moderate duty on British salt would yield as large a revenue in the course of a few years, if the monopoly were abolished, while commerce would be benefitted by the interchange of East India sugar and other native commodities for British salt; smuggling in salt, which is extensively carried on, would cease; and in place of arbitrary and harsh restrictions, the consumer would obtain a better article at a cheaper rate.

SALTPETRE. The chemical nature of this valuable substance is explained under POTASSIUM. About 14,000 tons of saltpetre were imported in 1850.

SALTS. The term Salt, originally restricted in its application to common salt, which it still means when used merely by itself, is now applied to a vast number of substances which have in many cases few properties in common. Common salt is the principal of a class composed of a metal and such bodies as chlorine, iodine, bromine, and fluorine, and the radicals of the hydracids. It was formerly believed that common salt was a compound of muriatic acid and of soda; and hence it was very commonly called muriate of soda. But it has been shown by Davy that salt is really chloride of sodium. The *Oxy-Salts* form another numerous and important class of compounds: these are formed when an oxacid is made to combine with an oxidised base; as, for example, when sulphuric acid unites with soda, the result being sulphate of soda. The sulphate of potash, lime, magnesia, &c., are similarly constituted.

In general properties the various classes of salts, and indeed the individuals of the same class, differ as widely as possible; some are crystallisable, others uncrystallisable; they are colourless, and of various colours; sapid and insipid; soluble and insoluble in water, alcohol, and other menstrua; volatile and fixed in the fire; decomposeable or undecomposeable by the same re-agent.

SALVADOR, SAN, or BAHIA, formerly the capital of Brazil, is still one of the greatest commercial ports of that empire. The bay presents a capacious basin with several islands and harbours, a depth of water varying from 8 to 40 fathoms, and ample room and shelter for all the fleets in the world. Three roads lead from Bahia to the interior of Brazil, by which the foreign goods reach the places of consumption, and the produce of the country is brought to market. The exports consist of sugar, cotton, coffee, tobacco, cigars, rice, rum, molasses, tallow, hides, horns, cocoa-nuts, fancy woods, bullion, &c. For the year ending September 30, 1849, Bahia exported 62,000 cases and 9925 bags of sugar; 19,500 bales of cotton; 20,238 bags of coffee; 82,866 hides; 9554 pipes of rum; and 10,901 bales of tobacco. The imports consist of different kinds of cotton fabrics, woollen stuffs and cloth, linen, iron and tin ware, provisions, flour, salt, fish, soap, wines, codfish, leather, furniture, &c.

SAMPHIRE, is a herb in much request in some parts of the country as a salad and pickle. The true samphire is the *Crithmum maritimum*, a plant belonging to the natural order *Umbelliferæ*. It grows on rocks by the sea-side. The species of *Salicornia* are often called samphire, and are used in the same manner, but they are very much inferior to the *Crithmum* as an article of diet.

SANDAL WOOD. This wood, yielded by one or more species of *Santalum*, is well known both in commerce and the arts as a fragrant-smelling wood. It is used as incense, and is also employed in the manufacture of necklaces, fans, elegant boxes, and cabinets. There are three kinds known, the white, the yellow, and the red. The last is the *Sanders' wood* (as it is often called) of commerce, which is used only as a dye wood and as a slight astringent in medicine. The white sandal tree, when felled, is barked, cut into billets, and buried in a dry place; the deeper the colour and the nearer the root, the more fragrant it is. As seen in commerce it is in compact pieces of a white colour and agreeable odour, but with little taste. The Chinese manufacture various articles with the yellow sandal wood, which is the most fragrant; they also burn it in their temples and private houses as an incense, and especially in the form of long slender candles, which are formed by covering the ends of sticks with the sawdust of sandal wood mixed with rice paste.

About 200 tons of sandal wood are annually imported into Calcutta from the Malabar coast, and about twice as much into Canton from the islands of the Indian Archipelago. The red sandal or sanders wood is imported in large billets, which, when fresh, are of a brilliant red colour, but which gradually deepens by exposure to air; it takes a very fine polish, and somewhat resembles Brazil wood.

SANDARAC. Although usually called a gum, sandarac does not possess the requisite characteristics; it consists of a mixture of two different kinds of resin and a little volatile oil. It exudes spontaneously from the bark of certain large trees which grow in Morocco; it concretes in irregular drops or masses on the surface, of a yellowish colour, and semi-transparent. A powder forms on the surface, which constitutes *pounce*. The sandarac easily melts and ignites, and emits a somewhat powerful odour. It is used for the preparation of varnishes; also occasionally for incense or pastiles, plasters, and ointments. Sandarac is sometimes used to adulterate mastic; and it is itself occasionally adulterated with a cheaper substance.

SANDIVER. This name is given to the saline scum that swims on molten glass when the ingredients first combine into a homogeneous mass. It is called by the French *sel de verre*, or *glass salt*. It is occasionally used as a tooth powder.

SAÔNE. The river Saône in France gives name to two departments, each of which presents a few interesting features connected with industry.

In *Saône-et-Loire* about 18,000,000 gallons of wine are made annually; the best kinds are those grown near Romanèche in the arrondissement of Mâcon, near which there is also the richest manganese mine in France. The department contains one of the richest coal fields in France. Fifteen mines are worked; and in their neighbourhood are numerous iron works, the ore used in which is partly mined in this district, but most of it is the produce of distant mines. At Creuzot, where iron and coal mines are worked, is one of the most important iron works in France, and great foundries in which cannon, anchors, steam machinery, mill castings, &c., are manufactured. There are large forests of oak, elm, beech, and fir, in the Morvan and Cévennes ranges, and in several other districts; in the eastern division of the department the forests contain also maple and poplar. To the industrial products of the department already mentioned are to be added steel and steel ware, glass bottles, copper ware, paper, beet-root, sugar, pottery, bricks, cotton cloth and yarn, linen, leather, felt hats, drugget, plaids, wine casks, oil, flour, &c.

In *Haute Saône* the mountainous regions abound in forests of oak, fir, beech, ash, &c., and are covered in many parts with good summer pasture. Minerals are abundant, including red and gray granite, green and violet porphyry, freestone, lithographic stone, grindstone, gypsum, white sand used in glass factories, limestone, marble, and iron. Several iron and coal mines are worked. Vast quantities of cherries for making kirschwasser are cultivated. About 8,000,000 gallons of inferior Burgundy wine, are made annually. The chief industrial product is iron, in the various forms of pig, bar, sheet, tin plates, steel, wire, or articles of ironmongery. This manufacture is carried on in about 60 forges, furnaces, and foundries. The other industrial establishments include glass-works, potteries and brickfields, distilleries, tan-yards, cotton mills, paper-mills, dyehouses, oil mills, &c. Straw and felt hats, hosiery, drugget, and hempen cloth are also made; and there is good trade in corn, flour, hay, timber, oak staves, deals, butter, cheese, salt and cattle.

There is one remarkable establishment in this department which deserves notice. It is the corn mill belonging to M. Tramoy, at Gray. This mill, which is of elegant construction, and the finest establishment of the kind in France, is driven by a current drawn from the Saône. It contains eleven water wheels, which drive eleven pairs of stones and a saw mill; and by ingenious mechanical contrivances, all the various processes in the grinding, sifting, and lifting of the greater part of the surplus corn of five adjacent departments ground in this vast establishment, are performed with the help of only fifteen workmen. The flour from these mills enters largely into the supply of Lyon and Marseille, whither it is conveyed by barges down the Saône and Rhône.

SAPAN-WOOD. This dye-wood is yielded by a species of *Cæsalpinia*, which grows in India and the Indian Archipelago. The wood has been used as a dye-wood from very early times in India, and is described as a medicine in Persian works. It found its way into Europe some time before the discovery of America, and it still continues to be imported. Its colouring matter differs little from that of Brazil Wood; but the best Sapan Wood does not yield more than half the quantity that may be obtained from an equal weight of Brazil Wood, and the colour is not so bright.

SAPINDUS, or *Indian soap*, is a plant, the berries of which are used for soap in many parts of Asia. In the East Indies several species yield berries which in their dried state may be bought in every bazaar, as they are everywhere employed as a substitute for soap. The fleshy part of these berries is viscid, and in drying assumes a shining semi-transparent appearance. When rubbed with water, they form a lather like soap. This is owing to the presence of a principle called by chemists *Saponine*, which is often united with an acrid principle, whence these berries are said to injure cloth which has been much washed with them. The bark and root have similar properties, and have been employed for the same purpose, as well as medicinally, in the countries where they are indigenous. The berries, which are about the size of cherries, enclose black shining nuts. The kernel of these nuts contains an edible oil, which is sometimes employed for burning. The fruits of some species are eaten, and the wood of others, which is close grained and hard, forms valuable timber.

SAPPHIRE. [CORUNDUM.]

SARCO'PHAGUS is the name given to the Egyptian stone coffins. These coffins consist of two parts, a case formed of one piece, and open at the top, in which the mummy was to be deposited, and a lid to cover the top. As these sarcophagi are generally of hard stone, and often extremely hard, the working of them must have been very expensive, and they could only have been made for kings and very rich persons. There are some fine specimens in the British Museum.

SARDINIA. This large Mediterranean island is well provided with forests; the best timber is in the mountainous districts. The cork tree grows very large and in great quantity in the northern part of the island. Timber is very scarce in the plains, and the want of roads prevents the people from making use of that of the mountain forests. Dwarf mulberry-trees grow in abundance. The vine is extensively cultivated, both soil and climate being highly favourable to it; and though the process of making wine is still very imperfect, Sardinia produces some excellent wines. *Malvasia*, or *Malmsey*, and *Muscat* are both Sardinian wines. There are several extensive olive-grounds, but the oil has not yet been largely exported, although this branch of commerce is on the increase. Cheese is a great object of rural economy; it is made chiefly from sheep and goats' milk, and being steeped in brine it has a salt bitter taste. Little butter is made, as the treatment of cows is not well understood, and fodder is scarce. Tobacco is grown in some districts, and is a royal monopoly. Salt is a monopoly of the government, and a profitable branch of the royal revenue. The salterns are round the gulf of Cagliari, at Oristano, Terranova, and on the northern coast west of Porto Torres; they are worked by convicts sentenced to the galleys, but the excavation of the mounds and the carriage of the salt is a labour forced on the adjacent villagers, for which they receive a small compensation. Flax is cultivated to a small extent, and is woven into linen. Wool is coarse, owing to the flocks being neglected, and it is manufactured into coarse cloth for the peasantry. A better quality of cloth and fine flannel are made of lambs' wool.

The fisheries of Sardinia are very productive, especially the establishments for taking the tunny fish, which are on various parts of the coast. The fishery lasts from April to July. Most of the tunnies weigh from 100 to 300 lbs.; and all the parts of the fish are turned to account, most of them being salted. Most of the tunneries are let to foreigners, who ship off the produce to various ports of the Mediterranean, and a comparatively small proportion is used in the island. There are fisheries of anchovies, sardines, coral, and pearls off the coast. The coral is polished and worked into necklaces, earrings, and other ornaments, at Genoa, Leghorn, Marseille, and Naples. The pearls are of inferior quality.

Sardinia was noted in ancient times for its mines, which were worked to a great extent, as is attested by vast excavations and remains of foundries. Gold and silver mines were at one time worked. Mercury, iron, and lead are met with in various parts. In the eastern mountains are found porphyry, basalt, alabaster, and marble. Chalcedonies, jaspers, carnelians, sardonyx, turquoises, and rock crystal, are found in the mountains of the west.

When we speak, in England, of the king of Sardinia, we allude to a kingdom which includes much more than the island of that name; it includes Sardinia, Savoy, Piedmont, Genoa and Nice, all of which are now under one king. The Continental States of the king of Sardinia have several fine carriage roads across the Alps and Apennines, which intersect their Territory. The plains of Piedmont are well supplied with canals, chiefly for the purpose of irrigation. The staple products for exportation are silk, rice, hemp, wine, and oil. The principal manufactures consist of paper, silks, woollens, linen, glass, and cotton yarn. The importation of colonial articles and English manufactures takes place chiefly through the port of Genoa. A considerable trade is carried on with Switzerland and Germany by the Lago Maggiore and the road of Mount St. Bernard leading to the Grisons. The commerce of the three principal ports of the Sardinian States, Nice, Genoa, and Cagliari, is illustrated by the following statement for 1846:—

Ships which entered and declared at

	Vessels.	Tons.	Crews.
Genoa	4692	576,705	39,743
Nice	5192	309,399	32,270
Cagliari	724	79,918	6,711
	10,608	966,022	78,724

The exports of British produce and manufactures to the Sardinian States in 1848, amounted in value to 611,992*l.*; besides the produce and manufactures of other countries. The imports from those states into England consist chiefly, (and indeed almost entirely) of silk.

SARDONYX. [AGATE.]

SASSAFRAS. The species of this genus of plants most known is the Sassafras Laurel, an inhabitant of the woods of North America, from Canada to Florida. It is mostly a small tree or bush, but sometimes attains the height of forty or fifty feet. In America the Sassafras is divided into two varieties, the red and white. Its great use is for medicinal purposes. It is however employed in America for making bedsteads and other articles of furniture, which are not liable to the attacks of insects, and give out a very agreeable odour. The root of the Sassafras Laurel is the official part in the London Pharmacopœia; but the whole plant possesses the aromatic odour common to the Laurels; and some assert that the bark of the stem and branches is stronger than that of the root; but this seems to be an error. The taste is sharp, acrid, aromatic, and, as well as the odour, resembles fennel. A kind of chocolate, called *Sassafras Chocolate*, is made from the nuts of the sassafras tree, to form a beverage for invalids.

SATIN. [SILK.]

SATIN SPAR is a whitish, fibrous, translucent mineral, which occurs at Alston Moor in Cumberland, and in North America, in tabular masses of an inch or two in thickness, in veins in slaty clay and shale. It consists chiefly, if not altogether, of carbonate of lime.

SATINWOOD. This beautiful wood is obtained from an East Indian tree called the *Chloroxylon Swietenia*. It is of a deep yellow colour, remarkably close grained, heavy, and durable, and comes nearer to box wood than the produce of any other tree. An essential oil, called *wood oil*, is obtained from the satinwood tree.

SATURATION. When common salt, or indeed most other saline and many vegetable bodies, are added to water until it ceases to dissolve them, the solution so obtained is termed a *saturated solution* of the substance dissolved. Saturation may exist with regard to one body and not to another. Thus water saturated with common salt will still dissolve sulphate of soda, and vice versâ; so also a saturated solution of common salt will dissolve sugar. There are many other cases in which the point of saturation may be determined by the cessation of solution; while there is a third class in which saturation cannot be determined by insolubility; as when both bodies are employed in a fluid state, or when the excess of a solid body is soluble in the water which holds the saturated salt in solution. The saturating power of bodies is in many cases greatly influenced by heat, while in others variation of temperature produces but little effect; thus cold water will take up nearly as much common salt as hot water; but sulphate of soda is more soluble in hot water than in cold.

SAW MANUFACTURE. Saws were used by the ancient Egyptians; a specimen, found among the tombs of Thebes, is deposited in the British Museum. There is a picture among the remains discovered in the ruins of Herculaneum, representing the interior of a carpenter's workshop, with two genii cutting a piece of wood with a frame-saw; and on an altar preserved in the Capitoline Museum at Rome there is a perfect representation of a bow-saw, exactly resembling, in the form of the frame, and the twisted cord for tightening it, those used by modern carpenters.

Saws are of various forms and sizes, according to the purposes to which they are to be applied. The *Cross Cut Saw* is used for dividing logs transversely. The *Pit Saw*, a long blade of steel with large teeth, and a transverse handle at each end, is used for sawing logs into planks or scantlings. The *Frame Saw* is a blade from five to seven feet long, used in a similar manner to the pit saw, but it causes less waste, because the blade, being stretched in a frame, may be made much thinner. The *Ripping Saw*, *Half Ripper*, *Hand Saw*, and *Pannel Saw*, are saws for the use of one person, the blades tapering in width from the handle. *Tenon Saws*, *Sash Saws*, *Dovetail Saws*, &c., are made of very thin blades of steel, of equal width throughout their whole length, and stiffened with stout pieces of iron or brass fixed on their back edges. *Compass Saws* and *Key Hole Saws* are long narrow saws, tapering from about an inch to an eighth of an inch in width, used for making curved cuts. Small *Frame Saws* and *Bow Saws*, in which very thin narrow blades are tightly stretched, are occasionally used for cutting both wood and metal. Saws are made for cutting bone, iron, brass, and many other hard substances.

The very commonest kind of saws are made of iron-plates, hammer-hardened, and planished upon an anvil, to give them some degree of stiffness and elasticity. The more useful saws are made either of shear or cast steel. The steel, reduced to thin sheets, is cut into pieces of suitable size and shape. The edges are perfected by filing, and holding the flat sides of the plates against large grindstones, which process prepares them for the cutting of the teeth. This operation is usually performed by a die-cutter in a fly-press, the motion of the saw-plate being duly regulated, so that the teeth shall be uniform; the larger teeth being cut one at a time; and the smaller, two, three, or more at a time, according to circumstances. The wire edges left on the teeth by the cutting-out press are removed by filing, after which the plates undergo the processes of hardening and tempering. The next operation is planishing by hammers, to make them more even and equally elastic; after which the saws are ground on large grindstones. The plate is held against the circular face of the stone by an interposing board, against which the grinder presses with all his force, in order to grind it as evenly as possible. He stands on tip-toes, stretching over the stone, which revolves with great rapidity; his hands, arms, breast, and knees being all brought into action to produce the desired effect. As this grinding impairs the flatness and elasticity of the saw-plates, they are submitted to a second hammering by the planishers, and their elasticity is restored by heating them over a coke fire until they attain a faint straw colour. The marks of the hammer are removed by again passing the saws lightly over a grindstone, after which the final polish is given by a fine hard stone, a glazing wheel covered with buff-leather and emery, or a wooden wheel, called the *Hard Head.* After being cleaned by women, the saws are handed to the *Setter*, who lays each alternate tooth over the edge of a small anvil, and strikes them so as to bend each uniformly into a slight deviation from the plane of the saw, and then, turning the saw-plate, he sets the remaining teeth in like manner, but in the opposite direction: sometimes peculiar tools are used for this setting. After being set, the saw is placed between two plates of lead, in a vice, and the teeth are sharpened with a triangular file. The size, form, and sharpness of the teeth, vary according to the purpose to which the saw is to be applied. The handles are then fixed on by nuts and screws, and the saws cleaned off, oiled, and packed in brown paper for sale.

Saws for cutting stone are without teeth, although they are sometimes slightly notched upon the cutting edge, that they may collect and retain the particles of sand that are conducted into the cut by a small current of water, and by the attrition of which the effect is mainly produced. The saw plate is tightly stretched in a kind of rectangular frame, of which it forms the lower side; and the frame, being suspended by ropes, is moved backwards and forwards by one or two men.

The saw manufacture is one of the most interesting departments of the industry at Sheffield. Saws are made in that town to an immense extent.

SAW MILLS. Although saw mills have not been very generally introduced till within a few years, they are by no means of recent origin. They were used in England in the 17th century, but not without great opposition. Many of the earlier saw mills were driven by water, and those of North America are still generally worked by that power.

The earliest kind of sawing-machinery was, in its essential features, the same as that still used for sawing logs of timber into planks. In this machine the saws are stretched in a frame which slides up and down on vertical guides; the reciprocating motion being imparted to the frame by a crank upon an axle turned by a connection with the water-wheel or other prime mover. The log is supported on a carriage resting upon rollers, and is made to advance a little at each stroke of the saws, which cut during their descent only. The saws are usually either six or eight in number. Attempts have been made to introduce sawing machines with two sets of saws, one of which should cut upwards; but they do not appear to have succeeded. A similar effect is sometimes produced by connecting two machines with one axle; the cranks being so adjusted that one saw-frame descends while the other rises.

The balks of timber to be divided into planks, of which two are generally operated upon simultaneously, are supported by rollers, and secured at the ends by suitable fastenings to a long iron carriage. This carriage is so connected to the saw frame by wheel and pinion work, that the carriage and balks of timber are propelled forward as fast as the wood is cut. In order to keep the balks of timber steady during the cut, their inner sides slide against polished steel plates fixed to the frame work of the machine, against which they are pressed by rollers.

The loss of power occasioned by the reciprocating motion of a long saw, has led to the adoption of *Circular Saws*, which, by revolving constantly in one direction, require less power, and may be driven with far greater speed than reciprocating saws; while their continuous action not only expedites the operation of sawing, but also makes the motion of the machinery more uniform. Perhaps the most interesting kind of circular saw is that used for cutting logs of hard wood into veneers. The late Sir M. I. Brunel, to whom England is indebted for many valuable improvements in this class of machinery, took out a patent in 1806 for a method of constructing very large circular saws, by attaching several pieces of steel plate to a flanch of iron turned perfectly true. In this way saws have been made of as much as 18 feet diameter; but such large saws can only be used for cutting veneers or very thin boards, which will easily bend so as to pass the flanch of the saw, which is necessarily of considerable thickness. In the principal room for cutting veneers at the City Saw Mills, London, there are eight saws varying from 8 to 17 feet diameter, and revolving from 70 to 90 times in a minute. By the largest saws logs of mahogany 3 feet square can be cut up into unbroken sheets of veneer, at the rate of about 10 to an inch, and so beautifully smooth as to require scarcely any dressing.

For cutting thinner boards, the circular saw is usually mounted in a bench or table, under which the axle passes, and having a slit or opening through which the upper part of the saw projects. The piece of wood to be cut is laid on the smooth surface of the table, and pushed towards the saw by hand. Small circular saws, so mounted, are often moved by means of a treadle and crank, and by a variety of ingenious modifications may be applied to many useful purposes.

In the beautiful and ingenious block machinery erected at Portsmouth, by Brunel, circular saws are extensively applied. [BLOCK MACHINERY.

Mr. Eastman, of the United States, patented some curious modifications of sawing machinery about 1824. He found that when a circular saw is propelled with great velocity, it will cut much more smoothly and easily if it have only a few teeth placed at equal distances round its circumference than if, as usual, its periphery be full of teeth. He made a saw which had four cutting instruments called section teeth, each consisting of two teeth resembling a hawk's bill in form. The saving of labour as compared with a common saw is estimated at full three-fourths, and it is stated that, when driven at a proper speed (which is from a thousand to twelve hundred revolutions per minute), it will cut nine or ten inches in depth into the hardest white oak timber with the greatest ease. Mr. Eastman contrived these saws for cutting up timber in an ususual way, not through the log, but from the circumference to the centre; so that the cuts form the radii of a circle, and the planks or boards produced are thicker at the outer than the inner edge. The boards cut by this machinery are much used for covering buildings.

SAXE; SAXONY. The numerous German states thus designated, present various degrees of industrial and commercial developement. We will rapidly glance at them in relation to these features.

Saxe Altenburg is hilly, richly wooded, and fertile. Agriculture and grazing are skilfully conducted. There are few minerals; but there are iron-mines in the vicinity of Ronneburg, and the extensive peat-fields near Altenburg yield abundance of fuel. A fine porcelain earth is found in the neighbourhood of Altenburg, which supplies the porcelain manufactory at Gotha. Manufacturing industry is chiefly confined to woollen cloths, stockings, and wooden wares. There are considerable tanneries at Altenburg, Kahla, Eisenberg, and Lukau. The articles of export are corn, cattle, wool, butter, and timber.

Saxe Coburg Gotha is chiefly an agricultural duchy. The forests yield timber, potash, and pitch. The rearing of live-stock is prosecuted with much activity. Iron is found near Friederichsstadt; there are also coals, sandstone, millstones, marble, alabaster, gypsum, lime, potters' clay, porcelain earth, and salt. There is considerable manufacturing industry in Gotha, but little in the other districts. Besides a fair amount of export trade, the duchy has a considerable transit trade, as the high road from Leipzig to Frankfort passes through it.

Saxe Meiningen has salt springs near Friedrichshall and Neusulza. The productions are similar to those of central Germany; the minerals are various and abundant. Agriculture and grazing are the chief employments. In some districts there are many furnaces, mills, and glass-houses. The ordinary manufactures are coarse linens, sail-cloth, woollens, and cottons; there are also distilleries, breweries, and tan-yards. The wooden toys made in this duchy are largely sold in England.

In *Saxe Weimar* the mineral and vegetable productions are similar to those in the other Saxon duchies. The rearing of cattle forms an important branch of industry. Manufactures have made little progress.

Saxony, being a kingdom and of much larger size, has more manufacturing and commercial importance than the duchies just named. The vegetable produce, besides corn, includes rape-seed, hops, flax, hemp, chicory, tobacco, madder, wood, saffron, medicinal herbs, anise, coriander, poppy, &c. Vegetables and fruit are very abundant. A considerable quantity of wine is made. Almost a fourth part of the country is covered with forests, consisting chiefly of pine and fir; other trees are less abundant.

The breed of cattle has been very much improved within the last century; but the most important animal is the Merino sheep, which has since 1765 yielded a supply of the finest wool. The mineral riches consist of gold, copper, iron, lead, tin, cobalt, arsenic, vitriol, bismuth, nickel, zinc, antimony, quicksilver, calamine, rock crystal, various precious stones, potters'-earth, the finest porcelain clay in Europe, basalt, serpentine, granite, marble, alabaster, fluor spar, sandstone, limestone, slate, porphyry, black amber, brimstone, alum, saltpetre, and coals.

Next to England and the Netherlands, Saxony has, in proportion to its population, the most extensive manufactures in Europe. It produces damasks and other linens, lace of great beauty, woollen, cotton, and silk manufactures; and there are paper-mills, tanneries, breweries, distilleries, foundries, and the celebrated porcelain works at Meissen. The centre of the commerce of the country is Leipzig. The inland trade is mostly conducted by the merchants of Leipzig, of which the book fairs are the most remarkable. The principal exports are—fine woollen manufactures to England, Spain, Turkey, and Russia; linen, lace, &c. to Italy, England, Spain, and France; thread, wool, worsted, smalts, porcelain, straw-manufactures, wooden-wares, glass, fruit, timber, and mineral products. The imports are salt, cotton, silk, flax, hemp, colonial produce, salt and dried fish, fancy goods, &c. Saxony is one of the members of the Zollverein or German Customs' Union.

Prussian Saxony, another member of the remarkable Saxe territories, is an active and busy province. The fine wool of the improved breed of sheep supplies not only the extensive woollen manufactures of the province, but furnishes a large overplus for exportation. The mineral products are chiefly copper, antimony, cobalt, and iron. The manufactures are woollens, leather, calico, and linen. There are several sugar-refineries, brandy-distilleries, tobacco-manufactories, and porcelain works. The exports are wool, corn, woollen and cotton manufactures, brandy, copper, iron and steel wares, and salt.

SCAFFOLDING. In ordinary buildings the scaffolding requires very little notice. Poles are erected in a vertical position a few feet from the walls, their lower ends being inserted in the ground. Wherever a platform is required for the workmen, a horizontal pole is tied to the uprights, parallel with the wall; and from this horizontal pole cross-pieces extend to the wall, into which their ends are received, to support a flooring of planks. As the building rises, the scaffold is strengthened by diagonal poles; and the several poles are fastened by ropes.

In the erection of important buildings of stone, a very convenient kind of scaffold has been recently adopted, consisting of large squared timbers well framed together, and terminating at the top in horizontal beams. Such a framing is erected on each side of the wall, unconnected with it, and rails are laid on the top beams, on which runs a carriage, capable of being moved by means of a winch-handle connected with the wheels. The carriage itself consists of a frame supporting another railway at right angles with that on which it runs; and on the upper railway is a smaller carriage, which supports tackle suitable for raising the stones. By this arrangement a stone may be lifted up, and moved, by the combined action of the two railways, to any point required on the wall.

In bridge building and similar works, the *centering* of arches is a peculiar kind of scaffolding; it is the wooden support or mould on which the arch rests while building. A centering usually consists of a number of distinct frames, resembling the trusses of a roof, placed equidistant from each other in vertical planes, and covered with a series of planks or beams of timber called bridging-joists, laid at right angles with the frames or trusses. This boarding or covering of bridgings forms a convexity coinciding with the internal concavity of the intended arch. For small arches the centering is usually covered with planks; but in large works bridging-joists, one laid for each course of arch-stones, are preferred, these being kept at the proper distance apart by blocks placed between them. The whole structure is stiffened by crossbars to keep the trusses equidistant and parallel to each other.

Mr. Hughes has invented a scaffolding, which he used for repairing the interior of a dome at Manchester. It consists of a vertical pole erected in the centre of the dome, to which is connected a framework, supporting a kind of ladder, corresponding with the form of the interior of the dome, and mounted on wheels, so that it may be moved round to any part of it, the vertical pole serving as an axis. Mr. Slacks, a mason, has invented a scaffolding for building an obelisk without scaffolding of the ordinary description. This simple and ingenious machinery was used in erecting an obelisk of sandstone, 100 feet high, not including the foundation, on the summit of a mountain called Whitaw, in Dumfriesshire, in honour of the late Major-General Sir John Malcolm. The Society of Arts rewarded the inventor with their gold Isis medal in 1837.

The finest scaffolding ever invented, perhaps, is that which now surmounts the Victoria tower at the New Houses of Parliament. It is made to travel upwards as the work progresses; and it revolves on a central axis, so that four extended arms of scaffolding may be brought over every part of the tower in turn.

If the scaffolding just mentioned is the most complete, perhaps that by which Messrs. Fox and Henderson have built the Crystal Palace is the most simple—so simple, indeed, that it can hardly be called a scaffolding; it is rather a system of ropes and pulleys.

SCAGLIO'LA, is an incrustation of artificial composition which is applied to columns, and produces the most perfect imitation of marble, from which it can hardly be distinguished either by the eye or the touch, as it takes an equally high polish and feels equally hard and cold. Scagliola has long been in use in Italy; but it was not introduced into this country before the latter half of the last century. The earliest application of it was in the columns of the Pantheon, in Oxford-street, London, built by James Wyatt. The composition or cement itself is prepared from the purest gypsum, which is first broken into small pieces, and after being calcined is reduced to powder. It is then passed through a fine sieve, and mixed with Flanders glue, isinglass, &c. In this state it is mixed up with colouring matter of the hue required.

SCANTLING, is a term used to express the transverse dimensions of a piece of timber; and also, in some cases, as a general name for small timbers, such as the quartering for a partition, rafters, purlins, or pole-plates in a roof, &c. All quartering or squared timber under five inches square is designated scantling. In masonry the same word is used to express the size of stones in length, breadth, and thickness.

SCARFING, is the name which carpenters give to the mode of joining two pieces of timber end to end, in such a manner that they may appear but one, and cannot be pulled asunder by a force applied in the direction of their length, without breaking off part of the wood at the joint. The scarfed pieces are usually bolted together; but there are various modes of forming the junction.

SCARIFIER. There are instruments used in agriculture, to which the names *scarifier*, *scaffler*, and *cultivator* are applied; and indeed other names have been also applied to them, according to slight modifications of form and action. All these instruments have a number of teeth or tines which, when the instrument is drawn forward, furrows and loosens the soil. One such is called the *Thirteen-hoed* scarifier, in which there are two large wheels for the movement of the machine, two handles behind to guide it, and thirteen hoes or tines to enter the soil. Another kind, *Williams' wrought iron scarifier*, has one small wheel in front, two small wheels behind, two handles for guidance, and seven tines.

SCARLET DYE. The finest scarlet dye is obtained from cochineal. [COCHINEAL.] According to Berthollet the dyeing of scarlet is performed at two operations; the first is called the boiling (*bouillon)*, and the second the *reddening*.

For a boiling intended to dye about 100 pounds of cloth, six pounds of bitartrate of potash (cream of tartar) are first thrown into water a little more than lukewarm; after the bath has been well stirred, and become a little hotter, half a pound of powdered cochineal is thrown in and well mixed. Immediately afterwards five pounds of clear solution of chloride (muriate) of tin are poured in and carefully mixed. As soon as the bath begins to boil, the cloth is introduced, and made to circulate rapidly two or three times; when it has been subjected to a boiling heat for two hours, it is removed and well washed.

For preparing the second bath, which is the *reddening*, five pounds and a half of powdered cochineal are put into a boiler, as soon as the water which it contains is about to boil, and after being properly mixed, fourteen pounds of solution of chloride of tin are added, and the cloth is thrown in, rapidly whirled for a short time, then boiled for an hour, taken out, cooled, and washed and dried.

SCENE-PAINTING, for the theatre, is executed in *distemper*, that is, with colours mixed up with size, the design being first sketched, and accurately laid down to scale, from which the perspective outlines are transferred to the larger surface. Instead of beginning with dead colouring and then gradually working up his picture, the artist puts in all his effects at once (as in fresco-painting) —the full tone of the lights and shadows finishing as he proceeds, and merely retouching those parts afterwards which require additional depth or brilliancy. It is important that the scene-painter should not only be well skilled in architectural delineation, but also well informed as to the styles of different countries and periods.

Much of the effect of scenery depends upon a skilful mode of lighting it; in which respect considerable improvements have taken place of late years, and the light is now occasionally thrown from above, as well as from the sides and the foot-lights. A variety of mechanical contrivances have also been brought to great perfection so as to imitate particular effects in the most deceptive manner, such as those of moonlight, where the moon breaks through the clouds and gleams upon water, &c.; changes of the sky from clear to stormy, or the contrary; the sudden glare of fire, &c.

With the exception of the Drop-Scene, which is let down between the acts, and is a single picture, the scenes of a theatre generally consist of several parts: of narrow upright pieces called Side-Scenes, or Wings; of Hanging-Scenes, painted to imitate a sky or ceiling; and of the Back-Scenes, which are either rolling scenes, let down from above, or Flats, which are pushed on from the sides, and meet in the centre. There are various other smaller portions of scenery used occasionally for balconies, &c.; and many other contrivances and arrangements in order to produce pictorial effect.

SCHLESWIG and HOLSTEIN. These Danish provinces, which have for the last three years been a scene of so much political contention, present but moderate attractions in respect to industry and commerce.

Schleswig produces corn, pulse, flax, hemp, rape-seed, hay, clover, garden vegetables, and potatoes; and exports much agricultural produce, live stock, and fish. Wood is scarce, both for building and fuel. The country contains limestone, chalk, and slate, but no metallic minerals. The chief occupations of the inhabitants are agriculture, the breeding of cattle, and the fisheries. The manufactures, though varied, are not of large extent. In the town of Schleswig there are manufactures of china, earthenware, lace, cambrics, thread, leather, sailcloth, woollens, starch, and refined sugar.

Holstein is on the whole fertile, especially in the marsh-lands which border on the German Ocean and the Elbe. The mineral products are, in the vicinity of Oldeslohe, salt, lime, and plaster of Paris, and near the Baltic, amber; but there are no metals. The surface is in many parts strewed with boulder stones. The agricultural products are corn, pulse, potatoes, some hops, flax, and hemp. There are no manufactures that need any particular notice. The exports consist of corn, timber, horses, cattle, butter, and turf; the imports, of colonial produce, wines, and manufactures. The herring fishery, and the Greenland whale and sea fishery, are a source of considerable profit. Trade is greatly facilitated by the Holstein or Kiel Canal, made in the years 1777-1784, at the expense of above two millions and a half of dollars, to form a communication between the German Ocean and the Baltic.

SCOTLAND. Under various headings, such as Glasgow, Lanark, &c., a few industrial statistics relating to Scotland will be found; and we here append a few others which relate to the country as a whole.

The factory statistics of Scotland in 1850 presented the following features. There were 168 cotton factories, in 10 counties; they had 1,683,093 spindles, 23,564 power looms, 7,712 horse power (steam), 2,842 horse power (water wheels), and 36,325 factory operatives, of whom no less than 27,528 were females. There were 182 woollen factories, 6 worsted factories, 189 flax factories, and 5 silk factories. The total numbers for all these five kinds of textile materials, in the whole of Scotland, presented the following results:—

Factories	550	
Spindles	2,256,403	
Power looms	23,811	
Moving power—		
Steam	13,857	19,861 horse power.
Water	6,004	
Operatives—		
Male	22,140	75,688
Female	53,548	

The Iron manufacture in Scotland in 1848 amounted in quantity to 539,962 tons, at 130 blast furnaces. The largest number of furnaces at one establishment was 16, at Messrs. Baird's iron works at Gartsherrie.

The quantities of exciseable articles made in Scotland in 1850 were as follow:—

Bricks	2,679,533 number.
Malt	4,639,159 bushels.
Paper	28,600,019 lbs.
Soap	22,996,251 lbs.
Spirits	7,132,556 gallons.

In 1848 the gross receipt of customs in Scotland was 2,040,840*l.*—rather less than in Ireland. Considerably more than half the amount was taken at the Clyde ports.

SCREEN. Screens are exceedingly beautiful internal features in the Gothic or pointed style of architecture; in which they were employed for a variety of purposes, not in churches alone, but in halls and other buildings. Great diversity is displayed in them as regards both design and material; for we meet with them sometimes solid or nearly so, at others almost entirely of open work; of stone or of timber, and occasionally composed of both; but agreeing in being more or less elaborately decorated. The Organ Screens, Altar Screens, Tomb Screens, &c. in some of our cathedrals and churches, are exquisite specimens of taste and workmanship. Screens of a different character were employed in the halls of domestic and collegiate buildings, for the purpose of cutting off a passage leading to the butteries and offices. Such screens were almost invariably of oak or other wood, and the space over them and the passage behind served as a music gallery. As a revival of mediæval taste, many beautiful examples of screen work have been sent to the Great Exhibition.

SCREW. This mechanical power generally consists of two parts, one of which is a solid cylinder of wood or metal, on whose convex surface is formed a projecting rib or fillet, frequently called a thread, which passes spirally round in such a manner as constantly to make equal angles with lines parallel to the axis of the cylinder. The other is a cylindrical perforation through a block of some material, the surface of the perforation having on it a spiral groove corresponding to the projecting rib or fillet on the solid cylinder. The first of these parts is called a convex screw, and the other a concave screw. When the two parts are in action, the convex screw, being turned round in the other by a power applied at its surface, moves at the same time rectilinearly in the direction of its axis: occasionally however the convex screw is fixed, and then the other being turned about, it acquires at the same time a like rectilinear motion.

As a mechanical power, the screw possesses the property of an inclined plane. In practice, a lever or wheel is always fixed perpendicularly to the axis, and the moving or sustaining power is applied near the outer extremity of the lever, or at the circumference of the wheel.

An *Endless Screw* consists of two or more spiral fillets or threads on a rod which is capable of being turned on its axis by a power applied to the handle of a winch, or to a string passing over the circumference of a pulley attached to the rod. The threads work between teeth on the circumference of a wheel, so that, while the revolution of the rod continues, the wheel turns on its axis. A *Double-Threaded Screw* is one in which a fillet is formed upon each of two continuous spiral lines on the surface of the cylinder; the two making equal angles with lines parallel to the axis. With apparently an equal distance between the threads on both screws, the power of the single-threaded screw is double that of the other. From the high ratio which the resistance bears to the moving power in the screw, the use of this machine for moving or compressing bodies is very great; it is also extensively employed in the construction of philosophical instruments for measuring small angles or distances. [MICROMETER.]

A *Differential Screw* consists of one convex screw which works in the interior of another convex screw. The latter works in a concave screw, which is fixed; and the former is capable of moving in a rectilinear direction only, being prevented from turning on its axis with the rotation of the exterior screw. Also the number of threads in an inch on the convex surface of this last is less by one than the number in an inch on the convex surface of the other. Thus, if the exterior screw have 100 threads in an inch, and the interior screw 101 threads, then one turn of the machine will cause the latter to move through the very minute extent of $\frac{1}{10100}$ inch, and this space may be further subdivided by means of a micrometer head applied to the exterior screw.

SCREW-JACK, is a portable machine for raising great weights by the agency of a screw. The apparatus introduced under the name of the Universal Screw Jack is particularly useful on railways, where it affords a simple means of lifting a carriage or engine that may have run off the rails, and then moving it laterally until the wheels are in their proper position over the rails.

SCREW MANUFACTURE. In the infancy of screw making the thread was formed with a file; but this process has long been superseded by the use of dies and cutters, which are applied in various ways. The cutting of the worm is sometimes performed in a lathe, the blank being fixed in a chuck, and projecting during its revolution between a pair of stationary cutters; the longitudinal motion of the blank, and consequently the size or inclination of the thread, being determined by a regulating or pattern screw attached to the mandril, which must therefore be changed for every different degree of fineness; while the shape of the thread or worm depends on the form and position of the cutters. Small screws are frequently wormed by a similar apparatus turned by a winch-handle attached to the mandril; and sometimes by means of a steel tap-plate. Many patented improvements have been introduced in this manufacture, chiefly in relation to the cutting of the worm. Several attempts have been made to produce screws by casting; but not with much success.

Screw-Bolts and other screws for working in metal are manufactured in a similar manner to common screws when the number required is sufficient to justify the expense of adjusting the machinery. When this is not the case, they are, if small, often cut by hand, without the aid of a lathe. In the screwing of metal work, there are required two portions, the external and the internal screw: these require contrary processes in their manufacture.

In cutting screws in wood, an internal wooden screw is cut by an external screw of iron or steel, and an external wooden screw by an internal screw of iron or steel: the cutter or *tap* being shaped according to the kind of screw to be produced.

The large iron screws used in vices, presses, waggon-jacks, &c., are sometimes formed by means of dies, turned with immense power by very long levers; the thread being made without cutting, by indenting and squeezing up the metal. The very best scrap-iron is required for the screws formed in this manner, on account of the twisting force to which they are subjected.

In the ordinary method of cutting screws in a lathe, the size of the worm, or the distance between the threads, is regulated by a pattern screw, and cannot be varied from it; but an ingenious machine is used in the Woolwich dockyard for cutting a great variety of different screws from one pattern.

Birmingham is the great seat of the screw-manufacture; millions of dozens are made in that town yearly.

SCREW PILES. [LIGHTHOUSES].

SCREW-PRESS. In the common Screw-Press the articles to be subjected to compression are laid upon a horizontal bed, forming the base of a strong frame, in the upper cross-bar or *head* of which a nut is firmly secured. The screw works up and down in this nut, and to its lower end is attached the *follower*, or moving piece which presses on the upper surface of the substance operated upon. The connection between the screw and this piece is such that the follower rises and falls, but does not turn round with the point of the screw; and the steady motion of the follower is provided for by making it fit closely to the side-pieces or cheeks of the press, which therefore act as guides. The screw is turned by a long iron lever. The screws of presses were formerly made of wood, but they are now almost uniformly made of iron.

While the diminution of the size of the thread affords the means of increasing the power of a screw-press, by reducing the distance traversed by the point of the screw during each revolution, it is attended with the serious disadvantage of diminishing its strength. This difficulty may be avoided by the use of a double or differential screw. [SCREW.]

SCREW PROPELLER. From the time of Archimedes it has been known that a revolving screw may be made the means of raising water; and it has also been known that a peculiar resistance to the motion of a solid in a liquid results from the revolution of a screw. A most important application of this principle has been made within the last few years to steam navigation; the *screw steam ships* wholly depend upon it.

The first vessel fitted with a screw propellor was a yacht, in which the screw was fitted into the dead-wood, between the keel and the stern-post; the screw consisted of a helix, making but one revolution around a horizontal axis passing longitudinally through the ship; and it was put in motion by a steam engine. The absence of the ponderous paddle wheels and paddle boxes of an ordinary steamer greatly improves the sailing qualities of a screw-propelled vessel; while the arrangement of the machinery may be such as to render the vessel far more commodious, and, if desired, to leave the upper decks open from end to end. The usual position of the screw propeller, immediately before the stern post, does not appear either to be disadvantageous to the application of the propelling power, or to interfere with the action of the rudder. An important use to which screw propellers have been advantageously applied, is as an auxiliary power, for occasional use during calms and contrary winds for vessels which are ordinarily moved by sails alone; such auxiliary screws have been supplied to some of the Arctic ships.

The most notable screw steamer ever constructed was the *Great Britain*. It was 320 feet long by 50 broad. The burthen was about 3000 tons; and the engines, consisting of four cylinders of 88 inches diameter by 72 inches stroke, were of 1000 horse power. It had a screw propeller 15½ feet in diameter, with six arms, mounted in the stern, and capable of being turned with great rapidity by the engine. After making four passages across the Atlantic, she was fitted with a new and much stronger propeller, weighing seven tons, of the same diameter as before, but consisting of only four arms or vanes. The subsequent disasters of this noble vessel are well known to most newspaper readers.

After varied experiments and trials a commercial company took up the subject of Screw Steam Navigation; and important results seem likely to follow. The company, formed in 1846, built two screw steamers, of 272 tons each for the Holyhead and Dublin trade. Two other vessels of 320 tons were afterwards added. In 1848 the company was remodelled, and commenced operations on a larger scale. Four screw steamers, from 450 to 560 tons, were built for the trade between England and Constantinople, and performed the service very satisfactorily. In 1850 the company entered upon a contract with the admiralty, for a monthly mail to the Cape of Good Hope; the first screw steamer started on this service on Dec. 18, 1850, and returned to Plymouth on March 12, 1851; and in respect to time and accommodation, the service is considered to have been amply performed. The company are now organizing arrangements for an extension of the system to Mauritius, Ceylon, Madras, and Calcutta; and should this be carried out, it is next contemplated to make a farther extension to the Australian colonies. It is calculated that screw steamers of 1700 tons burden and 300 horse power would reach Sydney from England in 64 days; and such vessels are now being built.—There seems much probability that the recent perplexities concerning an Australian mail will be solved by the success of the screw steamers.

There are also screw steamers in the Royal Navy. Screw steamers have just been started from Glasgow to London—a distance of about 800 miles, whether taken north or south. In April of the present year the first screw steamer started from Glasgow to New York, an entirely new steam route. An American Company are building screw steamers of very large burden, expressly for the emigrant traffic from Liverpool to New York.—Such are the energetic proceedings which the success of the Screw Propeller has engendered.

See further in respect to steam navigation under STEAM VESSEL.

We may here mention that attempts have been made to propel vessels by ejecting water from the stern. A propeller of this curious kind was patented by Mr. Purkis in 1849, and was tried on a boat of large size in the Thames.

SCULPTURE, in its strict sense, is the art of carving or cutting any material into a proposed form or shape. In its more general acceptation it is the art of representing objects by *form;* and is thus applied to carving, modelling (or the plastic art), casting, whether in metal or other materials, and to gem-engraving. Sculpture is practised in various ways; namely, in forming entire or insulated figures, as statues or groups, called, in technical language, 'the round;' or in representing objects more or less raised without their being entirely detached from a background. This latter is termed 'relief,' and the degrees of relief are defined by modern writers and artists by the expression *alto-rilievo,* when the object is so salient as to be nearly round; *basso-rilievo,* when it is slightly raised from the background; and *mezzo-rilievo,* when a medium is preserved between the extremely high and the very flat relief. There is another variety of this manner of working basso-rilievo, which is only or chiefly found in Egyptian sculpture; the outline is sunk into the plane or ground, and the parts are then formed and rounded on the principle of basso-rilievo. By this mode of working there is usually no projection beyond the profile or face of the original ground; to gain effect therefore in this kind of *relieved intaglio,* the Egyptian artists frequently painted the sculpture.

The materials for modelling used by the ancients, were clay, wax, and plaster. The clay model was usually baked, by which it acquired a hardness scarcely inferior to stone. These *terra cotta* works were generally painted. The materials used for carved works comprised every substance, hard or soft, that could by any possibility be employed for the purpose. The Egyptians, whose great objects were to render their works durable, chiefly employed porphyry, basalt, and granite. For casting—gold, silver, copper, lead (and their compounds) wax, and plaster, were all used. [BRONZE; FOUNDING.] *Polylithic Sculpture* was the name given to the combination of different marbles in the same work. When painting or colouring was resorted to it was called *Polychromic Sculpture.*

The consideration of the various schools and far-famed works of sculpture, as productions of genius and high art, lies beyond the range of the present volume; but the *mechanical* operations of sculpture come fittingly under notice here.

The technical or mechanical processes of sculpture are for the most part extremely simple. The sculptor usually begins by making a slight sketch of his subject, either drawing it on paper or at once modelling it on a small scale, in clay or wax. He next proceeds to build up his statue of the desired size. The first thing necessary is to construct a sort of nucleus, or skeleton, by which the clay may be supported. This is made of wood or iron, according to the strength required, and the limbs are usually made moveable by attaching the skeleton parts to the main support, or trunk, by wire joints. The figure is then built up in clay; and whether it is ultimately to be draped or not, it should always be modelled naked, in order that the true forms may be easily distinguished, and the drapery made to fall naturally. In modelling in relief, a plane, or ground as it is called, is prepared, upon which the sculptor carefully draws his design. The clay is then laid and pressed upon this, the outline of the figures being bounded by the lines of the drawing. When the work is completed it is cast in plaster

No. 36.

of paris, by means of a mould taken in that material.

In copying a model in marble, the first step is to prepare two stones of the same size, or at least with an exactly corresponding graduated scale marked on the front of each, on which the block of marble and the model are respectively to be placed. The fronts of the two scales are so constructed or fitted up, that a 'pointing instrument' can be applied to them. This instrument is usually composed of a pole or standard, to which a long brass or steel needle, capable of being extended and withdrawn, loosened or fixed, and moved in every direction by means of ball and socket joints, is attached. This is made to touch a particular part of the model. The whole instrument is then removed to the scale stone on which the rough block is placed, and the marble is cut away till the needle reaches as far into the block as it had been fixed at upon the model. A pencil mark is then made upon the two corresponding parts of the model and block, and thus what is technically called 'a point' is taken. This process is repeated till the numerous points at fixed depths, corresponding throughout with the surface of the model, are attained, and a rough copy of the sculptor's original work is thus mechanically made. The practice of different sculptors has suggested various changes in detail; but the principle seems to be exactly similar in all. The statue being rudely blocked out or pointed, the marble is in this state put into the hands of a superior workman called a carver, who copies the minuter portions of the work by means of chisels of various sizes, rasps, and files; the pencil marks or points showing him the limits beyond which he is not to penetrate into the marble. When the carver has carried the work as far as the sculptor desires, he proceeds himself to give it the finishing strokes, by retouching and improving the details of form and expression, by producing varieties of texture and surface, and by giving that general quality or appearance to the whole which constitutes what is termed harmony of effect.

SEA WATER. [Water.]

SEA WEEDS. A few details concerning the uses of various kinds of sea weeds will be found under Algæ; Archil; Iceland Moss; Kelp; Lichens.

SEAL ENGRAVING. The cutting of the very hard stones or gems used for seals is effected chiefly by the use of small rapidly revolving wheels, the edges of which wear away the substance of the stone applied to them. Under the articles Cameo; Diamond; Gem; Intaglio; Lapidary—will be found details sufficient to illustrate the general character of seal engraving.

SEALS; SEAL SKINS. These singular animals are captured eagerly, in seas and on coasts where they abound, for the sake of various useful services which they render. The species called the *Elephant Seal*, which is principally met with in the southern hemisphere, is the object of an extensive fishery, maintained for the sake of its skin and oil; and vast numbers are annually destroyed. The skin, though not valued for its fur, is extensively used for carriage and horse harness on account of its thickness and strength. The oil obtained is clear and inodorous, and is said never to become rancid, nor to give out any disagreeable savour in cooking. The quantity afforded by a large seal amounts to 1400 or 1500 lbs., for the blubber is often a foot deep. It is prepared like that of whales, excepting that the operation is performed on shore. This oil is employed in England chiefly in the manufacture of cloth; it is used to a considerable extent in China.

Many other species are valued for the skin, which has a beautiful fur when the animal is young. The *Walrus*, which is a species of seal, is highly valued; the tusks, the skin, and the oil are all commercially valuable; and the flesh is esteemed by the natives of Arctic regions.

Salted seal skins have recently been imported from Northern Europe, under circumstances which could not have occurred before the repeal of the Navigation Laws. Upwards of 45,000 were recently imported in one vessel from Denmark.

There were 753,141 seal skins imported in 1847; and 706,267 in 1848—chiefly from the Hudson's Bay Territories. They are used in making caps, and for various other purposes.

SECTOR (Drawing Instrument), is an apparatus which has the appearance of a small carpenter's rule marked with scales in every part; the greater number of these scales not being laid down parallel to the edges of the rule, but converging towards the pivot on which the moving arm of the rule turns while the instrument is opened. These converging scales only properly belong to the sector; the others are merely laid down for convenience on such blank spaces as are left by the converging or sectorial scales. The sector is, in principle, an aggregate of a large number of pairs of compasses packed up into one; each piece of the ruler being marked with the same scales.

The scales are so graduated as to facilitate many kinds of measurement and calculation, in geometrical and trigonometrical enquiries.

SEDLITZ. This is the name of a village

in the circle of Saaz in Bohemia, containing two bitter salt springs, from which the well-known salts called Sedlitz Powders are obtained. There are several such springs in the neighbourhood, including those at Seidschuz, in the circle of Leitmeritz. Above half a million of bottles of the water of Sedlitz and Seidschuz are annually sent to all parts of Germany.

SEEDS. Of those foreign seeds which are of sufficient importance to find a place in the Board of Trade tables, the following quantities were imported in 1848:—

Carraway	7,266	Cwts.
Clover	99,813	„
Flax and Linseed	799,650	Qrs.
Onion	1,385	Cwts.
Rape	79,970	Qrs.
Tares	48,929	„

Of most of these, the importation in 1850 was smaller than in 1848.

The economical uses of these seeds are described in other articles.

SEGAR MANUFACTURE. [CIGAR.]

SEINE. This important river of France connects Paris with the sea at Havre. By means of a lateral canal between Marcilly and Troyes, and locks to avoid the fall at Nogent, the river is navigable from Troyes to its mouth, a distance of 370 miles. From Paris to Rouen it is navigated by small steamers and by barges 150 to 180 feet in length, 30 feet wide, and with a draft of 6 feet. The tide ascends the Seine as far as Rouen, which city is accessible for vessels of 300 tons. Between Caudebec where the Seine begins to widen, and Quillebeuf, the navigation is dangerous, owing to the shoals and shifting sandbanks in the bed of the river. This has led to the undertaking of important works between Villequier and Quillebeuf, the object of which is to confine the river to a narrower bed by means of embankments; a portion of this undertaking, completed in 1849, gave the satisfactory result of a deepened current, which soon swept its bed clear of sands. The importance of the navigation of the Seine may be inferred from the fact that about 3500 sea-going ships enter and leave the ports of Havre and Rouen annually, besides a large number of coasters and small craft. Owing to the windings of the river its navigation is tedious. Steamers ply regularly between Havre, Rouen, and several other towns on the lower Seine. The articles of traffic on the river include almost every description of agricultural, mineral, and industrial products, home, foreign, and colonial.

The river gives name to four of the departments of France; viz. *Seine*, *Seine Inférieure*, *Seine et Marne*, and *Seine et Oise*.

In the department of *Seine*, a large portion of the surface of the department is laid out in gardens, for the growth of kitchen vegetables, fruits, and flowers; wheat, barley, oats, and potatoes are grown in large quantities, considering the smallness of the area of the department; but little wine is made, and that little is all bad. Montmartre and most of the hills consist of accumulations of gypsum; excellent building stone is quarried under the southern quarters of Paris, and at various other points of the department; fine clays for porcelain and pottery, chalk, sand for glass foundries, &c., are raised. The manufactures comprise almost every woven fabric in wool, flax, cotton, and silk; metallic articles; jewellery, watches, and clocks; glass, porcelain, furniture, hats, gloves, ribands, and small wares of all kinds; scientific instruments, and chemical products of every description, &c. The commerce in these various products, and in agricultural produce, coal, timber, and firewood, raw materials of manufactures, cheese, metals, salt, drugs, colonial produce, building materials, &c., is most extensive.

In the department of *Seine Inférieure*, hemp and flax are grown, especially along the coast between Fécamp and Havre; the hemp is almost exclusively used for making ropes and fishing nets. The department is remarkable for the vast number of its apple and pear trees. Great attention is paid to the rearing of horses, fat cattle, milch cows, and to the making of butter and cheese, both important articles of export. The Seine is valuable to fishermen for its abundance of salmon, sturgeon, sole, eels, &c. Large fleets of barks of 30 to 90 tons, and with crews varying from 15 to 30 in number, are employed in the mackerel, oyster, and herring fisheries. The minerals comprise marble, building and paving stone, chalk, flint, brickearth, potters' clay, sand used in glass factories, and marl. Iron mines were formerly worked near Forges. Peat is found. The department is famous for its industrial energy, which is exerted upon the spinning, dyeing, and weaving of cotton, wool, and flax; the manufacture of ginghams, cotton cloths, and calicoes of all kinds, broadcloth, flannel, serge, linen, and mixed cloths of wool and cotton. The cotton manufactures had a great development previous to the revolution of 1848; since then it is said they have received some check. Hand-loom weaving is carried on in almost every hamlet and cottage, and frequently on a pressure of orders the raw material is sent into the neighbouring department to be worked up. The department is famous for its bleach works, which are conducted on the most modern principles, and turn out linen of a purer whiteness than those bleached in any other part of France. The linen woven about Fécamp is of the best quality. Cotton printing has had a great extension during the last thirty years. Among the other manufactured products may be mentioned lace, watch and clock movements, articles of ivory, pottery, window glass, bricks, &c. There are also numerous sugar refineries, silk-mills, manufactories of chemical products, metal foundries, tan-yards, ship-building yards, and other establishments in which industrial and commercial enterprise manifests itself on a large and important scale. The commerce carried on with the interior of France, with its colonies, with the whole of Europe, the West Indies, and America, is most extensive, and includes almost every article of French import and export. Of the manufacturing industry and important commerce of the department other details are given under DIEPPE, HAVRE, and ROUEN.

In the department of *Seine et Marne*, the wine produced is bad, although some of the finest grapes grown in the north of France are gathered in the neighbourhood of Fontainebleau. The forests, which cover more than one-sixth of the whole surface of the department, contain chiefly oak, beech, maple, and birch. Milch cows are numerous; veal calves are fed for the supply of Paris; cheese, known in Paris as *fromage de Brie*, is made in considerable quantity. The quarries of Château-Landon and Nemours furnish very beautiful building stone, of which a very large quantity is raised. Other mineral products are millstone grit, paving flints, alabaster, limestone, gypsum, potters' clay, and white sand. The industrial products include writing and printing paper, pottery and porcelain, cotton yarn and printed calicos, leather, window glass, &c. Glass globes and cylinders of the largest size are made at Bagneaux, near Nemours, and also optical and common glass; in the central prison at Melun various articles are manufactured by the prisoners. The commerce of the department is confined chiefly to agricultural produce, wool, cattle, wood, and charcoal for the supply of Paris.

In the department of *Seine et Oise*, great numbers of milch cows, chiefly house-fed, are kept for the supply of Paris and Versailles with milk. Market gardening is a profitable occupation, and is carried on extensively. Filberts, walnuts, figs, peaches, apricots, grapes, apples, and other common fruits are abundantly grown. About 17,000,000 gallons of poor wine are made annually. In the northwest of the department, where the vine does not flourish, apples and pears are grown for making cider and perry, the common drinks of the inhabitants of that district. The most important forests are those of St. Germain, Rambouillet, Dourdan, Senart, and Montmorency; they contain chiefly oak, birch, and maple, with some beech, chestnut, and hazel. The minerals include only building stone, gypsum, limestone, paving flints, millstone-grit, chalk, marl, and potters' and porcelain clay. The industrial energy of the department has been greatly developed since 1789, when the gunpowder works of Essonne (now established at Bouchet), and the porcelain and glass works of Sèvres, were the only important establishments it possessed. There are now numerous mills and factories at various points of the department, producing cotton, flaxen, silk, and woollen threads, calico, cotton and woollen hosiery, paper, chemical products, woollen cloth, soap, oil, refined sugar, porcelain, glass, saltpetre, beer, toys, crinoline, &c.; besides metal foundries, brick works, and above 800 wind and water mills, the greater number of which are scattered over the arondissements of Corbeil, Etampes, and Pontoise. In the prison of Poissy, various articles of jewellery, cutlery, and furniture are made by the prisoners. The commerce of the department is carried on chiefly with Paris, and consists of the agricultural and industrial products above mentioned.

SELE'NIUM. This non-metallic, solid, elementary body was discovered in 1818 by Berzelius in iron pyrites. It has a metallic lustre, and the appearance of lead when in mass; when reduced to powder it is of a deep brown colour. It is inodorous, moderately hard, may be readily scratched with a knife, is brittle as glass, and easily reduced to powder. Its fracture is conchoidal, and perfectly metallic. Its specific gravity is about 4·30. It is a bad conductor of heat, and a non-conductor of electricity. It softens at 212°, and may be drawn out into fine threads, which are transparent, and of a red colour by transmitted light. When heated above 212° it becomes fluid, and boils at 650°. Selenium is soluble in hot oils and melted wax. It combines with many of the elementary bodies; but none of the compounds have yet been of much use in the arts.

SENEFELDER, ALOIS, deserves to be remembered as the inventor of lithography. He was born at Prague in 1771; and having written two or three plays while yet a youth, he became desirous of procuring the necessary apparatus for printing his own works. Being too poor to gratify this desire, he endeavoured to discover some other mode of printing, but was defeated in several plans by want of means. The result of a variety of experiments, persevered in in spite of every difficulty, was his discovery, through an accident, of the art known as Lithography. [LITHOGRAPHY.] In order to raise money to carry out his idea, Senefelder enlisted as a private in the artillery, as a substitute for a friend, who promised him a premium of two hundred florins; but this plan was frustrated. While at Ingoldstadt, he was led to conceive the peculiar fitness of his new process for printing music. He continued struggling until 1799, when he obtained an exclusive privilege for Bavaria for fifteen years, and carried on a considerable business, employing his two brothers and two apprentices. Mr. André of Offenbach, now became his partner, and they commenced arrangements for obtaining patents and establishing presses in Vienna, London, Paris, and Berlin. While engaged in this project, he visited London, but without succeeding in his object. Unfortunate circumstances led to a hasty dissolution of this promising partnership in 1800; and political events also contributed to his embarrassments. In 1806 however an extensive lithographic establishment was formed at Munich, by Senefelder, in connection with Baron Aretin and others. This partnership lasted about four years, during which period a great nnmber of works were executed; some of them for the government. Several other lithographic establishments were also in successful operation in 1809, when Senefelder obtained an engagement which rewarded him for the vicissitudes of the early part of his career. A royal lithographic office was formed about that time for printing the plans of a new survey of the kingdom, of which a great number were required. In 1809, he was appointed to the office of inspector, with a salary of fifteen hundred florins per annum, and permission to carry on his private business also. The subsequent improvements effected by Senefelder, such as the printing in colours, and upon linen, were attributed by himself to the ease and independence which this honourable engagement afforded.

SENEGAL SETTLEMENTS. On the banks of the Senegal and Gambia rivers in West Africa, different European governments have established settlements. These settlements in Senegambia (as the country is called) differ materially from those in other parts of the world. They are strictly commercial. The settlers have not acquired the property of any land, except the place on which they have settled, and no cultivation is carried on by them or their people, except at a few spots which are rather gardens than plantations. These settlements were originally established for the purpose of procuring negro slaves for the colonies in North America. The country however had other productions which were valued in Europe; and the natives of the interior were desirous of obtaining several articles of European manufacture, partly for their own consumption, and partly to sell them to the nations of Soodan. Accordingly these settlements were not abandoned on the abolition of the slave trade, like those on the coast of Guinea, and they continue in a thriving state. Each of the three European nations which have formed settlements has taken possession as it were of one of the three large rivers; the French of the Senegal, the English of the Gambia, and the Portuguese of the Rio Grande. Each has built a fortress on an island not far from the mouth of the river, which serves as a safe place of deposit for the goods imported, and thence the productions of the country are shipped. The merchants set out from these places in large river boats with their goods at certain seasons of the year, and ascend the rivers as far as they are navigable. They stop at certain points to which the natives bring their productions to exchange for European manufactures. In a few positions on the banks of the rivers small fortresses or blockhouses are erected, in which some black soldiers with two or three European officers are kept for the protection of commerce. Some merchants, particularly English and Portuguese, have formed commercial establishments not far from these fortresses in those villages which are advantageously situated for commerce. The French settlements are chiefly at St. Louis, Podhor, Bakel, and Goree. The English settlements are at Bathurst, Macarthy Island, and Fort St. James. The Portnguese settlements are at Bissao, Jeba, Bolula, Cacheo, and smaller ones in the interior. St. Louis, Bathurst, and Bissao, are flourishing towns.

Nearly all the articles of commerce which are exported from the European settlements in Senegambia are brought from the interior by small caravans or cafilas, which generally stop at certain places where commercial establishments are found, and take European merchandise in exchange for their goods. A considerable commerce is also carried on between Senegambia and the countries further east.

To such of the Senegambia settlements as belong to Great Britain, our exports in 1849 amounted in value to 35,770*l.*; consisting principally of clothing and firearms. These firearms were exchanged with the natives for the produce of the country.

SENNA. [Cassia.]

SENNAAR. In this little-known African country, situated between Egypt and Abyssinia, more industrial activity is displayed than might be expected. The branch of industry in which the Sennaarese are most distinguished is leather, which is of the best quality, and much superior to that made in Egypt or Syria; many useful articles are made of it by the natives. Where dates grow, cords and ropes are made of the fibrous interior bark of the palm date-tree, and in some places of reeds. Cotton cloth is made by the women for domestic use, but it constitutes also a considerable article of trade in Northern Africa, under the name of damour. The workers in gold, silver, and iron, are very skilful, and execute their work neatly with very simple tools. Pottery is made to a considerable extent; and also carved wooden vessels. In some places coloured straw hats are made with great neatness, and they are sent to different countries in the neighbourhood. An extensive foreign commerce is maintained at Sennaar. There is one caravan route to Cairo, two to the Red Sea, one south-westward to Begharmi, and another south-east to Alymuir. Few of the articles imported into Sennaar are brought from European markets; the imports are chiefly from various parts of Africa and Asia. The principal articles of export are slaves, the damour or cotton-stuff of Sennaar and Begharmi, gold, ivory, and ostrich feathers. The inland trade of Sennaar is very active, partly in consequence of the great number of caravans which continually traverse the country, and create a great demand for camels, which are brought to those places through which the caravans pass, and partly on account of the different productions of the several parts of the province.

SERAI is the name for a large building for the accommodation of travellers, common in Eastern countries. The word is Persian, and means 'a palace, the king's court, a large edifice;' hence *karâvân-seraï*, a place of rest for caravans. In Turkey these buildings are generally called khans, from *khân*, another Persian word, which has a similar meaning.

SERAPHINE is a musical instrument of the keyed kind, in which very short, thin, and narrow steel bars, or springs, put into vibratory motion by means of a bellows acted on by the foot, are used instead of pipes. The principle on which the sounds are elicited is the same as in the Accordion and the Concertina. The Seraphine is in the form of a chiffonier, about thirty-seven inches high, forty wide, and twenty-two deep. Its compass is five octaves, including all the semitones, and it is played on in the same manner as an organ. In small churches, a Seraphine is often a welcome substitute for a more costly and bulky instrument.

SERPENT. This musical instrument consists of a long conical tube of wood covered with leather, having a mouth-piece, ventages, and keys, and bent in a serpentine form. The compass of the serpent is from B flat below the base staff, to G, the treble clef line, including every tone and semitone between these extremes. Its use is now nearly superseded by the Ophicleide.

SE'SAMUM. This genus of plants is valuable for the oil which it yields. *Simpsca* is the Egyptian and Arabian name of one of the species, remarkable for the quantity and quality of the oil expressed from its seeds. The oil is employed as an article of diet in Eastern nations, on which account the seeds form an article of commerce from India and Egypt in the present day. The oil is bland, of a fine quality, and will keep many years without becoming rancid; it is often used in India as a salad oil. The leaves of the plant are mucilaginous, and are employed for poultices.

SEWERS. Covered drains or sewers of great size, and of very solid construction, still exist under the streets of some ancient Roman cities, and especially of Rome itself. In modern times the sewers of London stand unrivalled for extent and excellent construction, although much yet remains to be done to render them adequate to the necessities of an immense and constantly-increasing population. Full one-third of the sewers in the City of London were made in the ten years preceding 1834. Until 1847 there were seven Boards of Commissioners of Sewers in the metropolis, each having control over a particular district. It was often found that great inconvenience and expense resulted from the want of agreement between these boards; and at length a Metropolitan Commission of Sewers was appointed by Act of Parliament. The Commission commenced its labours in 1847. It has control over the whole of the metropolis except the City; but the City Comission has agreed to act as far as possible in conjunction with it.

All the sewers constructed by the Metropolitan Commissions of late years are of such dimensions as to allow a man to pass through them, for the purpose of inspecting or cleansing them. The smallest sewers in the City of London division are about four feet three inches high by two feet three inches wide, the dimensions being increased according to circumstances, up to ten feet by eight feet. The water brought down by the Fleet River is conducted from Holborn Bridge by two sewers, from twelve to fourteen feet high, and six feet six inches wide, one on each side of Farringdon Street. These sewers unite, towards the mouth, into one passage about eighteen feet by twelve.

The bricks and cement in the London sewers are of the best quality; but the form of the sewers varies greatly; some engineers preferring one form, some another. Nearly all the modern sewers however, have an inverted arch at the bottom; and curved forms are also generally given to the sides and the top. In the metropolitan sewers the inclination varies from a quarter of an inch to an inch and a quarter in ten feet. In some cases it is very difficult to obtain sufficient inclination in a sewer, and still to make it deep enough to drain the basement story of neighbouring houses; which may be readily conceived from the fact that some parts of London are below the level of high water. Wherever it is practicable, new sewers are built at a considerable depth from the surface. The depth of that in Watling Street, in the City of London, which is an extraordinary case, is from thirty-three to thirty-five feet. In many cases however there is a space of not more than three feet between the surface of the roadway and the crown of the arch of the sewer. Where private drains are to be laid into a sewer for the purpose of draining houses, it is necessary that the lowest pavement of the floor of the building be at least four feet above the level of the sewer; because the house would otherwise be liable to be flooded with water from the sewer, when unusually full. Drains leading from private houses are usually of a circular form, and nine inches in diameter, though some are of greater size.

The construction of gulley-holes and shoots for conducting the surface drainage of the streets into the sewers varies considerably in different parts of the metropolis. It has been usual, until very recently, to make apertures, called *Man-Holes*, at convenient distances, to enable persons, when necessary, to enter and cleanse the sewers,; these apertures in some instances, are built in the form of oblong shafts of brickwork, up to within about eighteen inches of the surface of the road, and covered with cast-iron plates, over which the roadway is made good. A later and better plan is that of side entrances. These are passages extending from the side of the sewer to the foot pavement, through which they may at any time be entered by unlocking and opening a cover or trap-door consisting of pieces of flag-stone mounted in an iron frame. When a person enters the sewer by one of these openings the cover is held open by a self-acting catch, and an iron grating which admits light and air rises into its place, and serves to prevent any passenger from accidentally falling in. These entrances greatly facilitate the operation of *flushing* or cleansing the sewers. The necessary body of water for flushing is produced by simply accumulating the ordinary contents of the sewer, which may be done either by a cast-iron grate, fitting closely to a frame-work built into the sewer, and rising to the height that the head is required to be, or by a drop plank or gate of the same material, sliding up and down in nearly vertical grooves. In either case the apparatus may be managed, by means of the side entrances, with the greatest facility. The ordinary run of water in the sewers has hitherto been found sufficient for the purpose; but in case of its proving otherwise, a supply of water for flushing might be readily procured from the water companies.

The subject of the application of sewage refuse to the purposes of manure has recently attracted much attention. Two companies obtained acts of parliament, the one in 1846, and the other in 1847, under the designations of the 'Metropolitan Sewage Manure Company,' and the 'London Sewage Chemical Manure Company.' The plan of the former company was to collect the contents of some of the sewers of Westminster and Pimlico, and convey them by a deep underground channel to Hammersmith, where a steam-engine and other apparatus would distribute the manure in a liquid state to the market-gardens of that neighbourhood. The plan of the second company was to collect the contents of three sewers which now fall into the Thames between Vauxhall Bridge and Westminster Bridge, and, after allowing the liquid part to flow into the Thames, to deprive the refuse of its offensive smell, and sell it as manure in a solid state, Very little has been done, however, towards carrying out either of these plans.

Since the Metropolitan Commissioners of Sewers commenced their operations in 1847 many steps have been taken towards a comprehensive sewerage for the whole of the metropolis. A survey of the metropolis is now being made for the Commissioners by the officers belonging to the Ordnance Survey. The survey will extend to a distance of 8 miles in every direction from St. Paul's, comprising an area of about 201 square miles. On a scale of five feet to a mile, the results of this survey would fill 900 large sheets, and would form a magnificent map of London eighty feet in diameter. While the survey and map are in progress, the Commissioners have invited tenders of plans for a comprehensive sewerage of the metropolis. A very large number of such plans were sent in to the commissioners in the early part of the year 1850; many of these embracing an application of sewage refuse to the purposes of manure.

The Metropolitan Commissioners have not yet begun to develope their great system for the drainage of London; but they executed in 1850 many important works which will be made compatible with their larger scheme. They expended 70,000*l.* during the year in forming 6 miles of brick sewers, 16 miles of pipe sewers, 46 side entrances, 304 air shafts, 565 gullies, 1137 drain mouths, and various repairs. Besides the 21 miles of new sewers executed at the expense of the Commissioners, there were 13 miles constructed for, and paid for by, private parties. About 18,000*l.* had been expended by the end of the year in the survey of London. Of the 900 sheets about 400 are to be engraved, and the rest (the marginal or country district) left simply as drawn plans. Nearly all the 400 are now (April 1851) engraved; they are printed on sheets of double elephant paper, and are sold singly at two shillings each.

The Commissioners determined on the adoption of two comprehensive schemes of drainage for the Metropolis; they directed their engineers to prepare plans, and reports were made in August 1850 and January 1851, respecting the south and north drainages respectively. The general principle of these schemes is understood to be accepted by the Commissioners: the southern to be commenced before the northern, as being more urgently wanted. Without entering into details, it may suffice to say, that the object both of the north and the south drainage is to keep the Thames clear of sewage from Galleon's Reach upwards; to carry the sewers as much as possible under the public streets and places; to make them of dimensions and at gradiants ensuring an unintermittent flow; to secure good house-drainage, and self-cleansing street drainage; to dispense, as far as possible, with periodical flushing; and to provide means for the eventual removal of all open sewers, ditches, and cesspools. A portion of the great scheme for the southern side of the Thames has been already commenced between Kennington and the Old Kent Road. To give some idea of the magnitude of the operations which the Commissioners have under their control, it will suffice to say that 700 miles of existing sewer have been examined north of the Thames, and accurate plans and sections taken of every part of every sewer. It will farther illustrate the scale of these operations to bear in mind that the estimate of expense for the northern drainage alone is nearly a million and a quarter sterling.

SEXTANT. The Sextant is a valuable instrument for measuring angles in navigation and surveying. There were various earlier instruments by Davis, Hooke, Newton, Godfrey and others; but Hadley's Sextant, invented in 1730, superseded all previous contrivances.

The Sextant has a plane glass, called the *Index Glass*, silvered behind, and perpendicular to the face of the instrument. It is fixed on a centre perpendicular to the instrument, and moves with the *Index-Bar*, the end of which slides over a graduated arc. There is another plane glass, the lower half of which, next the instrument, is silvered, and the upper half left clear. It is called the *Horizon Glass* and should be parallel to the index glass when the index points to 0° at the beginning of the arc. The Sextant also has a telescope for viewing the objects observed; whereas in the common quadrants there is merely a plate with a small hole for directing the sight. Suppose a ray of light to proceed from the eye, it will proceed in the direction of the telescope, and if it falls on the upper or unsilvered part of the horizon glass, it will pass forward in a continued straight line until it falls upon some exterior object. But if the ray falls upon the silvered part of the horizon glass, it will be reflected to the index glass (the horizon glass is so placed as to make equal angles with lines from the eye and index glass), and again reflected from the index glass outwards (*i.e.* from the observer), until it meets some external object. Now instead of supposing the rays to pass from the eye, suppose them to come from external objects to the eye; then there will be two images presented at the same time, one formed by the rays which pass through the unsilvered part of the horizon glass, and another formed by the rays which have been previously reflected by the two glasses; and the graduated arc measures the angle between the glasses, and also the angle between the objects observed. The Sextant furnishes the means of measuring the angle between any two well-defined objects, in whatever direction they may be placed (so that the angle does not exceed 140°), and without requiring more steadiness than is necessary for seeing the objects distinctly. There are sets of dark glasses of varying intensity, which may be turned before either the index or horizon glass when the sun's light is too intense.

SHAGREEN, is a sort of leather grained so as to be covered with small round pimples or projections. It is made chiefly of the skin of horses, asses and mules. The skin is soaked in water, scraped, and stretched on frames. While soft, small seeds, such as mustard seeds, are pressed into it, and it is then dried with the seeds in it. The seeds are afterwards beaten out, and the skin has then that pimpled graining which is peculiar to the leather. It is afterwards polished, soaked in a ley, and died of various colours.

SHANG-HAE. By the treaty of Nankin, in 1842, the port of Shang-hae (in the same manner as those of Canton, Amoy, Foochoo, and Ningpo) was thrown open to British merchants; a British consul resides there; and tariffs of imports and exports, as well as inland and transit duties, have been established. The result has been the formation of a large British trade at Shang-hae. In 1846 the vessels which entered and left the port amounted to 148, with an aggregate burden of 42,608 tons. The goods imported in that year were valued at 810,200*l.*, and those exported at 1,352,530*l.* The cottons and woollens imported, and the tea and silk exported, in the three years 1844-5-6, were as follow:—

Cottons..	3,001,794	pieces..	1,872,785*l.*
Woollens.	2,359,868	yards ..	424,020*l.*
Tea	21,020,633	lbs.....	967,230*l.*
Silk	30,834	bales ..	2,132,690*l.*

The magnitude of this foreign trade at Shang-hae is accounted for by the circumstance that there is no harbour on the Chinese coast between 30° and 35° N. lat. The Woosung is the first river south of these limits which is deep enough for the purposes of navigation; and hence the whole maritime commerce of this tract is concentrated at Shang-hae, at the mouth of the river. The country which lies at the back of the coast is the most populous part of China, and contains many very large towns. A steamer plies regularly between Shang-hae and Hong-kong.

SHAWL MANUFACTURE. The Hindoos have been the instructors of our manufacturers in the production of shawls. There are two modes of working the pattern in an Indian shawl; the one by embroidering it *upon* the material, and the other by working it *into* the web during the process of weaving. The first mode is a sort of needlework, and forms the less valuable kind of Indian shawl. In the production of the most costly kind, a number of skewers made of ivory, and sometimes of wood, about the size of a common packing needle, are used; they are sharpened at both ends, and each skewer is covered with a different coloured wool; and with these simple aids, the pattern is worked stitch by stitch into the web. The backs of these shawls show the effect of this minute and laborious handicraft, and present a totally different appearance from the European shawls, the patterns of which are woven entirely on the loom.

Paisley excels all other towns in the United Kingdom in the manufacture of shawls, in quantity and perhaps in quality. The common kinds are woven in the power loom; while the finer kinds require the more detailed aid of the hand loom weaver. In the common shawls cotton is mixed with the wool; but for the finer articles the best wool of Germany, of Australia, and even of Cashmere, is employed. Some of the finest of these shawls are equal to anything produced in any other country. The Paisley weavers are mainly dependent on French patterns, which they modify in details; but the School of Design in that town is gradually training up a corps of designers whose taste may shortly influence in an important degree the shawl manufacture.

It might seem strange that the paper duty should press injuriously on the shawl manufacture of Paisley; but such is the case. In weaving elaborate patterns it is necessary to employ the Jacquard loom; and in using this loom many hundred perforated pasteboard cards are employed for each pattern. Now the French weavers pay no duty for the paper used in these cards; whereas the English weavers are subject to an impost, the effect of which may be illustrated by one circumstance. In an elaborate Paisley shawl, woven for the Great Exhibition, the preparation of the loom for the intricate design cost 470*l.*, of which the mere duty on the card-board comes to 93*l.* A Jacquard loom, when once set up, will weave any number of the same pattern; but as the commercial success of any one pattern is always very precarious, the oppressive duty on the card-board employed may be a serious item even in every individual shawl woven of that pattern.

SHEEP. We shall give in this work a few details on such points, only, of the history of the sheep as relate to industrial uses.

When the Romans had conquered Britain, they turned their attention to the improvement of the country, and among other things they established a woollen manufactory at Winchester. So well did this succeed, that the woollen cloths of Britain soon began to vie with the productions of every other part of the Roman empire. The sheep employed in furnishing the material of these productions were the *Short-woolled Breed.* Winchester was situated in the centre of a country which then, as now, could support short-woolled sheep alone. It would appear to have been some centuries after this that the *Long-woolled Sheep* was introduced. The manufactures of the Winchester mills continued, however, to be duly estimated; and, in point of fact, the cultivation of the various breeds of sheep, and the manufacture of the fleece into many different kinds of cloth, had begun to constitute the chief employment and wealth of the country.

The covering of the original sheep consisted of a mixture of hair and wool; the wool being short and fine, and forming an inner coat, and the hair of greater length, projecting through the wool, and constituting an external covering. When the sheep are neglected or exposed to a considerable degree of cold, this degeneracy is easily traced; it is only by diligent cultivation that the quantity of hair or *kemps*, has been generally diminished, and that of wool increased in our best breeds. The filaments of wool taken from a healthy sheep present a beautifully polished and even glittering appearance. That of the neglected or half-starved animal exhibits a paler hue. This is one valuable indication by which the wool-stapler is enabled to form an accurate opinion of the value of the fleece. Among the qualities which influence the value of the wool, are fineness, and the uniformity of that fineness in the single fibre and in the collected fleece. This fineness, however, differs materially in different parts of the fleece. It is finest on the shoulders, the ribs, and the back; it is less fine on the legs, thighs, and haunch; and is still coarser on the neck, the breast, the belly, and the lower part of the legs. Sheep in a hot climate yield a comparatively coarse wool; in a cold climate they carry a closer and a warmer fleece. The fineness of the fleece is also much influenced by the kind of food. The woolly fibre consists of a central stem or stalk, from which there spring at different distances circlets of leaf-shaped projections, possessing a certain degree of resistance or of entanglement with other fibres, in proportion as these circlets are multiplied and they project from the stalk. They are sharper and more numerous in the felting wools, and in proportion as the felting property exists. They give to the wool the power of felting, and regulate the degree in which that power is possessed.

The South Down sheep supported the first manufactory at Winchester. The South Downs, and the Hampshire and Wiltshire breeds, were formerly of a very small size, and far from possessing a good shape, but the size and shape have been of late years greatly improved, and the wool is short, close, curled, and free from spiry projecting hairs. Mr. Luccock calculated that within a certain distance from the Downs there were 864,000 sheep of this breed, a number which is only to be accounted for by the great quantity of artificial food that is raised on the arable part of every farm. The average dead weight of the South Down wether varies from 8 to 11 stones. The average weight of the fleece used to be 2 lbs.; but from the altered system of management, it is now at least 3 lbs. in the hill sheep, and nearly 4 lbs. in the lowland sheep. This wool has likewise changed its character. It has become a combing instead of a carding wool. Formerly devoted to the manufacture of servants' and army clothing, and being sparingly mixed with other wool, it is now used for flannels and baizes, and worsted goods of almost every description, thus becoming of considerably increased value.

In the 13th century certain Florentine merchants were permitted to export from England to Flanders more than 1000 sacks of combing or long wool. In the 14th century the 1000 had extended to 100,000, and that continued during many years; and in the 15th century Edward IV. permitted his sister Margaret to export annually during her life 2000 rams to Flanders and Holland. There has been a very great improvement in the long-woolled sheep within the last half century, especially that kind called the *New Leicester.* The deficiency of the fleece was formerly objected to in this breed; but the truth seems to be that, with the early breeders, the fleece was a perfectly secondary consideration, and comparatively disregarded. There is now little cause for complaint on this head. The wool has considerably increased in length, and it has improved both in fineness and strength of fibre. It averages from 6 to 7 lbs. the fleece, and the fibre varies from 5 to more than 12 inches in length. Like all other British wools, it is applied to a purpose different from that to which it was formerly devoted, and is mostly used in the manufacture of serges and carpets.

The English wool being, from the increased coarseness of the fibre, rejected by the manufacturer in the construction of fine cloths, recourse was had to foreign wools, and to those chiefly that were derived from the Merino sheep. As early as the commencement of the Christian æra, the wool of the Spanish sheep was in great request for the production of the most costly dresses. In less than half a century afterwards we find Columella busily employed in improving the Spanish sheep, and the effect of his labours remained during the long dark ages that succeeded. The present Merino flocks seem to have been produced by a cross of the native breed with a flock sent from England. [MESTA.] By degrees the Merino sheep found its way to almost every part of the European Continent, and by careful management its fleece rapidly increased in fineness and in usefulness. In Australia the cultivation of the Merino sheep and its fleece has proceeded most rapidly and prosperously.

We may here refer to WOOL for further details concerning the application of the fleece.

In relation to the supply of sheep from foreign countries, the following have been the imports during the last three years:—

1848	128,406.
1849	126,248.
1850	137,646.

The sheep sold at Smithfield during the last ten or twelve years have varied from 1,500,000 to 1,800,000 annually.

SHEERS, or SHEARS. The shears used in masting ships consist of two large poles, the lower ends of which rest upon thick planks laid along the sides of the deck, while their upper ends are lashed together so as to cross each other exactly over the hole in the deck through which the mast is to be dropped, they being sustained in this position by ropes radiating from the top to various parts of the vessel. To this apparatus is attached the tackle necessary for lifting the masts out of the water, when they have been floated to the side of the ship, and lowering them gently into their places. Some ships are masted by the aid of tackle attached to old worn out ships of war called *sheer hulks*, while others are drawn up to the side of a *masting house* on a quay or pier.

SHEFFIELD, in the beginning of the 17th century, was still only a large village. It now displays all the features of a manufacturing town of the first importance. The principal manufacture is that of cutlery in all its branches, indeed of everything that can be fabricated of iron or of steel. The vast buildings used for the grinding of all kinds of tools and implements by steam power form one of the curiosities of Sheffield. Silver plate and plated goods form also one of the staple manufactures. Brass-foundries are numerous. Articles in Britannia metal and German silver are also manufactured. Brushes, buttons, combs, and optical instruments, are also made here to a considerable extent; and various workmen are employed on manufactures which are connected with the staple commodities of the town, such as cabinet-case makers, haft and scale presssers and cutters, powder-flask and shot-belt makers, silver refiners, wood turners, &c. There are also many mercantile houses, some of which confine themselves to the home markets, while others export to the Continent, to Brazil, the Cape of Good Hope, but especially to the United States of North America. The spring knife makers and table knife makers are the largest classes of artisans. The fork makers are an unfortunate class, owing to the injurious effects of what is called dry grinding: the dust of the stone and metal rises in clouds, and is necessarily inhaled by the workmen, the average duration of whose lives is thus very much shortened. It is to the immense coal bed occupying the surrounding district that Sheffield owes its prosperity; for much of the iron which is there converted into steel comes from Sweden.

It would be difficult to enumerate all the kinds of articles manufactured in this busy town, made principally of steel. They comprise pen, pocket, pallet, table, and other knives, anvils, vices, augurs, gimblets, awls, axletrees, traces and bits, Britannia metal goods, coach springs, razors, edge tools, fenders and fire-irons, files, German silver goods, mathematical instruments, machinery, saws, scales, shears, scissors, scythes, sickles, silver and plated goods, skates, snuffers, spoons, steel plates, steel ornaments, musical instruments, &c.—all of which are represented at the Great Exhibition. Some of the curiosities of Sheffield industry are mentioned under CUTLERY, and FILE; and we may here notice a contribution to the Exhibition, consisting of a clasp knife only three-eighths of an inch in length when open, and so small as to go within the stem of a tobacco pipe. It is not by these trifles, however, that the commercial importance of Sheffield industry is shown; it is in those larger and useful products which are known in every part of the world where English goods penetrate.

There is a School of Design at Sheffield, which is gradually infusing a taste into those who have to determine the patterns to which goods shall be wrought.

SHELL. For various applications of shells to useful and ornamental purposes, see CAMEO; MOTHER OF PEARL; TORTOISESHELL.

SHELL, is also the name of a hollow globe of iron, containing gunpowder, which is introduced at an orifice formed in the ball. In this orifice is driven or screwed the fuze or tube containing the composition by which the powder in the shell is ignited [FUZE]; and the shell, after being discharged from a gun, howitzer, or mortar, is consequently made to burst in pieces when it falls upon or near the object to be destroyed.

SHELLAC. [Lac.]

SHERBET, in Persia, Turkey, and other eastern countries where it is chiefly used, is a beverage composed chiefly of water, lemon-juice, and sugar, with the addition of other ingredients to render it more pleasant to the taste, as the pulp of fruits, perfumed cakes, rose water, &c.

SHIP BUILDING. The most essential conditions in the construction of a ship are, that it be capable of carrying its stores and its artillery or lading; that it be moved by wind or steam with great velocity, and that it readily obey the motion of the rudder; that it have the necessary stability, so as not to be overturned when acted upon by the wind or waves; and finally, that its rolling or pitching be attended with as little strain as possible on the timbers. In merchant ships an ample capacity is frequently of more importance than a great velocity in sailing. In ships of war the number and weight of the guns constitute the basis of the design; for from these the weight of the whole ship, or the volume of the water which it will displace, may be estimated. The draught of water (the depth to which the ship is immersed) may depend on the depth of water in the harbours and roadsteads; but it must also be determined from experience, so that the ship may be prevented as much as possible from making leeway. Finally, the form of the body must be that which is most favourable for velocity, by causing the least possible resistance of the water at the bows and along the sides; which allows the greatest lateral resistance, and which will permit the rudder to act with most effect in causing the ship to be turned about a vertical axis. Experiments have shown that when the quantity of sail is the same, the velocity of a ship is increased by increasing the ratio between its length and breadth.

It has been found that ships having the same proportions possess unequal sailing properties; it may be perceived indeed that a small ship built according to the proportions of a large one which is know to sail well, will not possess the like good quality; so that the sailing qualities depend on something more than mere form. That a ship whose hull has been constructed according to the best rules of art does not always fulfil the conditions required, may depend on several causes. The blocks, ropes, &c., may be too heavy, and the sails may be badly formed; or the burden of the vessel may be unskilfully distributed.

In building an ordinary ship the draughtsman draws a plan, analogous to that of an architect in building a house; the drawings represent the intended vessel in many points of view—not only as a whole, but in respect also to the curvatures of the various timbers. Thin pieces of lath are cut and marked so as to assist in determining the proper sizes and shapes of the timbers. For a large East Indiaman there are upwards of 100 of these *moulding pieces* (as they are called) prepared. The oak and elm trunks are then cut up to the proper forms for the timbers, by sawing, the moulding pieces serving as guides. All being cut and prepared, the building of the ship commences. The *keel*, which is formed of elm, is scarfed together very strongly. The *stem* and *stern-posts*, of oak, are raised and fixed at the two ends of the keel; and various pieces called *transoms, fashion-pieces*, &c., help to give form to the two ends of the ship. Stout timbers, called *floor timbers*, are laid athwart the keel; and around them solid wood, called *dead wood*, is packed in, to form a solid foundation. Then come the *ribs* of the ship, which are the curved oak timbers bending upwards and outwards from the keel to the top; these are formed of several pieces called *futtocks* or *foothooks*, which are securely bolted together. These various timbers are strengthened with inner timbers, called the *keelson*, *stemson*, *sternson*, *riders*, &c. All the outside is covered with oak planking, varying from three to six inches in thickness, and arranged in parallel rows called *strakes*. The filling up the interstices between these planks has been noticed under Rigging. The *beams* are timbers of great strength, to support the deck, and to bind the sides of the vessel together; while the *knees* are immense brackets which support the ends of the beams. The *decks* are formed of Dantzig fir or yellow pine, laid in boards from six to ten inches in width, and from two to four in thickness. The *treenails* are the oak pins or bolts by which the planks are fastened to the timbers of a ship. [Treenails.]

The *sheathing* of ships at first consisted of a second covering of planks applied on the exterior of the first, over the bottom and sides as far as they were under water; but this being found to impede the motion of the ship, a sheathing of milled lead (the invention of Sir Philip Howard) was subsequently employed. The application of plates of copper as a covering on the exterior of ships was first tried in 1760; and in 1783 all those belonging to the royal navy were ordered to be covered or sheathed with that metal. By this practice shells and sea-weeds are prevented from adhering to the sides and bottoms; the friction of the water against them is diminished, and the damage which would be caused by worms is avoided. Owing to the great expense of copper sheathing, which has the effect of limiting its use in mercantile shipping, many attempts have been made to substitute for it either other metals, or alloys in which it is mixed with cheaper metals, such as lead, or with such as might increase its durability, as zinc. Iron, protected by the galvanic action of zinc, has been used. Sheathing of brown paper, coated with tar, and a kind of felt, into the composition of which a considerable quantity of cow-hair enters, have also been tried. Copper sheathing is usually applied in sheets about 4 feet long and 14 inches wide, the thickness being such that a square foot weighs from 16 to 32 ounces, but most commonly from 20 to 28 ounces; and the mode of application does not vary materially whether the copper be laid upon the bare planking or upon an interposed layer of tarred paper, felt, or thin boarding. The sheets are pierced with holes, not only round the edges, but also at intervals of 3 or 4 inches over the whole surface; they are laid so as to overlap each other about an inch, and are secured to the ship with flat-headed copper nails. An East Indiaman requires re-coppering after two voyages; and the old copper is found to have lost three or four ounces of its weight in the square foot, by the action of sea-water, friction, and other causes.

The *masts* of ships are built of several pieces selected from the strongest parts of trees, and attached together both in the fore-and-aft and in the athwart-ship directions, the whole being bound together by hoops at intervals. Usually the central piece consists of one log of timber reduced to a many-sided form, and to the sides of this are applied other pieces, which are connected with it either by a longitudinal projection in each, which is let into a corresponding channel made in the central piece, or by blocks of hard wood which are let into both the central and attached pieces.

Vessels of iron are now very frequently constructed both for rivers and for navigation in the open seas, and they have many advantages over ships of wood. They are much lighter, or more buoyant. They are less liable to become arched, and are better able to withstand the effects of striking upon a rock. In the latter case a ship of wood would have its bottom pierced, or it might go to pieces, while the iron one would merely become indented. They are formed with rib frames at intervals, and with longitudinal hoops of iron; and they are covered with iron plates, which are fastened to the ribs by bolts or rivets. The lower part of the interior may be divided into compartments, which can be rendered air-tight; and thus, in the event of the bottom being perforated in any place, the water would be confined within that compartment till the damaged plate could be repaired or replaced.

Ships have different designations, according to the number of their masts or the disposition of their sails. The word *ship* is more particularly applied to those vessels which have a fore, a main, and a mizen mast, with a top-mast and top-gallant-mast to each; and in which the yards, in sailing before the wind, are braced square, that is, in vertical positions perpendicularly to the length of the ship, the mizen-sail alone being usually in a fore-and-aft position, that is, in a vertical plane passing through the keel. A *bark* is a vessel with masts and sails like those of a ship, except that the mizen-mast carries no top-sail or top-gallant sail. A *brig* has a fore and a main mast, with top and top-gallant masts and sails, like those of a ship; but it has no mizen-mast, and the main-sail has a position corresponding to that of the mizen-sail in a ship with three masts. A *snow* is rigged in the same manner as a brig, except that the main-sail is attached to a small mast abaft of and very near the main-mast. A *schooner* has two masts, and the sails attached to them are, in their usual position, in vertical planes passing through the keel: it has small or no top-sails. Lastly, a *sloop* (shaloop) has only one mast, with a main-sail, whose plane is usually in a fore-and-aft position. Each of the different kinds of ships has a bowsprit which carries a fore-stay-sail and a jib-sail.

In the British navy, ships which carry 70 or a greater number of guns are called *line-of-battle ships*. *Frigate* is a term which is supposed to have been first applied to a light galley moved by sails or oars; but it is now applied to ships of war, generally with two decks, and carrying from 36 to 60 guns. These are built narrower than line-of-battle ships in proportion to their length, and sail swiftly. They accompany fleets in order to watch at a distance the movements of the enemy, and they act singly against ships of a like kind. Ships of war of a lower class than frigates have the denominations of *sloops*, *corvettes*, *brigs*, *cutters*, *brigantines*, *ketches*, *schooners*, and *barks*. The sloops of war and corvettes carry from 4 to 20 guns, and some brigs carry 16 guns. The number of guns in a vessel of either of the remaining classes does not exceed 10.

The tonnage of a ship is, properly, an expression for the interior capacity by the number of tons of sea-water which it could contain; therefore, if the interior volume were found in cubic feet, on dividing that volume

35 (the number of cubic feet of sea-water which are equal in weight to one ton), the quotient would be the tonnage required. There have, however, been various modes of estimating ships' tonnage.

There are now employed in the yearly transit of Great Britain with the world and with her own shores, about 33,700 sailing vessels, and 1150 steam vessels, employing 240,000 seamen. Calculating the value of each ship and cargo, as the value has been estimated before parliament, at 5000*l.*, we have an aggregate value—sailing vessels, steamers, and their cargoes included—of about 174,000,000*l.* Further, supposing that the yearly wages of the seamen, including officers, was 20*l.* per head, the amount paid in wages would be 4,800,000*l.*

Various details bearing more or less closely on the subject of ship-building will be found under ANCHOR; BLOCKS; RIGGING; ROPE MANUFACTURE; SAIL MAKING; SCREW PROPELLER; SHEERS; STEAM VESSEL; &c.

SHOE TRADE. In addition to the few details given under BOOT AND SHOE MANUFACTURE, the following may not be out of place.

In the old statutes a shoemaker is called a cordwainer, apparently a corruption of the French *Cordonnier*, which means a worker of Cordova leather. The companies of shoemakers in our ancient towns were incorporated under this name; and where some of these companies still exist, they still go by the same name. As a legal term, cordwainer is yet in use.

The trade, as now followed in London and other principal places, is subdivided into about twenty branches. The following may be set down as the chief: the shoeman, or maker of the sole part of the shoe; the bootman, or maker of the sole part of the boot; and the boot closer, or joiner together of the leg, vamp, &c. The labour of these is especially directed to what is called the men's line; whilst others make the ladies' shoes or boots. There are many women, too, who get a livelihood by closing the shoe; while others again follow the various sorts of binding.

The mechanical processes, after marking and cutting out the leather, consist chiefly in various kinds of strong needlework, such as the lasting or tacking of the upper leather to the in-sole, the sewing in of the welt, the stitching to this welt of the out or top sole, the building and sewing down of the heel, and the sewing or closing of boot legs. The boot closer is the most skilful of the persons employed, and receives the highest wages.

No other common handicraft is exercised by so large a number of persons as that of the shoemaker. In the metropolis and in many parts of the country, women are extensively employed in the lighter parts of the business. The government contracts for the army and navy, the police, &c., are executed in London and at Northampton and Stafford; and the export market is almost entirely supplied from these quarters. The boots and shoes exported (chiefly to the East and West Indies and the colonies) are included in the general entry of 'leather wrought and unwrought,' in the parliamentary returns; but it is supposed that the value is about a quarter of a million sterling annually.

In 1850 there were imported, almost entirely from France:—

Women's boots and calashes	22,346	pairs.
Women's shoes	119,420	"
Men's boots and shoes	31,178	"
Children's boots and shoes.	1,698	"
Boot fronts	603,302	"

SHOT are the balls (generally solid) of iron which are discharged from guns, howitzers, or carronades. Solid shot vary in diameter from about two inches, which is that of a one pound ball, to about eight, which is the diameter of a 68-pound ball. For the naval service it has been proposed to discharge from howitzers hollow shot, or unloaded shells, which, having greater diameters than solid shot with equal weights, are capable of producing more destructive effects against shipping.

SHOT MANUFACTURE. The larger kinds of shot, such as pistol bullets and rifle balls, are generally cast in a mould, one at a time. Shot of the next smaller size, such as swan shot, are often produced by casting several at a time; there is a double mould formed something like a pair of nut-crackers, which, when closed, exhibits a range of little moulds into which the melted lead can be poured; and, when open, allows the shot so made to be removed from the mould. A ruder kind is sometimes made by shaking a number of small fragments of lead together in a bag or box, by which the corners or rough edges are worn away. In another mode of manufacture, a piece of thin lead is cut up into litle cubes, and these are placed between two flat stones, the upper of which works over the lower; so that by the combined pressure and movement the cubical fragments are worn to a cubical shape.

But the most remarkable mode of making shot is by *granulation*, which is the plan now adopted for the larger portion of shot now used. The shot are made either over the mouth of a deep well or shaft, or at the top of a lofty tower, so as to provide a vertical descent of one or two hundred feet. The elegant tower (intended originally as a shot-tower, but now applied to other purposes) near the foot of Waterloo Bridge, illustrates the latter of the two methods. In some of the shot works on the banks of the Tyne, an abandoned coal shaft is employed. There are about fifteen sizes of shot made by the granulation method, varying from $\frac{1}{5}$ to $\frac{1}{30}$ of an inch in diameter.

The lead has a little arsenic added to it, and is melted in a furnace or pot. Over the vertical shaft is placed a tripod or stand, and upon this a kind of colander, pierced with holes suitable in size to the shot to be made. A layer of dross from the surface of the melted lead is laid over the holes in the colander, to act as a kind of sieve or strainer, and to separate the liquid lead into small trickling streams before it reaches the holes. The melted lead is poured into the colander by a ladle; and it speedily falls as a sort of silvery rain down the shaft, into a vessel of cold water at the bottom; the lead is found to separate into almost perfectly spherical drops or shots; and these shots when cold, are brought up from the vessel below, dried on steam heated plates, and separated into sizes by sifting. The irregular or ill-shaped shot are separated from the others by a beautiful contrivance; they are made to roll down an inclined plane of smooth iron; and when they get to the bottom, the well-shaped shot have acquired an impetus which sends them into a box or cell, several inches distant; whereas the ill-shaped shot, having descended the inclined plane in an irregular way, have acquired very little velocity, and fall into a cell or box not so far distant as the other. By carefully adjusting the slope of the inclined plane, this separation of good from bad shot is effected with surprising accuracy. The shot are then placed in a kind of churn or revolving barrel, into which a little black lead is also placed: and they are revolved in the churn until they become polished and black leaded. They are lastly tied up in bags containing 28 lbs. each.

SHROPSHIRE. The coal-field of Coalbrook-Dale is the most extensive and most productive part of the carboniferous system of this county. It extends from near Wenlock, on the right bank of the Severn, across that river to Wellington on the N.W., and is prolongated in a N.E. direction to Lilleshall. The most productive portion of this field includes Broseley on the south, and stretches north of the Severn in a large triangular-shaped mass, having Lilleshall for its apex. In several places the seams of coal are numerous and of considerable thickness. At Hadley the number of seams is 16, and the total thickness of coal 15 yards; at Madeley, the seams are 24, and the thickness of coal $10\frac{1}{2}$ yards. The ironstone of this field is both concretionary and flat-bedded, and the various courses of it are known under various local names. The ores of iron are peroxides in sandstone, argillaceous carbonates in shale, and sulphurets in the coal. The sulphuret of iron is the most abundant mineral, and next to it is the sulphuret of zinc, or blende. Petroleum occurs in great abundance in both the upper and lower measures, and some of the beds of shale of the latter afford excellent fire-clay, which is used in the manufacture of pipes and pottery. The Shrewsbury coal-field extends from the Severn at the Breidden Hills on the west, to Shrewsbury on the east. The strata of this coal-field belong to the upper or youngest series of coal-measures. It varies in thickness from three to eight feet. The coal-field of Oswestry is situated on the western verge of the county, and is quite distinct. It contains only two seams of coal worthy of extraction, the upper being four feet thick; the lower, which is six feet thick, is a very inferior coal. The other coal-fields of Shropshire are situated on the south side of the county.

The farms in Shropshire are for the most part arable, but some are for grazing, for hay, for the dairy, and for rearing and feeding. The crops in general cultivation are wheat, barley, oats, peas, vetches, turnips, potatoes, and beans. The meadows adjoining the Severn, and other rivers and streams, are rich, and are often overflowed, and the water lies on them, especially near the Severn, for a considerable time. The rich coal-formations of this county and the iron-stone associated with them give employment to several thousand persons. The greater portion of these are engaged in raising coal, ironstone, and lime, and in the manufacture of iron, and a few in the lead mines on the western side of the county. Near Coalport china of every description and of exquisite workmanship is made; and at Caughley, in the neighbourhood of Broseley, there is another china manufactory, which is chiefly confined to the blue and white, and blue, white, and gold sorts. At Coalport there is a manufactory of earthenware, similar to the Etrurian or Wedgwood ware. There are flannel manufactories at Shrewsbury, Oswestry, Church Stretton, and Worthen. Carpets are made at Bridgnorth. Gloves are made at Ludlow, but not in such quantities as formerly. There are mills for dyeing woollen cloth at Le Botwood, &c., and there are paper-mills at Ludlow, Bridgnorth, Cleobury-Mortimer, Drayton, &c.

SIAM. This portion of south-eastern Asia is rich in natural productions. Rice is most extensively cultivated. On the alluvial soil of the Menam it generally yields forty fold. Maize, several leguminous plants, sweet potatoes, cocoa, and areca palms, are cultivated. Siam is noted for a great variety and abundance of fruit-trees, and their produce surpasses that of all other parts of India in flavour. Several plants are cultivated as articles of foreign trade. The most important is the sugar-cane, which indeed has been grown in Siam from time immemorial; but its culture for the foreign market has now become very large. Tobacco, cotton, and black pepper, are also exported. The forests, which cover nearly all the mountain ranges of this country, yield several articles of trade; among which are cardamums, gamboge, aquila-wood, sapan-wood, gum trees, and a great variety of timber trees. The elephant exists in the greatest perfection, and the ivory, hides, and bones are largely exported to China.

Gold is found in the mountains of the Malay peninsula, and at the southern extremity of those of Siam, and is worked in some places. Tin, iron, copper, lead, zinc, and antimony are met with in many places. The only precious stones which are known to exist in Siam are the sapphire, the oriental ruby, and the oriental topaz. Salt is made in the low wooded and uninhabited country which extends between the mouths of the Menam along the sea.

The Siamese do not distinguish themselves in any of the useful arts, and are much behind the Hindoos and Chinese. Even their vessels and trinkets of gold and silver are imported from China. Considerable manufactures are carried on: but they are mostly in the hands of Chinese who have settled in Siam.

Siam in a commercial point of view is considered the most important of the three empires which divide among them the countries between the Gulf of Bengal and China. As all the provinces of the empire produce some articles which are in demand in foreign countries, and nearly all the foreign commerce is at present concentrated in the town of Bangkok, the inland and coasting trade is very considerable. Large quantities of produce are brought down to Bangkok from the inland districts, by the rivers, especially the Menam. The most important branch of the foreign trade is that with China. It is partly carried on by Chinese vessels, but mostly in vessels built in Siam and navigated by Chinese. Very little if any commercial intercourse exists between Siam and the Birman empire. With Cochin-China there is much commerce. The most important trade, next to that with China, is with the European establishments on the Malay peninsula, and the Sunda Islands, especially with the British colonies of Singapore, Malacca, and Pulo Penang, and with the Dutch establishments of Batavia, Cheribon, and Samarang in Java, Pontianac in Borneo, and Rio in Bintang. Formerly the commodities of Hindustan and Europe reached the capital of Siam by being transported across the isthmus of Kraw and the Malay peninsula; but at the present day Singapore is a better emporium for procuring the goods, and the conveyance by this route is less expensive.

SIBERIA. This vast but little known region is very rich in metals. There are three extensive mining districts. The most western comprehends the mines of the Ural Mountains; which are rich in gold, silver, and copper; and they contain also iron, silver, and platinum in smaller quantities. The second mining-district is that of Bernaul, which yields much silver and copper, but less gold and lead. The mines from which these metals are obtained lie mostly in the Altai Mountains and in those valleys which open to the Irtish River. The third mining-district is that of Nertshinsk, which is situated on the east of the Yablonoï Khrebet, in the basin of the river Amur. These mines contain gold, lead, silver, iron, antimony, and arsenic. The western parts of Siberia get the salt which is required for their consumption from the salt lakes in the steppes of Ishim and Barabinsk, in some of which the salt crystallises spontaneously. The countries bordering on the river Lena obtain salt partly from some salt-springs which occur in the vicinity of the town of Ust Kutsk, and partly from the river Vilui. Da-Uria obtains its salt from one of the lakes of the Gobi, called Dabassuneï Lake, not far from that of Khara. Several kinds of precious stones occur in Siberia, and diamonds have been found along the eastern declivity of the Uralian range. The amethysts, topazes, emeralds, and red tourmalines, are of great beauty; zircons of extraordinary size have been found near Miask, south of Ekatarinburg. Lapis lazuli and talc of fine quality are met with. The tusks of the fossil elephant constitute an article of commerce, and many persons make the discovery of them the business of their life.

Siberia possesses tanneries, iron foundries, glass works, and manufactures of coarse woollens and linens; but their number is inconsiderable. There are smelting and refining works connected with the mines.

Siberia carries on an extensive commerce with Russia, Bokhara, Tashkend, and China.

The most important is the trade with Russia. The transport of the goods is effected by a road which leads from Perm in Russia to Ekatarinburg and Tobolsk. The commerce which is carried on at Kiachta with the Chinese has been noticed under KIACHTA. The goods from Irkutsk to Kiachta, and from Kiachta to Irkutsk, are conveyed from May to November, by large vessels which navigate the Lake of Baïkal and the river Selenga, and in November and December by carts on a mountain road. The inhabitants of Siberia have also some commerce with Tartary.

SICILY. The mineral productions of this island consist of copper, silver, cinnabar, and sulphur, of which last a large quantity is exported to Great Britain, marble, alabaster, and rock salt. A great deal of wine is made in Sicily of which the Marsala is best known in England. Dried raisins are exported from Messina. Messina is also the depôt for the currants of the Lipari Islands, of which about 12,000 barrels are yearly sold and exported to Trieste, England, and America. Oranges and lemons are fine and plentiful. Olive oil and linseed oil, lemon juice, as well as essences of lemon and other fruits, are made for exportation. A little silk is produced. Liquorice-juice is made in large quantities. Manna, almonds, pistachio nuts, sumach, and figs, are among the produce exported. Kid and lamb skins are dressed for exportation. The cattle, sheep, and horses, are mostly of inferior breeds, and not in good condition.

The manufactories of Sicily are neither numerous nor on a large scale. Cotton-cloth is manufactured at Messina, Catania, Palermo, and Caltagirone; silks at Palermo, Catania, and Nicolosi; leather at Messina; gloves, soap, artificial flowers, and paper at Palermo; coral from the coast of Africa is wrought at Trapani.

Concerning the chief commerce of Sicily, a few details will be found under SULPHUR.

SIERRA LEONE. This British colony was established in 1787, by some philanthropists, who intended to show that colonial productions could be obtained without the labour of slaves. In that year 470 negroes, then living in a state of destitution in London, were removed to it, and in 1790 their number was increased by 1196 individuals of the same race, who had been settled in Nova Scotia, but could not bear the severity of that climate. Ten years later 550 Maroons were transported from Jamaica to Sierra Leone; and in 1819, when a black regiment in the West Indies was disbanded, 1222 black soldiers and their families were settled there likewise. In 1820 the population amounted to 12,000 individuals. Since the abolition of the slave-trade (1807), the slaves captured by the British cruisers have been settled in the colony: and the population has increased so that in 1848 it amounted to 46,511. The towns, or rather villages in the settlement, besides Freetown, the capital (which has nearly 20,000 inhabitants), are—Kent, York, Calmont, Waterloo, Hastings, and Wellington. About 20,000 of the inhabitants are liberated Africans, and about an equal number are descendants of liberated Africans, born in the colony. The number of Europeans is very small. The chief article of export is ground nuts, from which is expressed an oil largely used in lubricating machinery: in 1846 the quantity amounted to 8697 tons, valued at 92,049*l.* The other chief articles of export are—ginger, teak timber, hides, palm oil, and camwood. Nearly one-third of the imports consist of British cotton goods. The vessels which arrived at Freetown in 1847 were 185. There are about 120 fishing boats belonging to the settlement.

Sierra Leone, like our other colonies, is gradually reaping the benefits attendant on steam navigation. The new mail screw steamers, which have lately begun to ply between Plymouth and the Cape of Good Hope, call at Sierra Leone going and returning; thereby placing the colony in advantageous connexion both with the mother country and with another colony.

The imports in 1848 amounted in value to 89,174*l.*; and the exports to 95,617*l.* In 1849 the imports from Great Britain were 60,290*l.*

SIGGAR, SEGGAR, or SAGGER. This name, the origin of which does not seem to be well known, is given to the oval vessels in which articles of pottery or porcelain are placed, to protect them from flame and smoke while exposed to the heat of the kiln. [POTTERY.]

SIGNALS. [TELEGRAPH.]

SIGNATURE, in Printing, is the name given to the letters or figures which are placed at the bottom of certain pages in each sheet of a book, to facilitate the gathering, folding, collating, and binding of it. [BOOKBINDING.]

SILESIA. This important Prussian province produces flax, tobacco, hops, madder, woad, teazle, and timber. The minerals are copper, lead, cobalt, arsenic, iron, zinc, sulphur, marble, alum, lime and coal. The linen manufacture of Silesia is of great importance; it is carried on with little aid from machinery, and chiefly by the country people, though this branch of industry affords them but a scanty subsistence; it is however their chief occupation. Woollen cloths are manufactured in some towns, and cottons at Reichenbach. There are sugar refineries in several places; woollen-cloth factories, tanneries, breweries, and brandy distilleries in most of the towns. The cotton manufactures are extending; steam machinery has been introduced into the manufactories; at the end of 1846 the province had three large and eight smaller cotton factories, with 35,524 spindles, and 1749 workpeople.

SILHOUETTE. This name is frequently applied to the black profile portraits commonly known simply as *Profiles*, or *Shades*. The latter name indicates the origin of this simple class of pictorial representations, they having been probably suggested by the shadow thrown upon a wall. Silhouettes are executed in various ways. One of the simplest is that of tracing the outlines of a shadow thrown on a sheet of paper, and then reducing them to the required size, either by the eye or by means of a pantograph. [PANTOGRAPH.] Another mode is tracing the outline upon a glass supported in a suitable position, and either coated with a solution of gum-arabic in water, in order to enable a lead pencil to mark upon it, or covered with a sheet of very thin tracing-paper.

SILEX or FLINT. This valuable substance is an oxide of *Silicium* or *Silicon*, which is regarded by some chemists as a metal, and hence the termination of its name in *um;* while others consider it as non-metallic, and more allied to boron, and these adopt the term *Silicon*. Sir H. Davy was the first to separate this substance from Silica. Silicium is of a dark brown colour, has no lustre, and is a non-conductor of electricity. It is insoluble in water, and incombustible in air or in oxygen gas; it neither fuses nor undergoes any other change when heated in the flame of the blow-pipe.

Oxygen and *Silicon* form only one compound, namely, *silex* or *silica*. Silica exists very largely in nature: it is indeed probably the most abundant of all substances whatever. Many of the forms under which it occurs are mentioned elsewhere. [FLINT; QUARTZ.] Rock-crystal is silica nearly or quite pure; and flints, or white sand, are but slightly intermixed with other bodies. Pure dry silica is an opaque white powder, inodorous, insipid, and gritty. It is infusible by the heat of ordinary furnaces, but by the oxy-hydrogen blowpipe it is more readily fused than lime or magnesia. Silica is a substance of the utmost importance in many respects; it enters largely into the constitution of minerals, rocks, and fossils, and is employed in the manufacture of glass, porcelain, pottery, bricks, tiles, and mortar.

SILK MANUFACTURE. China was undoubtedly the country in which men first availed themselves of the labours of the silk worm. Aristotle was the first Greek author who mentions the silk-worm; and he states that silk was first spun in the island of Cos, but the raw material was still an oriental product. For many centuries it was not known in Europe from what source silk was produced. It was not indeed until the sixth century that the obscurity which enveloped this subject was cleared up, by the successful result of a journey made by two Nestorian monks to China to unravel the mystery. The breeding of silk-worms in Europe was for six centuries confined to the Greeks of the Lower Empire. In the 12th century the art was transferred to Sicily; in the 13th century the rearing of silk-worms and the manufacture of silk were introduced into Italy, whence it was successively introduced into Spain and France, and in the 15th century the manufacture was established in England.

James I. was extremely solicitous to promote the breeding and rearing of silk worms in England; but all attempts of this kind have failed both here and in the United States, partly from the unfitness of the climate, and partly from the high-rate of wages, which renders this employment better adapted to the social condition of China, Italy, the south of France, and Malta, where the wages of labour have nearly reached their minimum. Mrs. Whitby, a lady who has made praiseworthy attempts to foster the growth of silk in England, communicated the results of her partially successful labours to the *Royal Agricultural Society*, in 1844, and to the Birmingham meeting of the *British Association* in 1849. The production of raw silk is fast extending in British India, and the quality has been for some years gradually improving. The countries in which silk is produced are now very numerous.

But although English silk-culture has been hitherto a commercial failure, there are from time to time attempts made which merit attention. To the Great Exhibition has been contributed a scarf woven by the wife of a clergyman, from silk reared by herself; and although such a production is a family curiosity rather than a commercial result, it may be interesting to read her own account of it. 'Having resided for about three years in a vicarage in Hertfordshire, the garden of which possessed a remarkably fine mulberry tree, I wished to give my family an idea of the habits and natural history of the silkworm, and the method by which silk is produced. With this view I procured a quantity of eggs early in the spring of 1847, which were hatched about May, and I placed the worms, 2000 or rather more in number, in an outhouse in the garden. There they were attended and fed by myself and some of the juvenile members of my family, and in due time they spun; and much wishing to turn the produce of their industry to some use, I directed my attention towards making the scarf which I have the pleasure to lay before you. The silk was wound from the cocoons by my daughter and myself on a winding machine, and afterwards I wove it into its present form. It has consequently never been in the hands of any manufacturer, and presents the same colour and quality as when taken from the cocoon. I may add, that the outhouse in which the worms lived had no windows to protect them from the weather, which was unusually cold for the season of the year; as I think this point may illustrate the fact that our English climate presents no insuperable obstacle to the cultivation of silk. The mulberry tree was the common kind.'

The silk is produced from that species of silkworm which, when in the moth state, is called the *Bombyx Mori*. This species, which was originally from China, is of a white or cream colour, with a brown fascia and two or more waved lines of a deeper colour crossing the upper wings. In this country the eggs of this moth are hatched early in May. The caterpillar, or silkworm, is at first of a dark colour, but soon becomes light, and in its tints much resembles the perfect insect,—a circumstance common in caterpillars. Its proper food is the mulberry, though it will likewise eat the lettuce and some few other plants; on these plants, however, it does not thrive equally well, and the silk yielded is of a poor quality. The silkworm is about eight weeks in arriving at maturity, during which period it changes its skin four or five times. When about to cast its skin it ceases to eat, raises the fore-part of the body slightly, and remains in perfect repose. In this state it is necessary that it should continue for some little time, in order that the new skin, which is at this time forming, may become sufficiently mature to enable the caterpillar to burst through the old one. This operation, which is apparently one of considerable difficulty, is performed thus:—The fore part of the old skin is burst; the silkworm then by continually writhing its body (but not moving from the spot) contrives to thrust the skin back to the tail, and ultimately to disengage itself altogether: this last part of the operation however is the most difficult, since it is no uncommon occurrence for them to die, from not being able to disengage the last segment of the body from the old skin.

When full grown the silkworm commences spinning its web in some convenient spot; and as it does not change the position of the hinder portion of its body much, but continues drawing its thread from various points and attaching it to others, it follows that after a time its body becomes in a great measure inclosed by the thread. The work is then continued from one thread to another, the silkworm moving its head and spinning in a zigzag way, bending the fore part of the body back to spin in all directions within reach, and shifting the body only, to cover with silk the part which was beneath it. As the silkworm spins its web by thus bending the fore part of the body back, and moves the hinder part of the body in such a way only as to enable it to reach the farther back with the fore part, it follows that it incloses itself in a cocoon much shorter than its own body; for soon after the beginning the whole is continued with the body in a bent position. From the foregoing account it appears that with the most simple instinctive principles all the ends necessary are gained. If the silkworm were gifted with a desire for shifting its position much at the beginning of the work it could never inclose itself in a cocoon; but by its mode of proceeding, as above explained, it incloses itself in a cocoon which only consumes as much silk as is necessary to hold the chrysalis. During the time of spinning the cocoon, the silkworm decreases in length very considerably, and after it is completed it is not half its original length; at this time it becomes quite torpid, soon changes its skin, and appears in the form of a chrysalis. The time required to complete the cocoon is about five days. In the chrysalis state the animal remains from a fortnight to three weeks; it then bursts its case, and comes forth in the imago state, the moth having previously dissolved a portion of the cocoon by means of a fluid which it ejects.

Silk is obtained also from the spider; not from the cobweb, but the silky thread which the female spider spins round her eggs. The silken fibres of the pinna form a strong and beautiful fabric; and some species of moths form cocoons which may be spun for curiosity, but not with a view to commercial profit.

Reeling from the cocoons is only performed in countries where the silk is produced. Silk reaches the weaver in three different states, in which it is called *single*, *tram*, and *organzine*, the preparation of which is the business of the throwster. In plain silk-weaving the process is much the same as in weaving woollen or linen; but the weaver is assisted by a machine for the even distribution of the warp, which frequently consists of eight thousand separate threads in a breadth of twenty inches. The Jacquard-Loom has been the means of facilitating and cheapening the production of fancy or figured silks to an extraordinary extent. Patterns which required the greatest degree of skill and the most painful labour are produced by this machine by weavers of ordinary skill, and with but little more labour than that required in weaving plain silks. [JACQUARD]. The power-loom has been only partially employed in the silk manufacture; and excepting for the commonest goods, it does not possess any great advantage over the hand-loom, as the delicacy of the material to be worked, and the attention which must be given to the process of the weft, frequently render it necessary to stop the machine.

The general processes of the silk manufacture have been treated at some length under RIBAND; and some other articles of silk manufacture are noticed under their proper names. *Brocade* and *damask*, the most sumptuous articles of silk manufacture a century ago, are now comparatively unknown. *Persian*, *sarsnet*, *gros-de-Naples*, *ducapes*, *satin*, and *levantines*, are the names given to plain silks, which vary from one another only in texture, quality, or softness. *Satin* derives its lustre from the great proportion of the threads of the warp being left visible, and the piece being afterwards passed over heated cylinders. Other varieties of silk goods are produced by mechanical arrangements of the loom, such as using different shuttles with threads of various substances, &c. The pile which constitutes the peculiarity of *velvet* is produced by the insertion of short pieces of silk thread, which cover the surface so entirely as to conceal the interlacings of the warp and woof. The process of weaving velvet is slow, and it is paid for at five times the rate of plain silks. There are several sorts of goods in which silk is employed with woollen materials, as *poplins* and *bombazines*.

A few of the circumstances which have marked the progress of the silk manufacture in England are noticed under SPITALFIELDS. Ten or twelve years ago, one half of the silk manufactories were in Cheshire, next to which stood Lancashire, Derbyshire, and Staffordshire; but Lancashire has recently advanced more than the other counties in this department of industry. The following were the statistics of silk factories in the year 1850:

Factories in England	272
Spindles	1,188,908
Power looms	6,092
Steam and water-power	3,571 horse power.
Male operatives ..	12,513
Female operatives	29,190

Of the 272 silk factories, 97 were in Cheshire (chiefly at Macclesfield and Congleton). There were only five silk factories in Scotland, employing 841 persons. There was no silk factory either in Ireland or in Wales.

The silk imported in 1850 amounted to:—

Raw..................	4,942,417 lbs.
Waste and husks	14,600 cwts.
Thrown	469,526 lbs.

The manufactured silk goods imported in 1850, including broad silk, satin, ribbons, gauze, crape, velvet, and plush, amounted in weight to 826,650 lbs.; together with 715,739 pieces of Bandanna and other silk handkerchiefs. Our exports were 260,085 lbs., together with 410,473 pieces of silk handkerchiefs —mostly to the colonies.

SILVER. This beautiful metal has been well known and highly valued from the remotest period — circumstances which are readily explained by the facts of its occurring frequently native, and possessing great lustre and fitness for immediate use without being subjected to any metallurgic process.

Ores of silver.—The ores of silver are extremely numerous. Besides the *Native silver*, the chief ores are the following:—*Antimonial silver*, *telluric silver*, *native amalgam*, *auriferous native silver*, *arsenical antimonial silver*, *horn silver*, *earthy corneous silver*, *silver glance*, *earthy silver glance*, *light red silver*, *ruby silver*, *miargyrite*, *biegsamer silberglanz*, *flexible sulphuret*, *brittle sulphuret*, *silberkupferglanz*, *romelite*, *brittle silver*, *selensilver*, *eukairite*. *selbite*, and *ganzekothig-erz*. Most of these are known by two or three names each; some occur only in irregular masses, the rest in crystals. The ores which yield silver most readily and most abundantly are native silver, horn silver (chloride), and silver glance (sulphuret). Silver is also procured by cupellation. [LEAD.]

Silver has a purer white colour than any other metal; it has great brilliancy; and is susceptible of a high polish. Its specific gravity is about 10½. It is sufficiently soft to be cut with a knife; and is very malleable and ductile, so that it may be beaten into leaves about 1—10,000th of an inch in thickness, and drawn into wire much finer than a human hair. It does not rust or oxidise by exposure to the air, but when the air contains sulphureous vapours it tarnishes, becoming first yellowish and afterwards black. Three metals only, viz. iron, copper, and platinum, exceed silver in tenacity; a wire $\frac{1}{14}$ of an inch in diameter supports rather more than 187 pounds without breaking. When exposed to a bright red heat silver melts; on fusion its appearance is extremely brilliant, and during this it absorbs oxygen from the air to the amount of about twenty-two times its volume, and this it gives out either by cooling or being poured into water. When leaf-silver, or fine silver wire, is heated by voltaic electricity, it burns with a fine green flame; if intensely heated in the open fire it boils, and a portion is vapourised.

Oxide of silver gives a yellow colour to glass and porcelain, and is the oxide which is the basis of all the common salts of silver. The chloride of silver is perfectly white, but by exposure to daylight it becomes slowly blueish-white, and eventually almost black. The direct rays of the sun produce this effect almost instantaneously. On this property is founded its use in photogenic drawing. By mere heat it undergoes no change except fusion, and when it has solidified on cooling it has the appearance of horn; hence the name of *horn silver* for the native chloride. It is largely and advantageously used in experimental chemistry. The protoxide forms with ammonia a compound called *fulminating silver*, on account of the facility and violence with which it explodes; in exploding it forms water, sets free nitrogen, and metallic silver remains. A very gentle heat or slight friction causes it to explode sometimes even before it is dry. Nitrate of silver, when moderately heated, fuses, and being then cast in a mould in small cylindrical sticks, it constitutes the Argenti Nitras of the Pharmacopœias, commonly called *lunar caustic*. When sulphur, phosphorus, or charcoal, is mixed with nitrate of silver, and struck on an anvil, detonation ensues, and metallic silver is obtained. Nitrate of silver is employed by precipitation with carbonate of soda, &c., for writing on linen: it is commonly called *Indelible Ink*.

Iron and silver combine with difficulty; they separate on cooling, the iron retaining about one-eightieth of silver, and the silver about one-thirtieth of iron. According to Faraday and Stodart, steel containing about one five-hundredth of silver forms a good alloy for cutting instruments. Iron and silver form a blueish-white granular alloy; tin and silver a white, hard, brittle alloy. When cobalt and silver are fused together, they separate during cooling, each retaining a portion of the other. Lead and silver give a dull brittle alloy; antimony and silver a white brittle alloy; arsenic and silver form a gray, brittle granular compound, containing about 14 per cent. of the former metal. Bismuth and silver give a yellowish-white, brittle, lamellar alloy; molybdenum forms a compact, brittle, gray, granular compound with silver; and tungsten a brown, slightly malleable button: copper and silver readily combine, and the silver is rendered harder by it without much deterioration of colour; the standard silver of this country is composed of 11·10 silver and 0·90 copper. Mercury and silver amalgamate readily, and this compound is sometimes employed for plating, but this operation is now most advantageously carried on by precipitation by means of voltaic electricity.

Silver ores are found chiefly in veins which traverse the primary and the older of the secondary stratified rocks, but especially the former; and also the unstratified rocks, such as granite and porphyry, which are associated with the above. In some of the mines in Peru, and in those of Kongsberg in Norway and Freiburg in Saxony, silver has been discovered in masses weighing from 100 to 800 lbs. In the mines of Europe the veins are numerous and slender. In some of the mines in the Harz Mountains and in the Hungarian mines the veins occur in a small number of spots, and are of considerable dimensions. In three of the richest districts of Mexico there is only one principal vein, which is worked in different places. One of these veins, in the district of Guanaxuato, is from 130 to 148 feet wide, and it has been traced and worked to an extent of nearly eight miles.

In Mexico there were 500 mining establishments, called *Reales*, at the time of Humboldt's visit, and from 3000 to 4000 veins or masses were worked. The average richness of all the ores in Mexico is from 3 to 4 ounces per quintal of 102 lbs. In one of the Mexican mines a working of one hundred feet in length yielded in six months 432,274 lbs. troy of silver, equal in value to about 1,000,000*l.* In Chili some of the mines yield only 8 ounces in 5000 lbs. of ore; but in the rich mine of Copiapo, discovered in 1832, the ore frequently contains 60 or 70 per cent. of silver. The average produce of the mines of Saxony is from 3 to 4 ounces in the quintal. The lead mines of Craven in Yorkshire contained 230 ounces per ton; and those of Cardiganshire, worked in the reign of Charles I., yielded 80 ounces. The average proportion of the lead mines of the north of England is 12 ounces per ton, Even when the proportion of silver is so low as 8 ounces, or one grain per ½ lb., it has been found profitable to separate it. The produce of the Mexican mines averaged annually 4,800,000*l.* from 1793 to 1803, of which nineteen-twentieths were silver. In the first ten years of the present century the average annual value was about 5,000,000*l.*, the quantity of pure silver annually produced in that time being 1,440,650 troy lbs. The mines of Potosi in Peru are the most famous in South America. [Potosi.] The produce of the Chilian mines in 1832 was about 1,000,000 ounces. At the commencement of the present century Humboldt estimated the annual produce of the silver-mines of Chili, Peru, Buenos Ayres, and New Grenada, at nearly 700,000 lbs. troy, valued at 2,074,476*l.* sterling. The proportion of silver to gold produced from all the American mines was, early in the present century, as 62 to 1; and from the mines of all countries as 52 to 1.

The most productive mines in Europe are those in Saxony, Austria, Hungary, Norway, Russia and Spain; but nearly all of these are less productive than they have been in former ages. The quantity found in Great Britain is extremely small. Silver has ceased to be abundant in Asia, except perhaps in China. In Africa none is met with.

The silver mines of Copiapo are those which are now attracting the most attention. In 1824 they produced only 310 lbs. of silver; about 1830 the yearly produce was 3000 lbs.; after the discovery of new veins in 1832 the production rose to 16,000 lbs.; and during the last eight years the following results have been exhibited:—

1843	39,599 lbs.
1844	61,497 „
1845	76,723 „
1846	80,397 „
1847	102,052 „
1848	130,552 „
1849	171,119 „
1850 (about)	200,000 „

The proportional value of gold to silver was 12 and 10 to 1 from the Anglo-Saxon times to the discovery of America; it is at present 14·28 to 1. In ancient Greece the proportion varied from 15 and 10 to 1, and in Rome from 12 and 7 to 1. Herodotus estimates it at 13 to 1. Since the discovery of America the proportion throughout the world has been between 17 and 14 to 1. The English silver coinage from 1600 to 1800 amounted to about 26,000,000*l.*; from 1800 to 1840 about 11,000,000*l.*

There are nine mints in Mexico, at which the coinage was as follows in the years named.

	Dollars.	£
1842	984,427	196,885
1843	620,532	124,106
1844	726,762	145,352
1845	783,910	156,782
1846	915,752	183,150

When silver is issued for coin, it is always alloyed with copper: the maximum of hardness is produced by one-fifth of copper. One lb. of standard silver of the English coinage contains 11 oz. 2 dwts. of silver and 18 dwts. alloy, or 925 parts of pure silver in 1000 parts of standard silver. For purposes connected with the manufacture of various articles of use and ornament, the alloy is greater. At Birmingham rolled sheets are made which do not contain more than 3 or 4 dwts. of silver to each lb. of the inferior metal.

Mr. Jacob estimates the annual consumption of silver in the United Kingdom at 3,282,046 oz., valued at 820,511*l.* He distributes it as follows:—

That paying duty	1,375,316 oz.
That used in watch-cases	506,730
That used in plating	900,000
That for other minor purposes	500,000
	3,282,046

The value of the stock of silver in the hands of the manufacturers and dealers is estimated by the same authority at 3,280,000*l.* The value of ornaments and utensils of the precious metals in Europe and America, if brought to the crucible, Mr. Jacob values at 400,000,000*l.*, one fourth more than the value of the coined metals; but Mr. M'Culloch thinks these estimates too high; and as they were made before the recent discovery of gold at California, some of them are likely to be modified by the abundance of gold.

SILVERING. A few illustrations of the mechanical working of silver will be found under Birmingham, Electro-Metallurgy, and Gold-Working; but we are here speaking of the singular operation of silvering one surface of glass.

In an ordinary looking-glass, the reflexion is derived from a film of mercury or quicksilver, in contact with the hinder surface of the glass, and rendered fixed by amalgamating with a sheet of tin foil. Silvering is here not a correct term, for there is no silver employed; the process is nevertheless a highly curious one. In the first place a large sheet of tin foil is unrolled, and laid down on a perfectly flat and very smooth stone table. Liquid mercury is poured on the foil, from the iron bottles in which it is imported, and made to float over the entire surface. The glass, brought perfectly clean, is laid upon the mercury with a peculiar sliding movement, which suffices to remove the slight film of oxide which soon forms upon the surface. The glass is then entirely covered with heavy leaden weights, which could not be done with safety unless the glass and the stone were perfectly flat. After remaining a day or two in this state, with the stone slightly inclined, it is found that all the superfluous mercury has been pressed out from between the glass and the foil; and moreover the mercury has chemically combined with the foil, in such a way that both adhere firmly to the back of the glass. So great is the tact shewn in this process that in a well silvered glass there will not be found the smallest spot which has not its due share of reflective amalgam behind it.

Mr. Drayton patented a new mode of silvering glass, a few years ago. It is not only nominally but really silvering. Nitrate of silver is combined with spirit and certain liquids, and is poured on the clean surface of the glass; a border of putty or some other substance being laid round the glass to retain the liquid. After remaining thus a few hours, the liquid is poured off, and a sediment of silver is found to be left adhering to the glass. This sediment or film is secured in its place by a varnish of bees' wax and tallow.

A recent novelty is Kidd's Embroidered Glass, by which any pattern or device can be embroidered on glass, and thus fixed and rendered conspicuous by a subsequent silvering. The peculiarity of the process is that the patterns have the appearance of being in relief, or embossed on the exterior surface, and illuminated in frosted and burnished silver; whereas the whole of the processes are effected on the under surface. The engraving or embroidering is effected by peculiar tools; a peculiar composition is laid on the embroidered glass before the silver is applied; and the silver itself is applied in a way different from that adopted in any other process.

Another new production is Mr. Thomson's silvered vessels, which display wonderful brilliancy and beauty. Glass vessels of any shape, and made of glass of any colour, are silvered within in such a way as to yield a reflexion of great lustre. Some of the specimens in which green and ruby glass are thus silvered produce an effect which for gorgeousness can hardly be paralleled in any other manufacture. The surface is often richly cut and diversified; and the silvering may be made to appear at any spots selected by the workman. The silvering agent is one of the salts or compounds of silver, as in Drayton's process; but arrangements of a novel and intricate kind are requisite to the due production of the required effects.

These graceful novelties in the glass manufacture appropriately find a place in the Great Exhibition.

SINDE. This portion of India is rich in productions. Though its botanical wealth is not great, the agricultural products are numerous; all the grains and pulse common to India are grown. Rice is the staple in the delta and in the country between the Western Narra and the Indus, but in the other parts wheat and maize are most extensively cultivated. Barley is grown in some districts. Indigo is largely grown in the north-eastern districts, but it is inferior to that of Bengal. Opium is cultivated near Shikarpoor, and in some other districts. The sugar-cane is pretty generally grown throughout the whole of the province, but its produce is inferior to that of Northern Hindustan and the Panjab. Cotton is cultivated everywhere, but the best is grown in the northern districts. Tobacco of good quality is grown in the vicinity of Khyrpoor. Hemp, cucumbers, water-melons, and musk-melons, are extensively cultivated. The gardens produce carrots, turnips, radishes, onions, and several kinds of pumpkins. Among the fruits are the date, mango, pomegranate, apple, grape, lime, citron, fig, and a variety of other fruits. Ghee and hides constitute important articles of export. Sheep and goats are met with almost everywhere in upper Sinde, and wool is exported from that tract which lies west of the Indus and north of Shikarpoor.

The manufactures of Sinde are not numerous; but they may be considered extensive, when the scantiness of the population is considered. Cotton-cloth of a coarse description is manufactured in the principal towns and villages, chiefly for home consumption, and a little is exported to Afghanistan and Persia. Among the silk manufactures those of Tatta have acquired a repute in India, especially a rich fabric of silk, cotton, and gold, variegated in pattern and of close texture.

SINGAPORE. The commercial history of Singapore is remarkable. Singapore is the name of a town, of an island in which that town is situated, and of a settlement, in which the town is the chief feature. It occupies the extreme south of the Malayan peninsula, and is the most southern point in Asia. If the commerce of Singapore were limited to the produce of the place, it would hardly give employment to more than two or three vessels. But Singapore has become the London of southern Asia in the Indian Archipelago. All the nations that inhabit the countries border-

ing on the Indian Ocean resort to it with the produce of their agriculture and manufacturing industry, and take in exchange such goods as are not grown or produced in their own countries. All of them find there a ready market, which at the same time is well stocked with European goods. This effect has partly been produced by the wise policy of declaring the harbour of Singapore a free port, in which no export or import duties, nor any anchorage, harbour, nor lighthouse fees, are levied.

The commerce of Singapore may be divided into the eastern trade, the Straits trade, and the western trade. The eastern trade, or that which is carried on with the countries east and south-east of Singapore, comprehends the commerce with China, the Spanish settlement of Manilla, the independent tribes of the Indian Archipelago, the Dutch settlements on the island of Java and at Rhio, the new settlements at Sarawak and Labuan, the Australian and New Zealand colonies, and the countries of the Peninsula beyond the Ganges which lie east of the Malay Peninsula. The most important branches of this commerce are those with China, Java, and Siam.

The commerce of the Straits is carried on with the Malay Peninsula and with the island of Sumatra. The harbours on the eastern side of the peninsula, which trade with Singapore, are Pahang, Tringanu, and Calantan, and this trade is rather active. The trade with the western coast of the peninsula is not important, and is almost entirely limited to the harbour of Salangore. The commerce between Singapore and the island of Sumatra is almost entirely limited to the ports along the eastern coast of the island. There is hardly any commercial intercourse with the Dutch settlements of Bencoolen, Padang, and Tappanuli, which are on the western coast. The commerce of the eastern coast is divided between Singapore and Penang.

The western trade of Singapore comprehends that with Calcutta, Madras, Bombay, the island of Ceylon, and Arabia, with the Cape of Good Hope, Mauritius, and Australia, and with Europe and America. To enumerate the articles which constitute the materials of these three great streams of commerce would be to name almost all that Europe sells to Asia or Asia to Europe; or which are interchanged among the nations of eastern Asia

It is estimated that 300,000 tons of shipping now enter Singapore annually. The British and Irish produce and manufactures exported to Singapore in 1849 amounted in value to 494,088*l.*

SIPHON is a bent tube whose arms are of unequal length. The shorter of these arms being immersed in a liquid which is to be drawn from a vessel or a reservoir, and the air being removed by suction, or by means of a syringe, the liquid immediately rises in the immersed arm in consequence of the pressure of the atmosphere on that which surrounds the tube; it then passes over the bend and flows through the open orifice at the lower extremity of the other arm. The length of the column of fluid in this arm being greater than in the other, its superior weight causes the flow to be continuous.

The phenomena presented by springs of water are explained by supposing that the rain which is absorbed in the earth occasionally finds its way by small channels to some interior cavity, and from thence by other channels, which may be considered as natural siphons, to an orifice on a lower level at the surface of the ground. At this orifice it issues in a stream of water, which continues to flow till the surface of the water in the cavity has descended below the tops of the vertical bends in the channels.

The siphon is used in many operations in which it is required to draw liquids from one vessel to another.

SISTRUM. This ancient musical instrument was constructed of brass, and shaped like the frame and handle of a racket, the head part of which had either three or four horizontal bars placed loosely on it, which were tuned, most probably, by some scale, and allowed to play freely, so that when the instrument was shaken, piercing ringing sounds must have been produced.

SKEW-BRIDGE is a bridge in which the passages over and under the arch intersect each other obliquely. Where space and neatness do not require to be considered, an oblique arch may be avoided, either by building the bridge square with the upper passage, and making the span so wide as to allow the stream to pass under it without being diverted; or by building the arch square with the stream, and of sufficient length to allow the upper passage to take an oblique course over it; but either of these is a clumsy expedient, although well adapted for some situations.

The skew-bridges built by George Stephenson on the Liverpool and Manchester Railway were the first in which the scientific principles of the method were properly applied. On that railway, out of rather more than sixty bridges, about one-fourth were built on the skew; one, built of stone, conducting the turnpike road across the line at Rainhill, being at an angle of only 34 degrees, by which the width of span is increased from 30 feet, the width of the railway from wall to wall, to

54 feet, the width on the oblique face of the arch. In the skew-bridge at Boxmoor, the angle is 32°, the square span 21 feet, and the oblique span 39 feet. The difficulty of building skew-bridges increases with the obliquity of the angle from 90° to 45°, which is supposed to be the most hazardous angle for a semicircular arch; but beyond that point, instead of increasing, it rather diminishes to about 25°, which appears to be about the natural limit for a semi-cylindrical arch. Elliptical oblique arches are deficient in stability, more difficult to execute, and more expensive, than semicircular or segmental arches.

The construction of skew-bridges of iron or timber is comparatively simple, the ribs or girders of which such bridges are composed being of the usual construction, laid parallel with each other, but the end of each being in advance of that next preceding it. The extraordinary iron bridge by which the Manchester and Birmingham Railway is conducted over Fairfield Street, Manchester, at an angle of only 24½°, is a fine example of this kind of skew-bridge. It consists of six ribs, of rather more than 128 feet span, although the width of the street is only 48 feet, resting upon very massive abutments of masonry.

SKINS AND FURS. Under FURS is given a brief account of the fur-trade, and of the uses of furs in manufacture. We will here glance at the extent of the trade in these products, so far as Great Britain is concerned.

The skins and furs imported into Great Britain in 1848 were the following:—

Bear	9,712
Beaver	41,132
Cat	7,752
Coney	61,599
Deer	37,737
Ermine	183,547
Fitch	82,140
Fox	72,939
Goat	241,333
Kid	601,119
Lamb	1,381,524
Lynx	47,317
Marten	219,195
Mink	223,254
Musquash	766,764
Nutria	18,546
Otter	14,684
Racoon	387,313
Seal	706,267
Sheep	259,223
Squirrel	2,674,602

Some portions of these were re-exported, but by far the greater part were worked up in England.

SKY. For the description of an instrument invented in order to measure the intensity of the blue colour of the sky, see CYANOMETER.

SKYLIGHT. Including under this term every mode of admitting light into an apartment through its roof or ceiling, we may here briefly notice that particular fashion of skylight distinguished in gothic architecture by the name of Lantern, though lanterns in gothic buildings were not so much intended to admit light as to supply ventilation and the means of escape to smoke. But the term lantern is also applied to the lower part of a tower placed at the intersection of the transepts with the body of a church, which, being open below, forms a loftier portion of the interior, lighted by windows on each side; and again to an upper open story, that is, one entirely filled with windows, on the summit of a tower, and frequently forming a superstructure different in plan from the rest, as in Fotheringay Church, and that at Boston, Lincolnshire, in both which examples the lantern forms an octagon placed upon a square. The upper portion of the tower of St. Dunstan's, Fleet Street, London, may also be described as a lantern.

Of skylights, however, properly so called (that is, which are nearly in the same plane as the general surface of the ceiling), no examples are to be met with in our ancient architecture; nor does anything of the kind occur in Italian architecture, except it be in the form of a cupola over a central saloon. An example of a church lighted entirely from above, without lateral windows, is furnished by that of St. Peter-le-Poor, Broad Street, London, which is a rotunda, covered by a cove, and a large circular lantern, whose tambour forms a sort of clerestory, consisting of a continuous series of arched windows, while the ceiling makes a very flat or slightly concave dome. Sir John Soane was one of the first who attempted to give importance and decorative character to skylights and ceiling windows, or windowed ceilings, as they may be termed, making them ornamental features in his interiors, varied in their design, and producing great diversity of striking effects, occasionally heightened by the light being transmitted through tinted glass, so as to diffuse a warm sunny glow over the apartment. The offices at the Bank of England afford many studies of the kind, while his own house, in Lincoln's Inn Fields, shows what he accomplished by a similar mode of treatment, upon a very limited scale.

The form of skylights more generally used for picture galleries, libraries, and other apartments of that class, is of the simplest kind, being lanterns, not like those in gothic architecture, of narrow and straight proportions, but spacious and low, and occupying a considerable surface of the ceiling. The light is admitted through the sides of the lantern, which are mostly filled in with panes of glass, so as to form a window continued on every side, without other divisions than the bars in its framework. Of other forms of lanterns and skylights in picture-galleries and sculpture-galleries, examples are furnished by those at the British Museum and the National Gallery, London, and the Fitzwilliam Museum at Cambridge, some of which are double skylights, a smaller skylight being raised over the first one.

There are a variety of other modes of lighting rooms from their ceilings, depending in a great measure on the taste and skill of the architect, and the necessities frequently imposed by the situation or purpose of the building.

The ridge and furrow skylights (if we may thus term them) of the Exhibition Building in Hyde Park, afford the largest and simplest example ever yet constructed; as the roof and the skylight are identical.

SLATE. The slaty cleavage or structure in stone appears to be the result of a general cause acting subsequently to the deposition and disturbance of the strata, capable of pervading and re-arranging the particles so as to systematise their mutual attractions, but not to fuse them together, destroy their original distinctness, or obliterate the evidence of their original condition. This force was so general, that along many miles of country, as, for example, in the whole Snowdonian chain, one particular direction (north-north east), in North Devon and Pembrokeshire another (nearly east and west), is found to prevail more or less distinctly in all the rocks. This dependence of the slaty structure on the nature of the rock is sometimes very positively pronounced, as in some classes of rock the cleavage does change and even reverse its inclination where contortions prevail. Pressure, in some peculiar application seems to be the grand agent in the production of slaty cleavage.

For economical purposes there appears little chance of obtaining in the British Islands good Slate (properly so called) from any but the ancient argillaceous strata superposed on mica schist and gneiss, and covered by old red-sandstone or mountain limestone. From these strata in Scotland, Cumberland, Westmoreland, Yorkshire, Charnwood Forest, North Wales abundantly, South Wales, Devonshire, Cornwall, the north and south of Ireland, slates of various value are dug. The thin flagstone of the coal formation in many parts of England and Wales, the laminated sandy limestone of Stonesfield, Collywiston, &c., which are often called slates, and are extensively used in roofing, are all obtained by natural partings parallel to the stratification. True slate is split by wedges from the apparently solid rock along planes often no more discoverable than those of a real crystal. In colour it is purple, blue, green, yellowish, or almost white, or striped across the planes. In some slates (west of Scotland, Ingleton, &c.) crystals of cubical iron pyrites are scattered. Much of the Cumberland slate (Borrowdale) appears full of fragments.

Some slate quarries are remarkably situated, and are wrought under circumstances of difficulty. At Honister Crag, between Borrowdale and Buttermere, there is a quarry near the top of a mountain whose sides are so steep, that the quarrymen take up a week's provision with them, to avoid the necessity of ascending and descending every day. The slates are lowered by sledges in a mode which would be perilous to any not accustomed to it. In all slate quarries the slate is extracted in large blocks; and the lamellar structure of the slate enables the blocks to be easily separated into thin layers by the use of a chisel and mallet. All the slates in ordinary use, both for roofing and for writing on, are brought to the thin slate so familiar to us by these simple means.

A considerable increase has taken place during the last half of 1850 in the export of slate from the various quarries in North Wales; a circumstance attributed to the repeal of the brick duty causing an impetus to the erection of houses. From the port of Caernarvon alone, the exports for the half year were 61,400 tons, being an increase of 11,000 tons over the prior half year, and for the month of February, 1851, the shipment has been to the extent of 6,200 tons. In other ports a large increase is apparent.

Slate is now used for a variety of purposes as a substitute for stone in some cases, and for lead in others. Pavements, cisterns, walls, partitions, &c., are constructed. A superior production called *enamelled slate* is used for ornamental table-tops, slabs for consoles and pier-tables, wash-stand tops, columns, pilasters, door furniture, mural tables, monuments, &c.

Slate pencils are simply narrow slips of a very soft kind of slate. An ingenious kind of slate pencil has been lately devised, in which the material, brought to a very small thickness, is slid into a groove in a wooden stem, through which it is propelled by a spiral apparatus, somewhat on the principle of the ever-pointed lead pencils. In 1849 Mr. Cohen patented a new kind of slate pencil, made from a mixture of alumina, French chalk, soap-stone, and water.

SLAVONIA. The produce and industry of the Slavonian provinces are briefly noticed under AUSTRIA.

SLIDE (or SLIDING) RULE. The sliding-rule is an instrument for the mechanical performance of addition and subtraction, which is converted into an instrument for the mechanical performance of multiplication and division by the use of logarithmic scales, instead of scales of equal parts. This instrument was invented by Oughtred, about 1630, and is very little known on the Continent.

The following are the principal kinds of sliding rule now in use. The common *engineer's rule* or *carpenter's rule* in its best form, is a double 12-inch rule, a slide of two radii with the same scale on one side, and a scale of one radius of double length on the other, with divisors. Bevan's *engineer's rule*, 12 inches, has slides on both faces (which may be exchanged), and serves for squares, cubes, square roots of cubes, &c. There are scales on the backs of the slides and in the grooves, for sines, tangents, inverted numbers, compound interest and annuities at five per cent. Henderson's *double-slide rule*, 12 inches, has two parallel contiguous slides, with scales of numbers fixed above and below, and solves at one operation most sets of multiplications and divisions not exceeding five operations; at the back are tables of divisors for solids. In Woollgar's Pocket Calculator, 8 inches, the two slides work in either of the grooves: the backs and the grooves have scales of sines, tangents, areas of polygons, circular segments; interest, annuities, certain and for lives, at several rates of interest. An addition may be made by a metal slip, giving the solution of the same questions as the last rule. Woollgar's Pocket-Book Rule, 6 and 8 inches, has two radii, one under the other, a line for sines, and duplicate proportions at the back of the slide. At the bottom of the groove are sometimes inserted lines for finding the relations of right-angled triangles, for cask gauging, and for cuttings and embankments. The Excise-officer's *sliding rule*, is an instrument of which the graduations are adapted to the calculation required by those officers.

SLING is an instrument with which stones or other missiles may be thrown to a great distance. In its simplest form the sling consists of a thong of leather, or a piece of cord or some woven fabric, both ends of which are held in the hand of the slinger. The stone or missile is placed in the fold or double of the thong, which is made wide at that part, and sometimes furnished with a slit or socket for the purpose of holding it; and the sling is then whirled round to gain an impetus. In the hands of an expert slinger, this instrument may be made to project missiles to a great distance, and with surprising accuracy.

The sling was long used, both as an offensive weapon and otherwise, in England. Strutt observes, that 'it is altogether uncertain whether the ancient inhabitants of Britain were acquainted with the use of the sling or not;' but that 'our Saxon ancestors certainly used it, and seem to have been skilful in its management.' Slingers formed a part also of the Anglo-Norman soldiery.

SLUICE is any kind of flood-gate or trap to retain water for a given time, or in a given direction. Sluices are extensively used in most hydraulic works, and vary much in their construction, according to the purposes for which they are required. In mill streams they serve to keep back the water when the mill is at rest, and to regulate the supply when it is going. They also act as 'wasters,' to allow the surplus water of a reservoir to escape. For these purposes many self-acting sluices have been contrived, to avoid the inconvenience and even danger which might arise from neglect, as well as to save the expense of a sluice-keeper. For canal-locks it is necessary to make the large gates meet in an angle in the middle of the stream, in order that they may be able to resist the pressure of the water; and as this pressure would render it impossible to open them against any considerable head of water, small sluices are provided either in the gates or in the masonry of the lock, by which the water may be let in or out at pleasure.

SMALT is a glass coloured of a fine blue, by means of oxide of cobalt. [COBALT.] When reduced to an impalpable powder it is employed to give a blue tint to writing paper and linen. Upwards of 150,000 lbs. of smalt were imported in 1848.

SMEATON, JOHN. Smeaton's name will always be held in respect as long as engineering skill calls forth admiration. He was born near Leeds in 1724; he came to London about 1742, and established himself as a mathematical instrument maker in Great Turnstile, Holborn. In 1751 he constructed a machine for measuring a ship's way at sea; and in 1753 was engaged in a course of experiments 'concerning the natural powers of water and wind to turn mills and other machines depending on circular motion.' The results of these experiments were published in 1759, and obtained for him the Copley gold medal of the Royal Society in that year. Smeaton had in

1753 been made a member of the Royal Society; and had contributed to the 'Transactions' even before that date. In 1754 he visited Holland and the Netherlands. In 1766 he commenced the great work which, more than any other, may be looked upon as a monument of his skill—the Eddystone Lighthouse. [LIGHTHOUSES.]

In 1764 Smeaton was the successful candidate for the office of receiver of the Derwentwater estate, the funds of which were, after its forfeiture in 1715, appropriated to Greenwich Hospital. While holding this office he greatly improved the estate, the mines and mills of which required the superintendence of such a man to make them of their full value. Increasing business induced him, in 1777, to relinquish this engagement. Of the many useful works executed by Smeaton, Ramsgate harbour perhaps holds, next the Eddystone Lighthouse, the most prominent place. This work was commenced in 1749, and was placed under his superintendence in 1774; but was completed by the two Rennies, father and son. Smeaton laid out the line of the great canal connecting the western and eastern shores of Scotland, from the Forth to the Clyde, and superintended the execution of great part of it. The Spurn Lighthouse at the mouth of the Humber, some important bridges in Scotland, and many other works of like character were executed by him.

About 1783 Smeaton's declining health rendered it necessary for him to avoid entering upon many new undertakings. He then devoted much attention to the publication of an account of the Eddystone Lighthouse, which was to have been followed by a 'Treatise on Mills,' and other works embodying his valuable experience as an engineer. He died Oct. 28, 1792; and his numerous professional reports were published after his death by a society of his friends engaged in kindred pursuits, in three quarto volumes, to which a fourth was subsequently added, consisting of his miscellaneous papers communicated to the Royal Society, &c. Besides the works already mentioned, Smeaton introduced many improvements in mathematical apparatus, and had an ardent love for science.

SMELTING. [IRON MANUFACTURE.]

SMOKE. The action of an ordinary chimney in conveying the smoke from a fire situated at its lower extremity is very simple. The air in the chimney, being rarefied by the heat, becomes lighter in proportion to its bulk than the surrounding atmosphere, and therefore rises, its place being supplied by fresh air forced in at the lower end by the pressure of the comparatively heavy cold air outside the chimney. A constant rising current is thus created, the force of which is sufficient to carry up with it any light bodies, such as the particles of soot which escape from the fire. The higher the chimney, and the warmer the air within it, the better will the smoke ascend. Franklin enumerated nine causes for the smoking (as it is termed) of ordinary chimneys:—the want of a free supply of air to the bottom of the chimney; the opening at the lower end of the chimney being too large; the chimney being too short; different chimneys in the same house having different degrees of draught, whereby one overpowers another; the situation of the house near a higher house or a hill; the lower level of a chimney than those which surround it; the injudicious arrangement of the doors of a room; the descent of smoke in a chimney out of use; and the occasional effects of high or contrary winds. He treated all these causes in succession, and proposed such measures as he thought likely to meet the exigencies of each.

The nuisance occasioned by the smoke of coal fires has formed a subject of complaint from the earliest times in which mineral fuel was extensively used; and the great increase of steam-engine and other furnaces, consequent on the extension of manufactures, has afforded, of late years, additional grounds for attempts to abate the nuisance. Such attempts are important, not only for the purification of the air but also for the economy of fuel; since the matter which gives smoke objectionable density and colour is unconsumed fuel in a finely-divided state. It appears therefore that if a supply of air could be thrown into a fire in such a way as to occasion the combustion of the carbonaceous matter, the result would be that a greater amount of heat would be obtained from a given quantity of fuel, at the same time that the nuisance of smoke would be abated.

The quantity of smoke emitted from furnace chimneys varies much with the state of the fire; being greatest when a mass of fresh fuel is thrown on, and least when the fire has burned clear, or the fuel is fully ignited. Attention to this circumstance, on the part of the stoker, will greatly diminish the nuisance; because if he throw on the fresh fuel in a thin layer, it will the sooner become perfectly ignited; and, by laying it in the fore part of the furnace, the dense smoke arising from it has to pass over that part of the fire which is in a state of more perfect combustion, and is thereby in a great measure consumed. Many of the contrivances introduced or suggested as smoke-consuming furnaces act on these principles; arrangements being adopted to insure the right feeding of the fire without much attention on the part of the firemen. The first important attempt made in this country for the combustion of smoke was that of Watt, who obtained a patent in 1785 for a method of constructing furnaces in such a way as to cause 'the smoke or flame of the fresh fuel, in its way to the flues, or chimney, to pass, together with a current of fresh air, through, over, or among fuel which has already ceased to smoke, or which is converted into coke, charcoal, or cinders, and which is intensely hot; by which means the smoke and grosser parts of the flame, by coming into close contact with, or by being brought near unto, the said intensely hot fuel, and by being mixed with the current of fresh or unburned air, are consumed or converted into heat, or into pure flame, free from smoke.' Since that time innumerable plans have been brought forward for introducing the necessary supply of air to the furnace; but while many of them accomplish the purification of the smoke as completely as could be desired, they are generally found either to increase the consumption of fuel, or to weaken the draught of the furnace. A singular plan has been introduced by Mr. Iveson, of injecting steam into the furnace; the steam being thrown into the fire in several minute jets, from a fan-shaped distributor in the fore part of the furnace. The steam not only destroys the smoke, but also greatly increases the intensity of the fire; so much so, indeed, as to sanction the supposition that the steam is decomposed, and that its component gases are consumed. One drawback to the scheme is the great consumption of steam. A patent was obtained in 1838, by Mr. Chappé, for the use of a stream or shower of hot water thrown into the furnace in the same way.

Besides the numerous plans for the combustion of smoke, various methods have been tried on a limited scale for conducting it to a distance from the buildings in which it is formed, by means of subterraneous channels; and for condensing it by means of a shower of water, so that the sooty matter might be conveyed away by the sewers.

SMOKE-JACK, is an apparatus believed to be of German origin, and as old as the 14th century, by which the rising current in a chimney, acting upon the inclined vanes of a wheel fixed in the funnel, gives motion, through a train of wheels to any matter which is hung before the fire to roast. This contrivance is now almost superseded by jacks impelled by the descent of a weight or the uncoiling of a spring.

SMYRNA. This is one of the most important commercial cities in Asiatic Turkey. The port is frequented by ships from all nations, freighted with valuable cargoes both outward and inward. The chief imports are—coffee, sugar, indigo, tin, iron, lead, cotton twist, manufactured goods, rum and brandy, spices, cochineal, and a variety of other articles. The principal exports are—silk, opium, drugs and gums, galls, cotton, wool, valonia, and fruit. Besides these exports there are various kinds of skins, goats' wool, olive oil, wax, and a variety of other articles. This large commerce has obviously arisen, not only from the advantageous situation of the port, but from the liberal policy of the Turkish government, which has imposed hardly any restrictive enactments with few duties, and those extremely low. Many of the European states have their consuls at Smyrna, such as England, Sweden, Prussia, France, Venice, &c.

SNUFF MANUFACTURE. Snuff is made from the tobacco stalk alone, from the leaf alone, and from the stalk and leaf mixed, according to the kind to be produced. The purest kind of snuff is that which is known by the name of *Scotch*; it is either made entirely of stalks, or of stalks mixed with a very small proportion of leaf. There are many kinds of snuff called *high-dried*, such as *Welch* and *Lundyfoot* (the latter being named after a celebrated maker); these owe their qualities chiefly to the circumstance that they are dried so much as to acquire a slight flavour of scorching. The snuff called *rappee* is made chiefly from leaf, to which is added the *smalls* or broken fibre of tobacco, which are too small to be smoked conveniently in a pipe. The dark colour is principally produced by wetting the powdered tobacco in a box, and allowing it to remain a considerable time, turned occasionally with a shovel; it undergoes a slight fermentation, the degree of which gives rise to the distinction between *brown* and *black* rappee.

The original quality of the leaf is as much attended to as the subsequent processes. Scotch snuff is made from the stalks of light dry leaves; whereas rappee and the darker snuffs are made from the darker and ranker leaves. A process of scenting has great influence also on the flavour of the snuff; since the manufacturer can introduce any kind of perfume which may please his customers. Thus *prince's mixture*, and many snuffs of higher price, owe no small part of their flavour to the kinds of scent introduced.

A curious example of division of labour is presented by the Snuff Manufacture. The maker does not grind his own snuff, although he may do all else that pertains to the manufacture. Nearly all the snuff made in London is ground in and near Mitcham, by the aid of the water power furnished by the river Wandle. The explanation seems to be this—that no manufacturer makes enough snuff to keep a snuff mill going; but that the mill owner, by grinding for many manufacturers, can afford to do it at a price which renders it prudent for them to adopt this system. The mills are provided with two kinds of grinding machines; in one of these a vertical stone rolls in a circle over the surface of a horizontal stone, and grinds the snuff between them: in the other there is a kind of large pestle and mortar, in which the pestle has a rolling motion given to it instead of a series of blows. The proprietor sends the snuff to the mill after a certain stage of preparation; and after it is returned from the mill in a ground state, it undergoes certain finishing operations. Many of the London manufacturers have small mills on their own establishments, for grinding small quantities of snuff, or for passing through any particular process the various kinds of fancy snuff; but the main bulk of the snuff is ground under the arrangements just described.

SOAP MANUFACTURE. The principal kinds of soap manufactured in England are *white* or *curd soap*, made chiefly from tallow and soda, but for some particular purposes olive-oil and soda; *yellow soap*, composed of tallow, resin, and soda, to which some palm-oil is occasionally added; and *mottled soap*, made from tallow, kitchen stuff, and soda; the mottled appearance is given to this soap by dispersing the lees through it towards the end of the operation. There is also a *brown soap*, made from palm oil and resin. *Soft soap* is generally prepared from fish-oil and potash.

The harder or soda soaps are prepared by boiling the fatty matter with an aqueous solution of caustic soda; when combination has taken place, or in other words, when the soap is formed, a quantity of common salt is added, which, dissolving in the lees, increases their density, and the soap then floats on the surface of the liquid. The fire being then extinguished, the semifluid soap, after a proper interval, but while yet hot, is removed from the lees and put into frames of wood or iron, where it remains until it has become cold and hard, when it is cut into bars for sale. In making soft soap no lees are separated, the whole of the solution of potash, which is made strong on that account, being combined with the oily matter used.

The soaps which have the alkalies for their bases are soluble in water, though the solution is in general milky; they are also soluble in alcohol, and the solution is used frequently as a test of what is called the hardness of water; acids also decompose soaps.

Fancy soaps or scented soaps are made in great variety, and have generally French names attached to them; for the French are the leading manufacturers of such articles. Among *soft toilet* soaps are *Naples soap*, *savon nacré*, and *crème d'amandes*. Among *hard toilet* soaps are *Windsor soap*, *Savon á la rose*, *Savon au bouquet*, *cinnamon soap*, *orange-flower soap*, *musk soap*, *bitter almond soap*, and many others. Most of these are scented by the substances which give them their characteristic names.

The soap manufacture is one of considerable importance. The principal seats in England are Liverpool and Runcorn, London, Brentford, Bristol, and Hull; there are also soap-works of considerable extent at Bromsgrove, Newcastle, Gateshead, Warrington, and Plymouth. In Scotland two-thirds of the total quantity of soap are made at Glasgow and Leith. In Ireland soap is chiefly made at Belfast, Londonderry, Limerick, and Cork.

In 1711 an excise duty of 1*d.* per lb. was first imposed on all soap made in Great Britain, which was raised in 1713 to 1½*d.* per lb. In 1782 the duty was again increased, and a distinction was for the first time made between hard and soft soap, the duty on the former being 2½*d.*, and on the latter 1¾*d.* per lb. In 1816 another increase of duty took place, and hard soap was subjected to a duty of 3*d.* per lb. In 1833 the duty was reduced to 1½*d.* per lb. on hard soap, and 1*d.* per lb. on soft. The present duty is 1½*d.* per lb. and 5 per cent. on hard soap; 1*d.* per lb. and 5 per cent. on soft soap. Notwithstanding the strenuous exertions made for its removal, the soap duty still remains a blot on the excise relations of this country.

The quantity of soap charged with excise duty during the last three years has been as follows:

1848	189,669,263 lbs.
1849	197,632,281 „
1850	204,410,826 „

The quantity exported to foreign countries during the same three years amounted to

1848	10,462,069 lbs.
1849	10,728,342 „
1850	12,555,493 „

SOCIETY OF ARTS. This society has been for so long a period connected with the progress of manufactures in this country, that it will be right to trace briefly its history. The object of this Society is 'to promote the arts manufactures, and commerce of this kingdom, by giving honorary or pecuniary rewards, as may be best adapted to the case, for the communication to the Society, and through the

Society to the public, of all such useful inventions, discoveries, and improvements as tend to that purpose.' It was projected in the year 1753; but the first public meeting took place in March, 1754. The plan was formed by Mr. William Shipley, a drawing-master, who acted for some time as secretary to the Society; and it was carried into effect by a few noblemen and gentlemen, among whom appear the names of Lord Folkstone, Lord Romney, and Dr. Stephen Hales. The services of Mr. Shipley were acknowledged by the Society voting to him, in 1758, a gold medal, 'for his public spirit, which gave rise to the Society;' and subsequently by the publication of his portrait as a frontispiece to the fourth volume of their 'Transactions.' The Society began, immediately after its formation, to advertise premiums for the encouragement of young persons of both sexes in the various departments of the fine arts; for improvements in agriculture and manufactures; for mechanical inventions; and for promoting the cultivation of valuable plants in British colonies.

For several years after the formation of the Society of Arts, there was no authorised publication of the papers communicated to the committees, or for making known the results of its labours. The publication of such information in an annual volume of 'Transactions' was contemplated soon after the commencement of the Society's operations; but the first volume did not appear until the year 1783. Many of the papers however, which would otherwise have appeared in such a work, were published, with the sanction of the Society, in Dossie's 'Memoirs of Agriculture and Œconomical Arts,' of which the first volume appeared in 1768, and the third and last in 1782. Some further particulars respecting the early proceedings of the Society are supplied by a 'Register of the Premiums and Bounties given by the Society instituted in London for the Encouragement of Arts, Manufactures, and Commerce, from the original institution in the year 1754 to the year 1776 inclusive.' This register, which was prepared by a committee of the Society, and is arranged in a tabular form, was printed in folio, in 1778.

The total amount of pecuniary rewards bestowed by the Society down to 1776 was, according to the 'Register' above referred to, 23,551*l.* 18*s.* 2*d.*; or, including the cost of medals, and pallets, 24,616*l.* 4*s.* 8*d.* This register was continued by manuscript additions to the end of 1813; and from these it appears that the pecuniary rewards bestowed from 1777 to 1813 amounted to about 2757*l.* 10*s.*, and that the medals and pallets distributed were 188 in gold and 464 in silver. Later than this there does not appear to be any condensed statement of the operations of the Society; but it has been stated for some years past, in their advertisement to the public, that upwards of 100,000*l.*, derived from voluntary subscriptions and legacies, have been expended in pursuance of their plan. It may be briefly remarked, in the words of the secretary's address at the distribution of prizes in 1841, that 'at a time when it stood alone in offering encouragement to the fine arts, it effected much good in that department; and that it can now point with proud satisfaction to the names of Bacon, Nollekens, and Flaxman, Cosway and Lawrence, Sharp and Sherwin, Pingo, Marchant, and Wyon, with many other eminent artists, the early manifestations of whose genius were noticed by the Society in a manner which, there can be no doubt, assisted very materially in its developement.' Still more important perhaps have been the effects of the Society's encouragement of poor operatives, in improving the processes with which they are practically acquainted. The history of those inventions connected with weaving, which have been the objects of their encouragement within the last forty years, was adverted to in the address just quoted, as an illustration of what the Society have effected; about twenty pecuniary rewards having been given, chiefly to Bethnal Green and Spitalfields weavers, for inventions of great utility.

As before stated, the first volume of the Society's 'Transactions' was published in 1783. For forty-seven years from that time a volume appeared annually; but since 1829 the volumes have been biennial. An index to the first twenty-five volumes was published in 1808, and two others, embracing respectively from the twenty-sixth to the fortieth, and from the forty-first to the fiftieth, have since appeared. In 1774 the Society removed from their original premises, opposite Beaufort Buildings, Strand, to their present house in the Adelphi, which was erected purposely for them; and in the years 1777-83 Barry decorated their great room with a series of pictures.

The Society of Arts has taken an active part in encouraging the Great Exhibition of 1851; many of the officers and influential members of the Society are also members of the Commissions and Committees relating to the Exhibition; and there can be no doubt that we are in part indebted for this admirable and honourable display to the proceedings of the Society. It would have been pleasant if this Exhibition had formed a centenary commemoration of the Society, in addition to its other attractions; in 1854 such a centenary period will actually occur.

SODA MANUFACTURE. This branch of manufacturing chemistry is a very interesting one as exemplifying the important advantages which we derive from our inexhaustible stores of salt, and from the numerous useful substances which this salt is made to yield.

What is usually called *soda* is not strictly such; it is *Carbonate of Soda;* but both are produced from common salt. Sulphuric acid is the agent which enables salt to yield these valuable products. In some of the chemical works at Glasgow and Newcastle, sulphuric acid is made by the aid of sulphur; and this acid and salt are used for further processes. When a high excise duty was laid upon common salt, soda was made from *kelp* and *barilla;* but now that salt is purchaseable at so low a price, all our soda is obtained from this source, for employment in soap making, alum making, bleaching, washing, &c.

In manufacturing soda a given weight of salt is placed in a reverberatory furnace, in a leaden pan, and sulphuric acid is dropped down upon it throngh a leaden pipe brought through the roof of the furnace. The salt liquifies in the acid, and a gaseous vapour ascends; this vapour is *Muriatic acid gas*, which takes away the chlorine from the salt, and which is condensed into a liquid in the way described in a former article [MURIATIC ACID.] The sulphuric acid forms a pasty mass of *sulphate of soda*, with the remaining ingre dients in the furnace. The sulphate is taken from the furnace, mixed with fine lime and fire coal, put into another furnace, and heated. The coal kindles, and melts the sulphate and lime into a viscid mass, which after being repeatedly raked and stirred, is removed from the furnace into iron trays. The mass, which is called *ball soda, crude soda*, or *British barilla*, is a mixture of carbonate of soda with sulphuret of calcium. The carbonate is separated from the sulphuret by steeping in water, which dissolves the former but not the latter; there is formed, in fact, a solution of carbonate of soda, which, in being evaporated, yields the solid carbonate almost entirely from sulphur. This is a yellowish earthy substance, called *soda ash* or *soda salt*, largely used in manufactures. But a more pure and crystallised carbonate is required for some purposes; this is produced by dissolving, settling, evaporating, and crystallising, whereby beautiful crystals of *carbonate of soda* are produced. By a further chemical process the carbonic acid is driven off, and *pure* or *caustic soda* results.

SODA WATER MANUFACTURE. A few details on this subject will be found under AERATED WATERS.

SODIUM. This metal is the base of the alkalies soda, natron, and the fossil alkali, in which substances it is combined with oxygen, forming the protoxide of the metal. It was discovered by Sir H. Davy in 1807. The properties of sodium are such as to prevent its occurrence in nature, except in combination, on account of its intense affinity for oxygen. Immense quantities occur combined with chlorine, forming common salt; and a considerable quantity is met with in the stato of oxide, or soda, combined with carbonic acid; these are its principal sources. [Sodium] has a colour and lustre resembling those of silver. It remains a soft solid at 32°, so that small portions may be welded together by pressure; it becomes much softer at 122°, fuses at about 190°, and by a white heat is volatilised. Like potassium, it speedily tarnishes by exposure to the air, owing to its great affinity for oxygen, and this occurs more rapidly when the air is moist. When thrown on water it decomposes it with a hissing noise, the results being hydrogen and oxide of sodium, or soda. When however it is placed on a moistened bad conductor of heat, as charcoal, it decomposes water with a vivid combustion. Its specific gravity is 0.972, so that although it is considerably more dense than potassium, it is yet less so than water. It is a good conductor of electricity and heat; but if too strongly heated in the air, it burns with a yellow flame.

Sodium and oxygen combine to form pure *soda*, which is a gray solid, resembling potash in appearance, but it is less fusible and volatile. It is extremely acrid to the taste, and is very caustic. It has a great affinity for water, dissolving readily in it, and in large quantity, and the solution has strongly marked alkaline properties. Sodium and chlorine form the valuable substance *common salt*, formerly called Muriate of Soda, and now Chloride of Sodium. Of all natural soluble salts this occurs in the greatest quantity. It is met with solid, constituting rock-salt, in solution in salt springs and in the ocean, and in small quantity in almost all spring and river water. [SALT.] *Nitrate of Soda* is used largely in making nitric acid and sulphuric acid. The *Carbonate of Soda* is noticed under SODA MANUFACTURE. The *Sulphate of Soda*, formerly called *Glauber's Salt*, is readily soluble in water, and the solution by evaporation yields colourless transparent prismatic crystals. It has a very bitter taste; it effloresces when exposed to the air, by losing water of crystallisation.

Borax, *Rochelle Salt* and many other useful substances, as well as *soda alum*, are prepared from some of the componnds of Sodium.

SOILS. The agricultural soils which have been formed from the disintegration and decomposition of the primitive rocks, such as granite, basalt, slate or limestone, and especially those which contain all these minerals minutely divided and intimately mixed, are always naturally fertile, and soon enriched by cultivation; the hard particles of quartz maintain a certain porosity in the soil, which allows air and moisture to circulate, while the alumina prevents its too rapid evaporation or filtration. The soils which have been evidently formed from the rocks which are supposed to be of secondary formation, are fertile according to the proportion of the earths of these rocks which they contain.

Each distinct formation gives rise to a great variety with respect to fertility, even where the basis remains the same; but it is of great importance to the farmer to ascertain the general nature of the rocks and strata on which his farm is incumbent, and no chemical analysis can determine the exact value of the land unless the geological situation of it is distinctly known.

The alluvial soils formed by the deposit of a variety of earths in a state of great division, and mixed with a considerable portion of organic matter, form by far the most productive lands. They will bear crop after crop with little or no additional manure, and with a very slight cultivation. These soils are found along the course of rivers which traverse extensive plains, and which have such a current as to keep very fine earth suspended by a gentle but constant agitation, but not sufficiently rapid to carry along with it coarse gravel or sand.

The simplest process of ascertaining the mechanical texture of soils is by washing with pure water. For this purpose nothing is required but a few flat plates and large cups. Some of the soil is formed into a very thin mud by stirring it in a cup nearly full of water. The finer particles are successively poured off from the sand or grit, which at last remains pure, so that the water added to it is no longer discoloured. This being dried and weighed, gives the coarse sand. The water and earth poured off are allowed to settle. A common soup-plate is found a very convenient vessel for this purpose. On the surface of the deposited earth will be found all the undecomposed vegetable matter, which with a little care is easily taken off, dried, and weighed. The finer portions of the earth can be poured off successively by shaking the whole moderately, till nothing but very fine sand remains. The alumina and impalpable silica will remain long suspended in the water, and allow any sand yet remaining to be deposited. They may be rapidly separated from the water by filtration through stout blotting-paper; but it is preferable to pour them into a glass tube about one inch in internal diameter, with a cork fitted in the lower end. In this tube the earths slowly fall to the bottom, and any variety in the size of the particles causes a line more or less distinct, which can be observed through the glass; and thus a very good idea may be obtained of the proportion of the different earths, as far as regards the size of their particles. In order to ascertain their chemical differences, they should be taken to a chemist and analysed.

The chemical and mechanical modes of treating various kinds of soil are briefly noticed under the names of the soils [Chalk; Clay; Loam; Marl; &c.,]; also under Manure, &c.

SOLDERING is the union of the surfaces of two metals, generally by the intervention of a third. In the ordinary mode of soldering, the alloy used as a solder must be more fusible than the metal or metals which are to be united, and must have a strong affinity for them. The solder usually contains a large proportion of the metal to which it is to be applied, in combination with some more easily fusible metals. To insure perfect metallic union between the solder and the surfaces to which it is applied, it is essential that they be made perfectly clean and free from oxide, and that the atmosphere be excluded during the operation, in order to prevent the formation of any oxide while the process is going on. This is effected in various ways, but most commonly by the use of borax, sal ammoniac, or rosin, either mixed with the solder or applied to the surfaces to be joined.

Various kinds of solders or alloys are used, according to the metal which is to be soldered. Platinum is soldered with gold. Gold is soldered with an alloy of fine gold, silver, and copper. Silver solders usually consist of silver mixed with brass, and sometimes with zinc. Brass, copper, and iron are soldered with an alloy of zinc with copper or brass. Articles of wrought iron, and some qualities of steel also, may be soldered with cast-iron; the cast-iron being repeatedly heated and quenched in water, by which it becomes sufficiently friable to be beaten to a coarse powder with an iron pestle and mortar. Common *plumbers' solder* is made of two parts lead and one part block tin; or of the same metals mixed in nearly equal quanttities; bismuth is added when it is desired to make the alloy more fusible. *Soft solder* has two parts tin to one lead; and other alloys of tin, lead, and bismuth, are used for uniting various articles of lead, tin, pewter, and other soft compounds. Such highly fusible solders are usually cast in ingots or strips, and melted as they are used by means of an instrument called a soldering-iron, which is tipped with copper—that metal being preferred for its greater affinity for tin. In soldering tin plates together, their edges are made to overlap; but in almost every other case the edges to be joined are made only to meet, the solder being run between their abutting edges.

A kind of soldering, called *burning-to*, has been long practised in some cases with sheet-lead, where it has been desirable to make a vessel entirely of that material; the junction being effected by pouring melted lead on to the edges to be united, until they fuse together. Somewhat similar to this is the process introduced some years ago under the name of *autogenous soldering*. This process, which is the invention of a French gentleman, M. de Richemont, consists of the union of two pieces of metal without the interposition of any solder, by fusing them at the point of junction by jets of flame from a gas blowpipe. The apparatus used for the purpose contains a hydrogen gas generator, bellows for atmospheric air, and valves for regulating the proportion in which the gas and air are to be mixed.

SOLVENT is that which has the power of rendering other bodies liquid; and chemically, a menstruum. Of all the solvents, water is the most universal and useful; it dissolves a great number of neutral vegetable products, as gum, sugar; and of saline bodies, as common salt, sulphate of soda, &c. The solvent of resinous bodies is alcohol, and of some similarly constituted substances; while caoutchouc is insoluble in it, but is dissolved by naphtha, oil of turpentine, and æther. The metals are insoluble in any solvent until they have suffered some change by its action, or by a similar change otherwise produced.

Heat has great power in altering the solvent power of bodies; in most cases it increases it, and hence, when it is required to crystallise certain salts, they are dissolved in hot water, and the solvent power of the water diminishing as the solution cools, the salt is deposited in crystals. In some cases, however, heat diminishes the solvent power. When any solvent has taken up as much of any particular substance as it is capable of taking up, the solution obtained is termed a Saturated Solution. That the change of form from solid to fluid is the result of chemical affinity, is shown by the fact that water which is saturated with one substance will take up another; thus a saturated solution of common salt will still dissolve sulphate of soda, and vice versâ.

The different solvent powers possessed by different substances are of the utmost consequence in many manufactures, especially those connected with manufacturing chemistry.

SOMERSETSHIRE. The geology of this fine county is rich in products valuable in the arts and manufactures. The great oolitic formation, which furnishes the fine-grained freestone commonly known as *Bath Stone*, has a thickness probably of 130 to 150 feet. Masses of this rock are found scattered on the slopes of the hills which it crowns, covering the subjacent clays and fullers' earth. The inferior oolite is extensively quarried in Dundry Hill, where it yields a good freestone. The coal-measures, mountain limestone, and old red sandstone belong to the carboniferous group of the Somersetshire and South Gloucestershire coal-field, and occupy the northern part of the county extending to the Mendip Hills, though covered in most places by more recent formations; in this field are numerous coal-pits. The mineral treasures of the Mendip Hills are important; zinc is obtained abundantly in the central and western parts of the range. There are numerous coal-pits in the villages which lie north-west of Frome; the coal seams are all thin; hardly any exceed three feet.

Somersetshire possesses a soil and climate well suited to the growth of wheat and all the agricultural produce usually raised in any part of England. In some of the vales, such as the extensive vale of Taunton, the soil is of a rich nature, and the wheat which is produced there is of superior quality. Excellent butter and cheese are made where the land is better adapted to pasture. The Cheddar cheese, which, from its superior quality, gives its name to a great portion of the cheese made in the county, is reckoned by many to be the best cheese made in England from pure milk, without any addition of cream: the real Cheddar cheese is consequently scarce, and bought up as soon as it is made. There are a few hops grown in the county, but no very extensive hop-gardens; nor is there much cider made, although there are some good orchards.

In respect to the external commerce of Somersetshire, a little has been said under BRISTOL and BRIDGEWATER. Considerable manufactures are carried on, especially the clothing trade at Frome and its vicinity, the glove trade at Yeovil, &c.

SOMME. This department of France produces oleaginous seeds, beetroot, pot-herbs, hops, dyeing and medicinal plants, grass-seeds, and apples for making cider and beer, which are the chief beverages of the inhabitants. A great deal of hemp and flax is grown in the north of the department. The minerals are building stone, paving flints, marble, chalk, vitriolic earth, potters' clay, and gypsum; coal has been found near Doullens, but no mines are worked. The manufactures are important, comprising fine and coarse woollen cloths, cotton fabrics of every description; also silks, linen, lawn, cambric, gauze, cashmere shawls, canvas, furniture, cotton, carpets, muslins, hosiery, ropes; locks, hardware, nails, leather, paper, oil, soap, glue, glass, pottery, mineral acids and other chemical products. The department has several bleach works, large cotton mills driven by steam machinery, beet-root sugar refineries, dye-houses, oil and tan mills. The commerce in the agricultural and industrial products named above, and in salt, colonial provisions, wine, brandy, coals, raw cotton, sheep and goats' wool, fish, &c., is very considerable.

SONOMETER. Mr. T. Wakley introduced, in 1849, an ingenious acoustic instrument, not for enabling partially deaf persons to hear, but to *measure* the extent of their power of hearing, so as to enable the aurist to adapt his curative means to the circumstances of each case. The instrument, which is called a *sonometer*, consists of a bell fixed to a table with its mouth uppermost. The hammer or clapper which is to strike the bell is attached to a spring, which catches into notches in a steel bar; and according as the spring is detained in a notch near the end or the middle of the bar, so does the hammer make a small or a considerable movement when released, and so does it elicit a soft or a loud sound from the bell. The aurist determines by experiment which of these sounds can be heard by the patient, and the instrument thus becomes a meter or measure of the auditive power.

SOOT is that portion of fuel which escapes combustion, and which is mechanically carried up and deposited in chimneys. The soot of coal contains sulphate and hydrochlorate of ammonia, a brown bitter extract, and an empyreumatic oil; but its great basis is charcoal in a state in which it is capable of being rendered soluble by the action of oxygen and moisture, and hence, combined with the action of the ammoniacal salts, it is used as a manure, and acts very powerfully as such. The soot of wood contains a greater variety of substances than that of coal, but much less both of carbonaceous matter and of ammoniacal salts.

It is in every way desirable that the formation of soot (unburnt fuel) should be prevented as much as possible, since it both wastes valuable material and contaminates the air. [SMOKE.]

SOUND-BOARD, or SOUNDING-BOARD, is a board placed over a pulpit or other place occupied by a public speaker, to reflect the sound of his voice, and thereby render it more audible. Sounding-boards are usually flat, and placed horizontally over the head of the speaker; but a different form and position, contrived by the Rev. J. Blackburn, of Attercliffe-cum-Darnell, near Sheffield, has been adopted in some cases with great advantage. In this arrangement the sounding-board is a concave parabola, which extends partly over and partly behind the speaker. The gutta percha tubes for the use of partially deaf persons in churches are noticed under SPEAKING TUBES.

SOUNDINGS are properly the depths of water in rivers, harbours, along shores, and even in the open seas; but the term is also applied to the nature of the ground at the bottom of the water. If the depth of the water is comparatively small, a man who is stationed for the purpose in the main or mizen chains, on the windward side, throws out a mass of lead, usually in the form of a frustum of a cone, and weighing 8 or 9 lbs., which is attached to one end of a line between 20 and 30 fathoms in length. On this line are fixed, at intervals of two or three fathoms, pieces of leather or cloth of different colours; and the mark which is next above the surface of the water when the lead strikes the bottom affords an indication of the depth. That which is called the deep-sea lead weighs from 25 to 30 lbs., and is attached to a line of great length, on which, at intervals, are knots indicating the depths. The bottom of the lead is covered with a coating of tallow for the purpose of ascertaining, by the sand, shells, or other matter which may adhere to it, the nature of the ground.

When soundings are to be taken in the survey of a coast, a harbour, or the mouth of a river, the surveying ship and its boats are disposed at convenient distances from each other (suppose from two to five miles); their distances with respect to each other and to remarkable objects on the shore being determined by the usual trigonometrical observations. The boats then row or sail along the directions of the lines joining each other, sounding as they proceed at equal intervals, suppose ten minutes, of time; and thus the outline of the shoal, reef, coast, or river, will be determined, as well as the depth of the water. All the soundings must be afterwards reduced to the depths below the surface of the sea at the level of low water.

SOUTH AUSTRALIA. A few commercial details respecting this colony will be found under ADELAIDE and AUSTRALIA. We will here add, that the imports of the colony in

1850 amounted in value to 632,689*l.*; the exports, 483,475*l.* The tallow exported was 5571 cwt.; the wool, 2,841,131 lbs.; the wheat, 14,498 qrs.; and the meal and flour, 1924 tons.

SOUTHAMPTON. This rising town depends for its importance on its connexion with the sea, and its easy communication with the metropolis. The harbour, which is secure, affords good anchorage. Ship-building is extensively carried on, though the vessels built are chiefly small. Southampton has a large coasting-trade, and a considerable trade to foreign ports and the colonies. The customs generally produce about 60,000*l.* a year, gross receipt. In 1849 the specie imported into Southampton amounted to 6,788,655*l.* The number of sailing-vessels registered Dec. 31, 1850, was 208 (12,843 tons). The number of steam-vessels was 10 under 50 tons, and 14 above 50 tons. Very large and convenient docks have been constructed on the eastern side of the town, chiefly for the service of steam navigation. In Dec., 1841, the mail-packet steam-ships to the West Indies commenced running. Passengers to the East embark here, there being a direct communication to India once a fortnight, as well as weekly, by steamers, to Vigo, Oporto, Lisbon, Cadiz, and Gibraltar, and daily to the Isle of Wight, France, and the Channel Islands. The South Western Railway runs to the very edge of the docks, and the trade of Southampton is also promoted by the Andover Canal, which follows the valley of the Anton, and by the navigation of the Itchen, which extends to Winchester.

The trade of the docks is annually increasing. In 1850, the tonnage of sailing vessels entered inwards at Southampton amounted to 187,435 tons, that of steam vessels to 155,566 tons. The dock and railway authorities have recently attempted to make Southampton the depôt for the new Cape Screw-steamers; but in this instance Plymouth has forestalled Southampton.

One of the largest coach factories in England is at Southampton, whence coaches of the finest build are procured. A sugar factory has lately been built near the docks, at an expenditure of 8,000*l.*

SOWING. The most common mode of sowing seed is by scattering it as evenly as possible over the ploughed surface, as it lies in ridges from the plough. The harrows follow, and crumbling down the ridges, cover the seed which has fallen in the hollows between them. It requires an experienced sower to scatter the exact quantity over a given surface, without crowding the seed in one spot, and allowing too great intervals in another. Hence the farmer who does not himself sow the seed, invariably chooses the most experienced and skilful labourer to perform this work. Notwithstanding every care and attention on the part of the farmer or master, the labourer will often relax and become careless, and the result appears only when it is too late to remedy it. This has given rise to various attempts which have been made to invent machines for sowing the seed, such as should insure perfect regularity. [Drilling.]

SOY. This favourite Indian sauce is prepared from a plant called *Soja hispida.* The seeds are about the size of those of kidney beans, and the soy is made from them in the following way:—The seeds are boiled until nearly all the water has evaporated, when they are taken from the fire and placed in wide-mouthed jars, exposed to the sun and air; water and molasses or brown sugar are added. The mixture is stirred well every day, and allowed to ferment; it is then strained, salted, boiled, and skimmed until clarified. The shopkeepers at Canton who sell soy have large platforms on the roofs of their houses, where the jars for preparing soy are arranged and exposed to the sun. The use of soy is enormously large in China; it is used as a sauce at almost all meals. The sauce made by the Japanese is said to be the best. The use of soy in England is but limited.

SPAIN. If the inhabitants would do as much *with* their country as nature has done *for it*, Spain would be rich and prosperous; since in climate, in minerals, and in vegetable produce, it has many of the elements of commercial greatness.

The most common kinds of grain which are cultivated in Spain are wheat, maize, barley, and rice. Other objects of agriculture are hemp and flax, especially in the basin of the Ebro, and madder and saffron on the table-land of Cuença. In the southern districts the sugar-cane and cotton are cultivated. The most common vegetables are onions, garlic, pumpkins, cucumbers, melons, water-melons, potatoes, beans, and peas. Many fruit-trees are cultivated, as almonds, figs, pomegranates, lemons, oranges, pistachia nuts, carobas, dates in the southern districts, walnuts, hazel-nuts, and especially chestnut-trees, which in some of the northern districts cover large tracts. Olive-trees occur in all parts, except the northern mountain tracts, and the vineyards are extensive, except on the most elevated regions. Several of the Spanish wines are considerable articles of commerce, as Xeres (Sherry), Malaga, Alicante, Malvasia, Tinto, and Val de Peñas. Brandy and raisins also are articles of export. Among the wild trees are the sweet-acorn oak, the cork-tree, the kermes oak, and the sumach-tree. On the Montañas de Asturias and Aralar, and also on the western offsets of the Pyrenees, there are large forests of fine timber-trees. The liquorice-plant is abundant in the vicinity of Sevilla and near the mouth of the Ebro, and the prepared juice is sent to all parts of Europe.

The sheep are noted for their fine wool, which forms an important article of export. [MESTA.] In no country of Europe, except Italy, is so much silk obtained as in the eastern and southern parts of Spain. The cochineal insect has been reared of late years in Andalusia, Granada, and Estremadura, and thrives well. Bees are very abundant, and much honey and wax are obtained.

Spain abounds in minerals. Gold and silver are known to exist in several places. Platinum and copper are met with. A rich mine of quicksilver is worked near Almaden. [ALMADEN.] Lead is very abundant, especially in the Sierra de Gador. Iron ore is very abundant in the Sierra de Aralar and other places. There are also tin, calamine, bismuth, cobalt, alum, vitriol, and sulphur. In some parts large quantities of saltpetre are collected. Coal occurs in the Montañas de Asturias and in the Sierra Morena, but it is not much worked. Many kinds of marble are got in Catalonia. Several precious stones are found, as rubies, topazes, amethysts, turquoises, and garnets. Salt is got near Cardona in Catalonia, from the lagune called the Albufera de Valencia, and from the sea-water along the coast between Cape Trafalgar and the boundary of Portugal.

Few countries of Europe equal Spain in natural commercial advantages, whether we consider its situation or its products. The coasts are extensive, and the ports numerous and commodious; the inhabitants, inured to a warm climate, visit the tropical regions with comparative safety; yet it is far behind most other countries of Europe in commercial importance. During the 17th century most of the Spanish trade with America was carried on in Dutch or English vessels; and, with the exception of wine, wool, and oil, few if any of the productions of the Peninsula found their way to that market. About the close of the last century, under the enlightened administration of Count Florida Blanca, Spanish commerce revived, and several manufactures were established throughout the country. These, however, were all destroyed during the Peninsular war, and the subsequent separation of the American colonies from the mother country has completely annihilated the maritime trade of Spain. At present Catalonia is almost the only province of Spain where manufacturing is carried on to any extent. The chief exports of Spain consist of wines, dried fruits, corn, oil, wool, quicksilver, lead, and some iron. The silk of Valencia, which is equal to that of Italy, is bought by the French manufacturers.

Cadiz is the chief port in Spain; about 3000 vessels arrived there in 1849. The next in rank are Barcelona, Carthagena, Corunna, and Tarragona.

The British produce and manufactures exported to Spain in 1849 amounted in value to 623,126*l*.

SPAR. This name is given in mineralogy to a great number of crystallised earthy and some metallic substances, but chiefly the former. Thus calcareous spar is crystallised carbonate of lime; fluor-spar, fluoride of calcium; heavy spar, sulphate of barytes, &c. By miners the term is frequently used alone, to express any bright crystalline substance; but in mineralogy, strictly speaking, it is never so employed.

SPEAKING TUBES. Instruments for enabling the human voice to be heard at a great distance appear to have been known to the ancient Chinese. The modern speaking-trumpet appears to have been an invention of Sir Samuel Morland, in the year 1670. This first trumpet was of glass, 2 feet 8 inches long; and he afterwards made one of copper, recurved in the form of a common trumpet. Its total length was 16 feet 8 inches, the large end 19 inches, and the small end 2 inches in diameter. With this the voice was heard about a mile and a half. Morland made another of the same form, still larger, and two others of the straight form, and 5 feet and a half long. With the latter a man could make himself heard a mile and a half; and with one of the largest trumpets, tried at Deal Castle, the voice was conducted a distance of between two and three miles over the sea.

The efficiency of the speaking-trumpet is generally ascribed to the repeated reflection of the sound from side to side in passing through it, and its ultimate reflection from the mouth of the trumpet, in such a way as either to collect the rays of sound into a focus at a distance, or to project them forward in parallel lines, instead of allowing them to diverge in all directions. But Sir John Leslie accounts for its effect in the following manner:—'The tube, by its length and narrowness, detains the efflux of air, and has the same effect as if it diminished the volubility of that fluid, or increased its density.' 'The organs of articulation,' he continues, 'strike with concentrated force; and the pulses, thus vigorously excited, are from the reflected form of the aperture, finally enabled to escape, and to spread themselves along the atmosphere.' The effect of a speaking-trumpet is the same, whether the metal tube be used simply, or wrapped round in such a way as to prevent vibration. It is also heard at the same distance when the inner surface is lined with linen or woollen cloth to diminish reflection; and the range of a cylindrical trumpet is the same as that of a conical one.

The most valuable speaking tubes, however, are not those which are intended to convey sound to a great distance, but those intended to aid persons whose sense of hearing is defective. Something has been said on this subject under ACOUSTICS. The principle of the SONIFERON, described in that article, pervades all instruments of this kind; they collect and concentrate the waves of sound, so as to make them impinge upon the tympanum of the ear with greater force. They are in principle the reverse of the speaking trumpet; for in this the sound proceeds from the small end to the larger, whereas in speaking tubes or ear trumpets it proceeds from the large end to the small. Many varieties are made, under the names of *auricles, ear-cornets, ear-conches, conversation-tubes, table-soniferas,* &c., adapted to different requirements of partially deaf persons. See also SONOMETER.

It has lately been found that gutta percha—so invaluable for many other purposes—is the best of all materials for speaking tubes, since it conveys the pulses of sound with surprisingly little diminution of intensity. In churches, in ships, in warehouses and factories, and in various other buildings and places, gutta percha speaking tubes are now used to a considerable extent. The mode of applying these tubes to the assistance of partially deaf persons in a church is curious. A funnel of the material is placed either inside the pulpit, quite out of sight, or, if ornamented, in front of the pulpit, so as to come immediately beneath the desk. A tube from this funnel then passes downwards beneath the floor, and is carried along the aisles, with branches off on each side to the pews occupied by people of defective hearing. The termination of the tube is all that appears in sight, and the ivory ear-piece being applied to the ear, the slightest whisper of the preacher is clearly heard.

SPECIFIC GRAVITY, or more properly Specific Weight, is the weight of any gas, liquid, or solid, under some given volume, as a cubic foot, a cubic inch, &c. Distilled water is the substance usually employed for the purpose of comparing together the weights of all substances except the gases; and because the volume of any substance varies with its temperature, in determining from experiment the specific gravity of any substance, the weight under a given volume is reduced to that which it would become at one constant temperature.

In the Parliamentary Regulations, which were made in 1825, a cubic inch of water is stated to weigh 252.458 troy grains, the temperature being 62° Fahrenheit, and the height of the barometrical column 30 inches; and 7000 troy grains are made equivalent to one pound avoirdupois; hence it follows that a cubic foot of water should weigh 997.136 ounces. This number is sufficiently near 1000 to make it very proper that it should be adopted for the specific gravity of water, since a change in the value of the avoirdupois ounce, which would be scarcely appreciable in the ordinary transactions of commerce, would render the ounce an accurate and convenient unit of weight, while the cubic foot constitutes the unit of volume.

On the Continent, since the employment of the decimal scale of weights and measures has become general, the cubic centimetre (.061028 cubic inches English) is the unit of volume, and the gramme (15.407 troy grains) is the unit of weight; the gramme having been determined by the weight of a cubic centimetre of distilled water of the temperature at which its density is a maximum (38.25° Fahrenheit).

The hydrostatic balance which is employed in determining the specific gravities of bodies is constructed similarly to an ordinary balance, but with as much delicacy as possible; and a particular contrivance is adopted in order to ascertain the weight of any substance within, for example, one-hundredth part of a grain. Thus, from the lower part of the scale containing the substance to be weighed, there is suspended a brass wire, whose volume and weight have been previously determined, and part of its length enters into water which is contained in a vessel underneath the scale. The scales with this wire thus attached to one of them being previously put in equilibrio when the surface of the water is at a certain mark on the wire, the substance to be weighed is introduced into the scale above the wire, and weights are placed in the opposite scale till one grain more would be found too great: then gently raising the whole balance till, by the increase of the weight on the side of the scale containing the substance, in consequence of a greater portion of the wire being out of the water, an equilibrium takes place. The wire being graduated so that 100 divisions correspond to a weight equal to one grain, the number of graduations on it between the surface of the water and the fixed mark before mentioned will enable the experimenter to determine the number of hundredths of a grain by which the weight of the substance in the scale exceeds the number of grains already placed in the opposite scale.

The weighing process varies in its details according to the kind of substance to be weighed. Thus—a solid which is heavier than water, a solid which is lighter than water, a solid which is soluble in water, a solid which will imbibe water without being dissolved, a solid in the form of sand or powder, a liquid, a gas or vapour—all require peculiar methods for determining their specific gravity; methods which are fully described in treatises on Hydrostatics, but which we need not dwell upon here.

The following are the specific gravities of several airs and gases, at a temperature of 60° Fahr., and a barometrical pressure of 30 inches: atmospheric air being taken as a standard, or = 1·000:—

Hydrogen	0·070
Ammoniacal gas	0·590
Aqueous vapour	0·625
Do. (in contact with water at 212° Fahrenheit)	0·484
Nitrogen	0·969
Atmospherical air	1·000
Oxygen	1·111
Muriatic acid gas	1·284
Carbonic acid gas	1·519
Nitrous oxide gas (laughing gas)	1·527 to 1·614
Chlorine	2·508
Iodine, vapour of	8·678

The following are the specific gravities of various liquids and solids, at a temperature of 60° Fahr., a pressure of 30 inches, and water being = 1·000:—

Naphtha	0·708
Æther, muriatic	0·730
Do., nitric	0·909
Alcohol, pure	0·796
Water, at 212° Fahr.	0·956
Do., at 60°	1·000
Sea-water	1·026
Beer	1·023
Port Wine	0·997
Oil of turpentine	0·870
Whale oil	0·923
Muriatic acid	1·194
Nitric acid	1·217
Sulphuric acid (pure)	1·848
Gums, Animal Substances, &c.	
Indigo	0·769
Butter	0·942
Bees-wax	0·965
Camphor	0·989
Blood	1·028
Milk	1·032
Copal	1·060
Mastic	1·074
Gamboge	1·222
Opium	1·336
Honey	1·450
Gum arabic	1·452
White sugar	1·606
Ivory	1·826
Woods.	
Cork	0·240
Poplar	0·383
Yellow Pine	0·440
Spruce Fir	0·518
Larch	0·530
Willow	0·585
Elm	0·588 to 0·800
Lime or Linden-tree	0·604
Cedar, from Palestine	0·613
Mahogany	0·637 to 1·063
Teak	0·666
Walnut-tree	0·671
Elder	0·695
Oak, English	0·743 to 0·760
Beech	0·853
Box, French	0·912
Olive	0·927
Logwood	0·931
Heart of Oak, 60 years old	1·170
Ebony	1·177
Vine	1·327
Box, Dutch	1·328
Lignum Vitæ	1·333
Earths, Stones, &c.	
Pumice-stone	0·915
Gunpowder (closely shaken)	0·932
Amber	1·078
Cannel Coal	1·270
Slate coal, English	1·250 to 1·370
Phosphorus	1·714
Nitre	1·900
Brick	2·000
Sulphur (native)	2·033
Gypsum (opaque)	2·168
Porcelain (china)	2·385
Stone (paving)	2·416 to 2·460
Flint	2·590
Carnelian	2·600
Glass	2·642 to 2·892
Marble	2·649 to 2·838
Brazil Pebbles	2·653
Granite (red Egyptian)	2.654
Quartz (crystallised)	2·655
Agate	2·667
Slate (common)	2·672
Alabaster	2·762
Emerald (from Peru)	2·775
Chalk (British)	2·657 to 2·784
Talc (Muscovy)	2·792
Basalt	2·864
Hone (white), razor	2·876
Lapis-lazuli	2·767 to 3·054
Limestone (white fluor)	3·156
Diamond	3·444 to 5·531
Beryl	3·549
Adamantine Spar	3·873
Sapphire	3·994
Garnet	4·000
Topaz	4·011
Vermilion	4·230
Ruby	4·283
Metals.	
Sodium	0·865
Potassium	0·972
Antimony	4·064
Molybdena	4·738
Manganese	4·756
Copper (from Cornwall)	5·452
Tungsten	6·066
Uranium	6·440
Zinc	6·862 to 7·191
Iron (cast)	7·157 to 7·248
Tin (pure)	7·291
Iron (forged)	7·600 to 7·788
Copper (native)	7·600 to 7·800
Nickel (molten)	7·807
Cobalt (molten)	7·812
Steel	7·818 to 7·833
Brass	7·824 to 8·544
Mercury (precipitate, red)	8·399
Copper (wire-drawn)	8·878
Bismuth (native)	9·020
Mercury (brown cinnabar)	10·218
Silver (hammered)	10·511
Lead (molten)	11·352
Mercury (fluent)	13·568
Do. (congealed)	15·630
Gold	15·709 to 49·500
Platinum (purified)	19·500 to 22.069

The most convenient method of obtaining the specific gravities of fluids is by means of what chemists call a 'thousand-grain bottle.' This is a bottle of a globular form, with a ground glass stopper, so adjusted as to contain exactly 1000 grains of distilled water, at the temperature of 60° Fahr., and accompanied by a weight, which is an exact counterpoise for the bottle when thus filled. In order to determine the specific gravity of a fluid by this means, it is simply necessary to fill the bottle with that fluid at the temperature of 60°, and place it, together with the adjusted weight, in the opposite scales of a delicate balance; then the number of grains which it will be found necessary to add to one of the scales, in order to produce equilibrium, will be the difference between the specific gravity of the fluid and that of water, taken at 1000.

SPECTACLES. The mention of magnifying-glasses by Roger Bacon, who died about 1292, justifies the supposition that something like what are now called spectacles were in use at least several years earlier. Extensively as these useful instruments are employed, there can be no doubt that, were the subject more generally understood, the amount of advantage obtained from them would be greatly augmented. The eyes of an individual whose sight is much tried often receive the most serious injury from improper delay in the use of spectacles; while the sight of many persons is prematurely worn out by the use of glasses of too high a power, or too short a focal length. The use of a single reading-glass instead of spectacles is very injurious; since, by occasioning one eye to be more used than the other, the focal lengths of the two are rendered unequal. The unsteadiness of the glass is also a disadvantage. Varieties in the conformation of the eyes, and in the manner and degree in which they are affected by use, render it impossible to lay down any rule for the focal length of convex glasses for persons of a given age.

It is very essential that the frame of the spectacles should fit comfortably to the head, and be of such a form as to bring the centre of each lens exactly opposite the centre of the eye it is intended to serve. The endless variations met with in the width between the eyes, the total width of the head, and the form of the nose, render it frequently difficult to suit an individual out of even a very large stock. Convex spectacles, being used for viewing near objects, may generally be placed lower down upon the wearer's nose than those used by short-sighted persons. The oval form is usually preferred for the lenses, because it allows most room for the motion of the eye in a lateral direction, without giving unnecessary weight.

The *Periscopic Spectacles* of Dr. Wollaston were contrived in order to allow considerable latitude of motion to the eyes without fatigue, by conforming the shape of the glasses to that of the eyes. This is effected by the use of lenses either of a meniscus or a concavo-convex form, the concave side being in both cases turned towards the eye. Divided spectacles, each glass consisting of two half-lenses, are sometimes used, the upper half of each glass being occupied by a concave lens, or one of very slight convexity, for seeing distant objects, while the lower half has a strong magnifier, for examining things near the eye. The present Astronomer Royal finds that one of his eyes refracts the rays of light to a nearer focus in the vertical than in the horizontal plane; and this defect he has succeeded in remedying by using a double concave lens, one surface of which is spherical and the other cylindrical.

As an article of manufacture, the best spectacles are made by the leading opticians of London; but the medium and inferior kind are made on a large scale in Birmingham.

SPE'CULUM. This name is frequently given to a mirror used for any scientific purpose, as in a reflecting telescope. If a pencil of rays diverge from a radiant point in the axis of a concave speculum of a spherical form, all the rays will, after reflexion, converge nearly to a certain point in the same axis, at which the image of the radiant point is said to be formed. This point is called the *Focus*. None of the rays are, in strictness, reflected to the focus, but all those which are reflected from the mirror at points very near its intersection with the axis fall extremely near it. The image in a convex mirror is always upright, and in a concave one always inverted, except when the object falls between the principal focus (or middle point of the radius) and the mirror.

The best composition for the metal of reflecting telescopes is a subject which has been much investigated. About 70 different mixtures were tried by the Rev. John Edwards, the particulars of which are stated in the 'Nautical Almanac' for the year 1787; he found copper 32, tin 15, brass 1, silver 1, white oxide of arsenic 1, to form an alloy which was the whitest, hardest, most reflective, and took the highest polish.

In the 'Philosophical Transactions' for 1840, Lord Rosse, then Lord Oxmantown, published an account of a speculum 3 feet diameter which he had then executed; and from this we learn that after many trials to determine what combination of metals were most useful for the purpose, with respect to whiteness, porosity, and hardness, one of copper and tin (the materials employed by Newton in the first reflecting telescope) united in the proportion of 126·4 parts of copper to 58·9 parts of tin, was found the best. It is stated that the compound is of admirable lustre and hardness, and has a specific gravity of 8·8, that of water being 1. Lord Rosse has subsequently cast specula 6 feet in diameter, of the like composition, and each in one piece, with complete success. One of these is mounted at Parsonstown, in Ireland, in a telescope 56 feet long, with which important discoveries have been made in the heavens. These specula were cast in moulds made by binding together layers of hoop-iron; and both the grinding and the polishing were executed by machinery which was put in motion by a small steam-engine. The speculum of the largest telescope, when mounted, rests on a bed consisting of twenty-seven triangular pieces of iron, supported at their centres of gravity on the corners of nine other triangular pieces, which are also supported at their centres of gravity. By this contrivance any change in the form of the box or tube, by warping or otherwise, produces no effect on the speculum.

SPELTER. [Zinc.]

SPERMACETI, is a fatty material which is obtained from the *Physeter macrocephalus*, a species of whale, generally met with in the South Seas, but occasionally also on the coast of Greenland. The spermaceti occurs chiefly in the head. During the life of the animal the spermaceti is in a fluid state; and on the head being opened, has the appearance of an oily clear white liquid. On exposure to the air the spermaceti concretes and deposits from the oil. They are then separated, and put into different barrels. The head of a whale sixty-four feet in length has been found to yield twenty-four barrels of spermaceti, and from seventy to one hundred barrels of oil. When brought to England, the spermaceti has not a white shining silky appearance, but a yellowish colour, owing to the presence of some oil. To separate this it is filtered, pressed, and subjected to various operations. When perfectly pure, it becomes cetine.

Spermaceti possesses the properties common to fatty matters. It is bland and demulcent, with considerable nutritive qualities, when taken internally. It was formerly much used in medicine; but it is now chiefly employed externally as an ingredient in ointments and cerates. It is also largely used in the making of candles. 4,712 tons of spermaceti were imported in 1848.

SPHERELATA. *Spherelata*, or hammered metal-work, has been found in great profusion among the Etruscan monuments of antiquity. Statues, busts, bronzes, tripods, vases, amphoræ, basins, incense vessels, shields, candelabra—all these have been met with, fashioned out of pieces of metal chiefly by the aid of the hammer. This art is supposed to have long preceded metal-casting, as a mode of manufacture. In the works of the earliest Greek poets, these hammered metal productions are repeatedly referred to. Large surfaces of metal were hammered, thin plates were twisted, ornaments were chased, and separate pieces were fastened together by nails or rivets—all without the aid of casting or soldering.

SPICES. The following quantities of the principal spices were imported into Great Britain during 1849 and 1850:—

	1849.	1850.
Cassia Lignea	472,693 lbs.	988,017 lbs.
Cinnamon ..	759,088 „	700,101 „
Cloves	274,713 „	740,625 „
Mace	45,978 „	76,365 „
Nutmegs	224,021 „	312,418 „
Pepper	4,796,042 „	8,082,518 „
Pimento	2,884,144 „	2,290,176 „

SPINET, was a musical instrument of the harpsichord kind, formerly much in use. The Spinet had but one string to each note, which was struck by a quilled jack, the latter being acted on in the usual manner by a key. It was smaller than the harpsichord.

SPINNING. Whatever be the substance operated upon by the spinner, whether cotton, wool, flax, or silk, it is necessary in the first place to lay the fibres or filaments parallel with each other, so as to form them into a soft continuous ribbon or cord, sometimes called a *sliver*. Excepting in the case of flax, this is done by a carding or combing process, the object of which is to disentangle and straighten the tangled filaments. If such a sliver or cord be firmly griped or compressed at two points rather farther apart than the average length of its component filaments, it may be extended or drawn out to a greater length; the filaments sliding upon each other. When two or more such cords have been extended in this way, until they will stretch no longer without separating or being pulled asunder, they may be laid parallel to each other, and combined by being slightly twisted together. The compound cord thus formed may be again extended by stretching or drawing; and the repetition of the processes of doubling, twisting, and stretching will enable the spinner to extend the length and diminish the thickness of the cord until it becomes a fine compact thread or yarn.

The primitive modes of spinning by the spindle and distaff, and by the spinning-wheel, which are still extensively practised in the East, and not entirely superseded in some remote districts of Scotland, only enable the spinner to produce a single thread; but with the almost automatic spinning-machinery which has been called into existence by the cotton manufacture, one individual may produce nearly two thousand threads at the same time. The history of the series of inventions by which this result has been gradually attained is briefly noticed in the articles ARKWRIGHT and COTTON SPINNING. In respect to flax, the preliminary processes are described under FLAX. As the fibres of flax have not the same tendency to mutual entanglement as those of wool and cotton, it is necessary to moisten them with water to make them adhere to each other during the process of spinning, and also to render them more pliable and easy to twist. Until recently, cold water was used for moistening the flax for machine-spinning; but the substitution of hot water for that purpose has been found a great improvement. We must refer to the same article [FLAX] for an account of the present efforts to improve and extend this important manufacture.

The manufacture of yarns or threads of silk is a process essentially different from the spinning of cotton, wool, or flax. Instead of combining a number of short fibres into a long thread, the silk-throwster receives the silk in the form of very long and exceedingly fine filaments, which merely need cleansing and twisting together until the requisite strength is attained. The twisting process is, in this case, called spinning. There is however besides the best portion of the silk, which is wound off from the cocoon, a quantity of loose or *floss* silk, which forms a soft tangled mass enveloping it. This, with the refuse of the superior part of the silk, under the general name of *waste*, is converted into yarns for coarse or inferior articles, by a process very similar to that of spinning other fibrous substances. This waste silk was formerly cut by a machine, to reduce its filaments into short lengths, and then treated much in the same way as cotton wool; but the process of manufacturing it into yarns has been recently much improved by the adoption of contrivances similar to those used in flax-spinning, by which the filaments are heckled or drawn out into a sliver without being cut. The spinning of hempen fibres into cordage is described under ROPE MANUFACTURE. In many of the smaller kinds of ornamental spun-work, caoutchouc or India rubber is now largely used. [INDIA RUBBER MANUFACTURE.]

SPIRIT, in Chemistry. This word, especially when employed by itself, is now almost exclusively applied to spirit of wine, or alcohol. Formerly however the word spirit was given to most substances capable of being vaporised and condensed by distillation, and to some not obtained by distillation. It will be requisite merely to name a few of those compounds to show how extensively it was used, and misapplied to substances of very different origin and composition. Thus nitric acid was called Spirit of Nitre; hydrochloric acid, Spirit of Salt; Sulphuric acid, Spirit of Sulphur; chloride of tin, Spirit of Libavius; solution of ammonia, Spirit of Sal-Ammoniac, and so forth.

SPIRIT-LEVEL, is a tube of glass nearly filled with spirit of wine or distilled water, and hermetically sealed at both ends, so that when held with its axis in a horizontal position, the air which occupies the part not filled with the spirit or water places itself contiguously to the upper surface. The tube being supposed to be perfectly cylindrical, the exact horizontality of its axis is ascertained by the extremities of the air-bubble being at equal distances from the middle point in the length of the glass. The spirit-tube is placed within a brass case having a long opening on the side which is to be uppermost, and is attached to a telescope; the telescope and tube are then fitted to a frame, or cradle, of brass, which is supported on three legs.

The use of the spirit-level in accurate surveying requires great care in the adjustment of the tube and the attached telescope.

The *Levelling-Staff* till lately in general use for finding the relative heights of ground is a rod consisting of two parts, each six feet long, which, by being made to slide on one another, will indicate differences of level nearly as great as twelve feet. The face of the rod is divided into feet, inches, and tenths, or into feet with centesimal subdivisions; and a vane, or cross-piece of wood, perforated through the middle, is moved up or down upon the rod by an assistant till a chamfered edge at the perforation is seen by the observer at the spirit-level to coincide with the horizontal wire in the telescope. The rod proposed by Mr. Gravat is divided into hundredths of a foot by stripes which are alternately black and white, and are numbered at every foot in the usual way with figures large enough to be seen on looking through the telescope; the tenths of a foot are indicated by lines longer than the others. A similar staff has been proposed by Mr. Sopwith and Mr. W. P. Barlow.

SPIRIT TRADE. The manufacture of different kinds of spirits is noticed under Brandy, Distillation, Gin, Rum, &c.

The duty on foreign spirits is 15*s.* per gallon; on colonial spirits 8*s.* 2*d.* for England, 4*s.* for Scotland, and 3*s.* for Ireland. On British spirits distilled in England the duty is 7*s.* 10*d.*, in Scotland, 3*s.* 8*d.*, and in Ireland, 2*s.* 8*d.* per gallon—all estimated at proof strength.

The quantities of Rum, Brandy, and Geneva, imported into Great Britain in 1849 and 1850 were:—

	1849.	1850.
Rum	5,306,827 galls.	4,188,639 galls.
Brandy	4,479,549 „	3,237,598 „
Geneva	471,236 „	337,042 „

The home-made spirits charged with excise duty in the same two years amounted to the following quantities:—

	1849.	1850.
England	9,102,472 galls.	9,378,790 galls.
Scotland	6,935,003 „	7,132,556 „
Ireland	6,973,333 „	7,408,086 „

The English spirit is made from mixtures of malt with grain, molasses, and sugar; in Scotland more than half is made from pure malt; in Ireland nearly all is made from malt and grain mixed.

SPITALFIELDS. No part of London is more remarkably connected with a particular manufacture than Spitalfields is with that of silk. For many generations nearly all the silk-weavers of the metropolis have resided in or near this district.

When the Edict of Nantes was revoked by Louis XIV., in 1685, many thousand silk-weavers were expelled from France, and sought refuge in England. Stow writes:—"Spittlefields and parts adjacent became a great harbour for poor Protestant strangers, Walloons and French; who, as in former days, so of late, have been forced to become exiles from their own country for their religion, and for the avoiding cruel persecution. . . . Great advantage hath accrued to the whole nation by the rich manufacture of weaving silks, and stuffs, and camlets, which art they brought along with them." The refugees introduced the various silk fabrics known by the name of *lustrings*, *alamodes*, *brocades*, *satins*, *mantuas*, *paduasoys*, *ducapes*, and *tabbies;* and the silk manufacture of Spitalfields speedily became important.

From that time to the present, the Spitalfields weavers have been unfavourably distinguished for their perpetual attempts to secure 'protection' for their trade in every possible way, reasonable or not; and the statute book contains numerous enactments bearing more or less closely on this point. Their wages have at most periods been small, and the weavers have been poor; but there is no proof that matters were otherwise when protective measures were resorted to; and there is not wanting evidence that renewed energy is shewn by the Spitalfields manufacturers, now that all hopes of a protective system are abandoned.

All the silk spun or *thrown* in this country is spun in large establishments called silk-mills, situated in different parts of the country, none is spun in Spitalfields: it is only the weaving which is here conducted. The *tram* for the weft or cross-threads is spun in England; but a good deal of the *organzine* for the warp or long threads is imported from Italy. The manufacturer gives out the organzine and tram to the hand-loom weaver, who takes it to his humble abode, weaves it into one of the many kinds of silk goods, and takes it back to the manufacturer, who pays him a certain stipulated price for his labour. There are supposed to be about 16,000 silk-looms in the Spitalfields and Bethnal Green district; and it is further estimated that not less than 60,000 persons are wholly dependent for their daily food on the employment of these looms.

A School of Design has been established at Spitalfields, which, if fostered by the manufacturers, may render much service by improving the taste of the designers employed in preparing patterns for the weavers.

SPONGE. The organic origin of sponge is a matter which lies beyond the scope of the present work to treat; nor do the simple uses of sponge require much comment. The use of sponge by surgeons, in its natural state, to absorb fluids, needs no notice, but it is also employed by them under the name of *Sponge Tent*, when prepared in a particular manner. This consists in dipping the sponge in melted wax, and compressing it between iron plates till it hardens on cooling; it is then cut into cylindrical or other forms. The pieces are introduced into sinuses and other narrow canals, with the intention of dilating them by the expansion of the sponge, when the wax melts by the heat of the part. Sponge Tents are however little used by modern surgeons.

When sponge has been cut into pieces, beaten in order to free it from little stones and shells, and burnt in a closed iron vessel till it is black and friable, it is then called *Burnt Sponge*, and contains a quantity of Iodine. It has been almost completely superseded in the treatment of Bronchocele and Scrophula by Iodine and its preparations.

SPRING, in Mechanics, is an elastic plate or rod, which is employed as a moving-power, or a regulator of the motions of wheel-work; also to ascertain the weights of bodies, or to diminish the effects of concussion. The use of a spring as a moving-power may be best exemplified in its application to watch-work. The main-spring of a watch is a thin and narrow plate of well-tempered steel, which is coiled in a spiral form: one of its extremities is attached to a pivot or axle, and the other to the interior circumference of the cylindrical box in which it is contained. In being wound, the spring closes round the axle, and afterwards, in the effort by its elasticity to recover its former position, it turns the cylinder in a contrary direction: thus the chain which is attached to the exterior circumference of the cylinder and to the fusee causes the latter to revolve.

A slender and highly-elastic spring of a like form is employed to produce a vibratory motion in the balance ring of a watch. One extremity of the spring is attached to the axle of the balance, and the other to some part of its circumference. The elastic power of the spring varies with the tension, and is directly proportional to the angle through which the spring is wound about the axle; and thus the vibrations of a spring, like those of a pendulum in a cycloidal arc, are isochronous. The length of the spring and the diameter of the balance are increased by heat and diminished by cold; consequently, without some compensating power, the times of vibration will vary according to the changes of temperature.

SPRING-BALANCE, is a machine in which the elasticity of a spring of tempered steel is employed as a means of measuring weight or force. One of the simplest kinds of spring-balance is the *Spring Steelyard*, or *Pocket Steelyard*. This instrument consists of a helical spring placed in the interior of a tube of brass or iron, closed at both ends; one end of the spring abutting against the plate which closes the lower end of the tube. A rod, having a hook or loop at its lower extremity, passes through a hole in the bottom of the tube, and up the inside of the spring. At the upper end of this rod is a small plate, which slides up and down like a piston in the tube, and rests upon the upper or free end of the spring; thereby causing it to collapse when a heavy body is attached to the hook at the bottom of the sliding rod. The extent of the motion of the spring, and consequently the weight of the body suspended from it, are indicated by the degree to which the rod is drawn out of the tube; for which purpose a graduated scale is engraved upon the rod.

Many improved varieties of spring-balance are now manufactured; and similar instruments are applied to many useful purposes besides weighing. Marriott's Patent *Weighing Machine* has a spring which is a perfect ellipsis, with its longer axis laid horizontally. The stem to which the ring for holding the apparatus is attached is fastened by a nut and screw to the middle of the upper side of the spring; and the rack, with the hook which holds the article to be weighed, to the corresponding point on the lower side of the spring. The spring, rack, and pinion are inclosed in a circular box at the back of the dial-plate, the periphery of which serves as a stop to prevent the spring from being overstrained. A similar apparatus, contrived by M. Regnier, has been used as a dynamometer, as well as a weighing-machine.

SPRING, CARRIAGE. Various methods are adopted for lessening the concussion occasioned by the rolling of a wheeled carriage over a rough road. One of the simplest means is that often adopted in light carts, of suspending the seat from the sides of the body by leather straps or lashings. Next to this is the use of straps to suspend the body itself, an expedient which seems to have been occasionally resorted to from a very early period. To remedy the defects of the primitive slung carriage, it was desirable to render the pillars from which the straps were suspended somewhat elastic. This could not be readily effected with wood, because the pillars were necessarily short, and therefore stiff. Hence arose the use of elastic steel supports, which have gradually assumed the form now well known as C-Springs. These were formerly used for almost all kinds of carriage-springs; but the great improvement of our roads has made way for the introduction, in all stage coaches, and in many private carriages, of the more compact straight and elliptic springs.

Carriage-springs are usually formed of several thin plates of steel, of various lengths, so laid and fastened together that the spring shall be thick in the centre, or at the end by which it is fixed, and thin, or consisting of only a single plate, at the end or ends where the greatest play is required. The steel used is of coarse quality, and has little carbon in its composition.

Coach-makers apply distinct names to a great many varieties of springs. The straight spring, if single, or acting only on one side of the point at which it is fixed, is technically named the *Single-Elbow Spring*. The *Double-*

Elbow-Spring is a straight spring, acting on both sides of the fixed point. *Elliptic Springs*, which are usually but little curved, are used single in some carriages, between the axle and the framework. Elliptic springs are often used in pairs under the name of *Nut-Cracker Springs*, the two springs being hinged together at each end, so as to form a long pointed ellipsis. *C-Springs*, which are chiefly used in private carriages, usually consist of two-thirds of a circle, lengthened out into a tangent; the tangent being laid horizontally, and bolted down to the framework of the carriage. *Telegraph Springs* are combinations of straight springs in sets of four. *Tilbury-Springs* are another combination of straight springs used for the two-wheeled carriage called a tilbury. *Dennet-Springs* are a combination of three straight springs, two of them placed across the axle, and attached at their fore ends to the shafts or the framing of the body, and the third placed transversely, suspended by shackles from their hinder extremities, and fastened to the body at its centre. To meet the deficiencies of the springs in common use, Mr. Adams contrived one on the principle of the bow, which will yield in any direction, and may be made capable of adjustment, by means of screws, to a light or heavy load.

SPRUCE BEER. This fermented liquor is made from the leaves and small branches of the spruce-fir, with sugar or treacle. There are two kinds of spruce beer—the brown and the white—of which the latter is considered the best. In the manufacture, essence of spruce is fermented much in the same way as grape-juice in wine-making. In places where spruce-firs abound, a simple decoction of the leaves and small branches is used instead of the essence of spruce. This agreeable and wholesome beverage is useful as an anti-scorbutic.

STAFFORDSHIRE. This county is rich in coal. [COAL.] Gypsum is quarried in Needwood Forest and in the adjacent part of the valley of the Dove; the pure white gypsum, or that slightly streaked with red, yields plaster of Paris, which is much used in the potteries for moulds. Near Dudley is a mass of basalt, locally termed Rowley Rag; it is quarried for mending the roads and paving the streets of Birmingham. The coal-works of the county are very numerous and important; in the south they supply the iron and other hardware manufactures of Birmingham, Dudley, Wolverhampton, Wednesbury, Bilston, Walsall, &c.; and in the north they supply the fuel to the Pottery district. Perhaps the neighbourhood of Birmingham is the cheapest district for coals in England, and the consumption is prodigious. Ironstone is abundant in the Dudley coal-field.

The canals of this county are numerous. The most important is the Trent and Mersey Canal, or, as it is sometimes called, the Grand Trunk Canal, which crosses the county. The Birmingham Canal and the Birmingham and Liverpool Junction Canal may be regarded as forming another important line, entering the county near Birmingham, and passing through the iron and coal district, by Dudley and Wolverhampton, and then running into Shropshire. There are several smaller lines which belong to the coal and iron districts of South Staffordshire. The county is also well supplied with railways.

The manufacturing towns of Staffordshire are numerous and important. The pottery towns are noticed under POTTERIES. The iron and coal works of BILSTON and BROMWICH are noticed under those headings. *Cheadle* has manufactures of copper in its vicinity. *Leek* is one of the silk manufacturing towns. *Lichfield* is rather an agricultural centre than a seat of manufactures; and the same may be said of *Tamworth*. *Newcastle-under-Lyne* has a considerable manufacture of hats. *Stafford* is one of the depôts of the shoe manufacture. *Tipton* is situated in the centre of the South Staffordshire iron and coal district, and its present size and importance are quite modern, and have arisen from the rapid extension of the iron manufactures. In *Walsall* the inhabitants are employed largely in manufactures of iron and brass; and there are coal-mines and freestone and limestone quarries in the neighbourhood. *Wednesbury* is also in the heart of the South Staffordshire coal and iron district, and it has considerable manufactures of fire-arms, machinery, edge-tools, files, screws, &c. *Wolverhampton* produces largely manufactures of fire-irons, tinned and japanned iron-ware, locks, guns, files, screws, and a variety of other articles.

STAINED GLASS. [GLASS PAINTING.]

STAIRCASE. It was not till about the time of Elizabeth that staircases began to be planned commodiously in this country, and made a decorative feature in the interior of a mansion. At a later period, staircases in mansions of a superior class were made disproportionably spacious, being upon a scale as to size with which the apartments themselves were not at all in keeping. One of the most simple and effective, yet least common arrangements of a staircase, is that which may be described by the term *Avenue Staircase*, the stairs being continued in a straight line.

though broken by spaces into a succession of flights, within what would else be a level corridor or gallery; and occupying its entire width. Simple as such plan is in itself, it is by no means adapted to general application, because, although it requires only moderate width, it requires considerable length, short flights, and ample spaces between them, and stairs with low risers and broad treads. In public edifices or large mansions, whatever be the plan of the principal staircase, it is generally *branched*, that is, there is first a wide central flight, and then two other narrower flights branching off from it on each side, either at right angles to it, or as return flights parallel to it; and it is hardly necessary to observe that in all such staircases the foot-spaces are large and there are no winders. The staircase at Goldsmiths' Hall, which is parted off from the vestibule by a glazed screen, is an example of more than ordinary splendour, being lighted by a dome. The new staircase at the British Museum is also of this kind.

The grand staircase of the Reform Club House, London, is an example, somewhat unusual in this country, though common enough in Italy, of what may be called an *Enclosed Staircase.* The flights are shut up between walls, and consequently there is no open well, nor can the whole be seen at one view.

The architectural effect of a staircase will greatly depend upon the mode of lighting it. Where it is carried up only one floor, the best mode is to light it entirely from above, either through a dome or lantern in the ceiling, or by making the upper part of the walls, just beneath the ceiling, a continued lantern.

STAMPING PRESS. Many articles of metal manufacture receive their form by stamping. One half of the impress is on the lower surface of the hammer or falling weight; the other half is on the upper surface of the anvil or bed; and a piece of metal being placed between the two, it receives an impress on both sides. In making spoons, ladles, and forks, the impress is given to the handles and to the bowls or prongs by distinct operations of different dies; and the pattern being thus partially produced, the articles are finished by filing and hammering. There is, however, a patented method of stamping spoons with one pair of dies, which produce the handle and the bowl at one time.

Various illustrations of the stamping of metals will be met with under BUTTON MANUFACTURE, CHASING OF METALS, and MINT.

STANDARD MEASURES AND WEIGHTS. Measures are wanted for two distinct objects, the commercial and the scientific. The wants of natural philhsophy have grown up within the last two centuries; while so early as Magna Charta it was one of the concessions to the grievances of the subject, that there should be one weight and one measure throughout the land. But though a few acts of Parliament were sufficient, in process of time, substantially to establish the political rights which that charter was intended to grant, hundreds of them, down to the present time, have been ineffectual in producing the use of one weight and one measure. This unity was for commercial not scientific purposes; and the resemblance of natural objects was supposed to be a sufficient reliance for obtaining it. Some of the old statutes expressly make the inch to be the length of three barleycorns, placed end to end, round and dry, from the middle of the ear. Standards were made no doubt from this definition; or at least it was supposed that if the existing standard should be lost, the barleycorns would enable its restoration to be effected. The average length of three barleycorns, whether we call that length an inch or by any other name, among many thousands, would doubtless always be the same under similar conditions of growth.

A commercial standard might be easily recovered from many different modes of proceeding: for example, the average height of the barometer at a given place throughout any period of five years is so nearly the same from one five years to another, that a commercial standard might be sufficiently well obtained from it. It would be of little consequence if the yard were wrongly recovered by one-hundredth or even one-tenth of an inch, in any matter of buying and selling.

It is the *scientific* standard at which the government has been aiming during the last century. The object here is, first, to measure the old standards to the utmost accuracy of which our senses, assisted by microscopes, are capable; secondly, to discover the means of reconstructing a lost standard. In the more delicate operations of natural philosophy and astronomy, our knowledge cannot go down to posterity unless they know within the thousandth of an inch what it is that we call a yard. The public at large has never understood the reason why so much trouble has been taken; and perhaps the members of different administrations, while trusting such investigations to men of science, and relying on them for the whole conduct of the matter, may have wondered at the great difficulty which there seemed to be in the way of furnishing the shopkeepers of all generations with yard measures and pound weights of the same values.

The following is the existing legal definition of standards according to the act of 1825:—

1. The straight line or distance between the centres of the two points in the gold studs in the straight brass rod now in the custody of the clerk in the House of Commons, whereon the words and figures 'Standard yard, 1760' are engraved, shall be the original and genuine standard of that measure of length or lineal extension called a yard . . . the brass being at the temperature of sixty-two degrees of Fahrenheit's thermometer. The act goes on in many words to say that the pendulum vibrating seconds of mean time in the latitude of London in a vacuum at the level of the sea is 39.1393 inches of the said standard.

2. The standard brass weight of one pound troy weight, made in the year 1758, now in the custody of the clerk of the House of Commons, shall be the original and genuine standard measure of weight. . . . . The act goes on to say that the cubic inch of distilled water, weighed in air by brass weights, at 62° of Fahrenheit, the barometer being at 30 inches, is equal to 252·458 grains.

The last event in the history of this subject was the report (in 1841) of a commission of men of science appointed in 1838. After reciting that the standard yard was rendered absolutely useless by the fire at the House of Commons, and that the standard troy pound was altogether missing, the commissioners begin by recommending the total disuse of all attempts to procure a natural standard, and the return to the old plan of standards manufactured in metal; that four copies of the best existing representations of the old standards should be made, and carefully compared; that one of these copies should be hermetically sealed, and imbedded in the masonry of some public building, marked by an inscription, and only to be opened by Act of Parliament; that the standard of capacity be defined by that of weight, not by that of length; that various precautions, minutely named, be taken for the preservation and safe custody of the others; that the avoirdupois pound, and not the troy, be the standard; that the government purchase all the known copies of the old standards which have been noted in scientific operations; that no circumstance would contribute so much to the introduction of a decimal scale in weights and measures as the establishment of a decimal coinage, which is strongly recommended; that the old Gunter's Chain be preserved in the measurement of land; that a measure of 1,000 or 2,000 yards receive a name, and be used co-ordinately with the mile, with a view to the gradual disuse of the latter; &c. Steps have been taken to recover a standard yard, by comparison of the existing scales which had been compared with the last standard.

Although not directly of great importance to manufacturing and trading affairs, the determination of these standards is indirectly advantageous; and the subject is at any rate worthy of more general public attention than it usually receives.

STANNARY. This term sometimes denotes a tin-mine, sometimes the tin-mines of a district, sometimes the royal rights in respect of tin-mines within such district. But it is more commonly used as including the tin-mines within a particular district, the tinners employed in working them, and the customs and privileges attached to the mines, and to those employed in digging and purifying the ore.

The great stannaries of England are those of Devon and Cornwall, of which the stannary of Cornwall is the more important. The stannaries of Cornwall and Devon were granted by Edward III. to the Black Prince, upon the creation of the duchy of Cornwall, and are perpetually incorporated with that duchy. In general both stannaries are under one duchy-officer, called the lord-warden of the stannaries, with a separate vice-warden for each county. The stannary of Cornwall is subdivided into the stannary of Blackmore, in the eastern parts of the county, and the stannaries of Tywarnhaile, Penwith, and Helston, in the west.

All tin in Cornwall and Devon, whoever might be the owner of the land, appears to have formerly belonged to the king, by a usage peculiar to these counties. King John, in 1201, granted a charter to his tinners in Cornwall and Devonshire, authorising them to dig tin and turves to melt the tin anywhere in the moors and in the fees of bishops, abbots, and earls, as they had been used and accustomed. This charter was confirmed by Edward I., Richard II., and Henry IV. In Cornwall the right of digging in other men's land is now regulated by a peculiar usage, called the custom of *bounding*. This custom attaches only to such land as now is or anciently was *wastrel*, that is, land open or uninclosed.

As part of the stannary rights, the Duke of Cornwall, as guarantee of the crown, has or had the pre-emption of tin throughout the county, a privilege supposed to have been reserved to the crown out of an original right of property in tin mines, but in modern times it is never exercised.

The duties payable to the Duke of Cornwall on the stamping or coinage of tin were abolished by an Act passed in 1838; and the stannary courts were remodelled by other Acts in 1836 and 1839. By that of 1839 a stannary courts' duty of one farthing in the pound sterling was imposed on tin and tin ore.

STAPLE. A staple, or market, was the term applied in the middle ages to indicate those marts both in this country and at Bruges, Antwerp, Calais, &c., on the Continent, where the principal products of a country were sold. The staples were confirmed or appointed in England by the king. All merchandise sold for the purpose of exportation was compelled either to be sold at the staple, or afterwards brought there before exportation. This was done with the double view of accommodating the foreign merchants, and also enabling the duties on exportation to be more conveniently and certainly collected. Afterwards the word staple was applied to the merchandise itself which was sold at the staple. The staple merchandise of England at these early times, when little manufacture was carried on here, is said by Lord Coke to have been wool, woolfells or sheepskins, leather, lead, and tin. Incident to the staple was a court called 'the court of the mayor of the staple.' This court was held for the convenience of the merchants, both native and foreign, attending the staple. Many early enactments exist regulating the proceedings at the staple and the court held there; most of these were passed during the reigns of Edward I. and Edward III. A variety of other statutes were passed in the same and succeeding reigns, in some respects confirming, in others altering, the provisions of the leading statute. As commerce became more extended, the staples appear to have fallen into disuse.

STARCH (called also *Farina* and *Fæculum*) is a proximate principle of plants, chiefly found in the seeds of corn and pulse, in many kinds of tubers, and sometimes in wood, bark, and leaves. In all these instances it is associated with other principles, which are either employed with it, or separated by different processes, according to the use intended to be made of it. In wheat it is associated with variable proportions of gluten, sugar, and gum; in potatoes chiefly with gum and sugar. It is mostly lodged in the cells of the cellular tissue, and consists of granules, always white, generally of a roundish and seldom of an angular figure. The granules differ in size, often in the same seed, being generally smallest near the circumference. They differ also in different plants. The granules are lodged mostly in the cells or compartments of the cellular tissue; and each granule consists of a membrane, containing a transparent colourless material resembling gum.

The insolubility of the membrane in cold water affords a means of separating the starch from the gluten in wheat-flour, and from the fibrous matter in potatoes and other tubers. Wheat-flour is formed into a paste with water, and then kneaded under a stream of water so long as the water runs off of a milky appearance; what remains behind is chiefly gluten, while the water has carried off the starch suspended in it; and gum, sugar, and some phosphatic salts, either dissolved or suspended in it. The water charged with these matters is permitted to stand for a few days in summer, but for a week or two in winter, to allow the acetous fermentation to occur, by which the sugar and other principles are got rid of. The acid liquor termed *sours* is drawn off, and the starch thrown upon sieves, and washed; the bran and other impurities are retained on the sieves, while the starch is carried forward into large vessels called *frames*. In these the starch subsides, and the water, which has become perceptibly sour, drawn off, and the *slimes* removed. The starch is then washed, passed through a sieve, and finally allowed to subside. Thus purified it is put into boxes lined with canvas and perforated with holes, by which the superfluous water escapes. Afterwards it is cut into squares, put on bricks, and exposed to the heat of an oven, where it splits into irregular prisms. When free from any artificial admixture, it is perfectly white, and termed white Starch or French Starch: but in general, azure (smalt) or indigo is added, when it is employed for stiffening linen, to which it imparts a more agreeable hue than the dull white of that material.

Starch, when pure, is nearly devoid of odour and taste. The best bread is formed by flour which contains the greatest proportion of gluten. The relative proportions of starch and gluten differ not only in the different cereal grains, but in the same species or variety, according to the season when they are sown, or the manure which has been applied to the land. Starch exists in larger proportion in Carolina rice than in any other grain. Potatoes yield the purest starch, variable in quantity with the kind of potato used, the mode of cultivation, the time of setting, and, above all, the time of year when the process is applied.

Starch is most extensively used in the arts, but it is little employed in medicine, except for its demulcent properties, and as a vehicle for opiate injections. Some of the calico printers use a kind of stiffening material or starch, which they call *British gum*, and which was brought into use on account of the high price of gum senegal; it is prepared from wheat flour, and is midway in quality between common starch and common flour-paste.

STATUARY. [SCULPTURE; STONE MASONRY.]

STEAM. Water converted into steam occupies more than 1700 times its former space. Steam will be produced at a proportionally lower temperature if we diminish the pressure of the atmosphere on the water, which may be done either by ascending a mountain or by drawing away a portion of the air by means of an air-pump. When we continue to apply heat to ordinary steam, under a constant bulk, its elasticity rapidly increases, and it is then termed *high-pressure;* steam of the ordinary temperature being termed *low-pressure*.

The following table gives the temperature of boiling water and the corresponding pressures of the air, measured in inches of barometrical pressure.

Heat of boiling water.	Corresponding pressure of air.
215°	31.8
212	30.
209	28.2
200	22.8
180	15.2
160	9.45
120	3.27
100	1.97
10	1.03

Calling 30 inches of pressure *one atmosphere*, we have the following pressures for high temperatures:

Atmospheres.	Barometer.	Temperatures.
1	29.8	212°
2	59.6	250.3
4	119.2	293.4
8	238.4	343.6

The following table shews the elastic force of the vapour of water in mercurial inches, with the corresponding temperatures.

Temp.	Elasticity.	Temp.	Elasticity.
32°	0.20	200°	23.60
55	0.42	212	30.00
65	0.63	220	35.54
75	0.86	240	51.70
80	1.01	250	61.90
90	1.36	260	72.30
100	1.86	280	101.90
120	3.30	290	120.15
140	5.77	300	139.70
160	9.60	305	150.56
180	15.16	310	161.30

Steam has lately been employed in a considerable number of novel modes, as an effective agent in the arts. A remarkable employment of steam in charcoal making is noticed under CHARCOAL. M. Violette, in a paper communicated to the Academy of Sciences in 1848, states that bread and biscuits may be well baked by means of a current of steam at a temperature of about 400° Fahrenheit. He also thinks that the cooking of meat may be effected by the same agent. The extraction of wood vinegar (pyroligneous acid) is another process which seems to come within the same range; and as the temperature of the steam, and consequently the heat of the whole process, may be regulated at pleasure, it is thought that the acid may be extracted without the empyreumatic oil which usually accompanies it in the ordinary process. The extraction of wood alcohol (pyroxylic spirit) is attainable by the same means. The drying of wood by highly-heated steam adds another to the list of proposed uses.

STEAM-CARRIAGE. The application of the steam-engine to the purpose of locomotion upon railways, has been noticed elsewhere. [RAILWAY.] In a steam-carriage for use upon a common road, provision must be made for passing over rough, soft, and constantly-varying surfaces, and for surmounting acclivities of considerable steepness; the machine must be provided with a steering apparatus, by which it may be guided with ease and certainty along the sinuosities of a common road or street, among other vehicles, and round sharp corners; the weight must be kept within the smallest possible limits; and the machinery must be compacted within a small space.

There were various attempts to construct such machines in the last century; but the first invention which claims notice is that patented in 1802 by Messrs. Trevithick and Vivian, and shortly afterwards brought into operation. Their carriage was mounted upon four wheels; the principal weight resting upon the hind wheels, which were of large diameter, while the fore wheels, which were used for guiding the carriage, were small, and nearer together than the others. The boiler and the steam-cylinder were placed at the back of the hind axle, and the cylinder was horizontal. The carriage, shortly after the date of this patent, was exhibited in London with sufficient success to prove the practicability of the invention. The inventors, however, soon gave up their experiments on common-road locomotion, and adapted their machinery to use upon a railway.

For about twenty years after the experiments of Trevithick, no steam-carriages for common roads were constructed; but when the improved state of the turnpike-roads rendered steam-locomotion more practicable upon them, steam-carriage projectors arose in rapid succession. Mr. Griffith's steam-carriage, patented in 1821, had the boiler and machinery suspended from the framework by chains and helical springs. Mr. David Gordon's machine, patented in 1822, had its wheels surrounded by cogs or projecting teeth. Another machine, by the same inventor, had two long propellers or legs, intended to obviate the supposed tendency of wheels to slip, when ascending a slope. Of others who have invented and built steam-carriages between 1824 and the present time, the names of Goldsworthy Gurney, Burstall and Hill, W. H. James, Walter Hancock, Summers and Ogle, Messrs. Heaton, Dr. Church, Dance and Field, Squire and Macerone, Scott Russell, Hills, and Sir James Anderson, are the most prominent, although many others have appeared upon the field. Several of these inventors have produced carriages capable of maintaining an average speed of from ten to twelve miles per hour for considerable distances, and a much more rapid rate of motion for a short time; and some have succeeded in performing extensive journeys with their steam-carriages. The greatest amount of success yet attained was in a steam-carriage constructed by Mr. Gurney, and brought forward by Mr. Charles Dance, who established a regular steam-conveyance between Gloucester and Cheltenham; but commercial failure has hitherto attended all these attempts.

The forms of apparatus in these carriages are of course various. As to the boiler, the essential requisites are the power of generating steam very rapidly; strength, to secure it from explosion; lightness; and compactness. A great number of contrivances have been tried with the hope of accomplishing the desired union of these qualities; all of them consisting either of small tubes, or of separate chambers. The means adopted for producing a strong draft in the fire are of two kinds; viz., by an air chamber, and by air-fans. Many different arrangements have been adopted for communicating the power of the pistons to the wheels of the carriage; as indeed is also the case in respect to railway locomotives. The operation of steering is usually performed by a hand-wheel in the fore-part of the carriage, giving motion, by means of a rack and pinion, or a chain and pulley, to the fore-axle. The *Brake*, by which the motion of the steam-carriage may be arrested when necessary, usually consists of metallic bands, capable of being pressed against either the nave or the periphery of one or both of the hind-wheels.

STEAM-ENGINE. The earlier steam-engines, even Captain Savery's, which was long employed in this country, were only pumps for raising water; a partial vacuum was formed in close vessels by the condensation of steam within them, and the atmospheric pressure raised the water to a certain height, whence it was forced higher by the elasticity of the steam admitted to act on its surface.

The first steam-engine which formed the connecting link between the steam-pumps and the modern steam-engines, was invented by Newcomen (1705). It contained a cylinder open at the upper end, fitted with a piston; and the upward movement of the piston was occasioned by the pressure of steam beneath it; whereas the downward movement was caused by the pressure of the air. Newcomen's engine was successively improved upon by Smeaton, Brindley, and other engineers, previous to Watt's time; and from its intrinsic merits it remained in general use under the appropriate name of the *Atmospheric Engine* during the greater part of the last century, but was only used for pumping water. Its guiding principle was, that the steam was solely employed to produce a partial vacuum by its condensation, its elastic force at high temperatures not being made use of.

The first and most important of Watt's improvements on the steam-engine consisted in effecting the condensation in a separate vessel, termed the *Condenser*, which communicated with the cylinder; whereas Newcomen condensed his steam by a jet of cold water in the cylinder itself. This condenser being filled with steam from the boiler at the same time with the cylinder, the jet of cold water, admitted into the former only, effected the condensation of the whole volume of steam, both of that in the cylinder as well as of that in the condenser. As the cylinder was thus not coooled by a jet, a vast economy of heat resulted. The second of Watt's improvements consisted in closing the cylinder at top, the piston-rod being made to pass steam-tight through a cylindrical neck in that top, termed a *Stuffing-Box*. The object of this alteration was to admit of the elastic force of the steam being employed to impel the piston downwards, instead of simple atmospheric pressure. For this purpose the steam was admitted from the boiler above the piston at the same moment the condensation took place in the condenser; the steam-passage being made double for the purpose, so that the communication with the condenser could be cut off when that with the cylinder was opened, alternately. Such is the general principle of Watt's *Single-Acting Engine*, which hence became a Steam-Engine, and was no longer an Atmospheric Engine; it became a *Double-Acting Engine* by removing the counterpoise, and producing the upward motion of the piston by admitting steam below as well as above it.

The changes in the engine introduced by Watt created the necessity for two pumps, and commonly three, which are worked by rods attached to the beam. The first of these is the ***Hot-Water*** or ***Air-Pump***, intended to remove the air, condensed water, and steam from the condenser, in which they would otherwise accumulate, and finally stop the action; the second is a ***Force-Pump***, required to return the water, drawn from the condenser by the first, back to the boiler; and the third, termed the ***Cold-Water Pump***, supplies the cold-water cistern which contains the condenser.

In the mechanism of a steam-engine, the ***Piston*** is one of the most important parts, as it must be steam-tight, and yet work easily in the cylinder. The better class of engines have now usually what are called *Metallic Pistons*, of which there are different kinds, invented by Cartwright, Jessop, Barton, and others. The body of these pistons is metal, made in pieces or segments, acted on by springs radiating from a centre; so that while the friction is diminished by both surfaces being metallic, the piston, owing to its construction, can adapt itself to the irregularities of the cylinder. The steam is admitted to the cylinder by various ingenious contrivances, among which the *four-passage cock*, the *conical valve*, and the *slide valve* are the chief. For the opening and shutting of the valves, an *Excentric* is now generally used; this is a peculiar contrivance, worked from the fly wheel. This *fly-wheel* is necessary when the engine is employed to drive machinery of any kind; it is a heavy wheel, whose weight tends to equalize the motion of the beam and piston.

When Watt substituted the elastic force of steam for the pressure of the atmosphere, he introduced a source of power which might be increased to an indefinite extent, provided it were found advantageous to employ it. Generally it is more advantageous to employ steam of a comparatively high elastic force; accordingly the pressure was increased, in engines constructed by Watt, from 4 to 8, or even 12 lbs. on the inch. Modern boilers are so skilfully made, that steam of 100 lbs. on the inch may frequently be safely used. In the common engine, if the pressure on the piston continue uniform during the stroke, as it would do if the communication with the boiler remained open, the piston would move with an accelerating velocity till it arrived at the end of the cylinder, by which it would produce mischief; hence the steam is cut off at a particular stage in the descent; and when the steam possesses considerable elastic force, the communication with the boiler is cut off sooner, and the piston is urged forward by the expansive force of the steam, which, although decreasing as the space increases, is yet sufficient to carry the piston to the end of the stroke.

Although the Condensing Engine is very perfect and economises fuel, it is necessarily heavy, and occupies considerable room. For cases where the two last-named particulars are of importance, the *Non-Condensing Engine* was invented. A locomotive for railways is the most important form of non-condensing engine; but such engines are frequently valuable for other purposes. Since the pumps of the condensing-engine are dispensed with in the non-condensing engine, the beam may be so likewise; and a still further simplification results from an oscillating movement given to the cylinder. Such engines are termed *Vibratory Engines*, and are successfully used where space must be economised, as with marine engines. Non-Condensing Engines are frequently termed *High-Pressure Engines*, in contradistinction to *Low-Pressure* or Condensing Engines.

Marine Engines, or those used for propelling vessels, are in this country generally condensing engines, their situation admitting the abundant use of cold water. The principal peculiarity in the arrangement of the marine engine is the position of the beam, which, for the purpose of economising room, is placed lower than the cylinder, and is double, there being one on each side. In all vessels of any magnitude, there are two engines complete, so arranged, that while the rod and crank of one are in their neutral position, those of the other are in that of greatest effect. In steam-vessels of smaller size, the *direct action* is often used; that is, the piston-rod turns the shaft without the intervention of any beam. In American steam-vessels the engines are frequently high-pressure.

Engineers have always been induced, by the obvious advantage of a continuous over an alternating motion, to aim at contriving a steam-engine in which the steam should act directly to produce such a motion. Watt accordingly patented more than one of such *Rotatory Engines*, and many others since have from time to time brought forward arrangements for the purpose; but none have come into permanent and general use. The fact is, that the employment of steam in this way is productive of a greater waste of power, with a greater increase of friction, than can be compensated by any real advantages.

The peculiarities of the *Locomotive Engine* are noticed under RAILWAY.

No part of a steam-engine exhibits more variety, according to the purpose to which it is to be applied, than the *Boiler*. Rapid generation of steam, security, compactness, and lightness, must be aimed at in boilers for marine or locomotive engines, even at the cost of a comparative waste of fuel; while for those intended for pumping or driving machinery, economy of fuel must be the paramount object, the weight, form, and space occupied by the boiler being secondary considerations. As very large boilers are unsafe, it is customary to use two or more small boilers instead of one large one; and the principle, carried to its limit, constitutes that of the *Tubular Boiler*, in which the steam is generated in a series of independent metal pipes of small diameter, all communicating with a common steam-chamber, or reservoir, itself small, and strong enough to resist great pressures. The *safety valve* is a contrivance for letting off some of the steam from the boiler when the elasticity is dangerously high. *Gauges* are employed to measure the quantity of the water, and the pressure of the steam in the boiler.

Whenever the steam-engine is employed to execute any work which is variable in its quantity or intensity, there must be some means of adjusting the force of the engine to this varying resistance it has to overcome. The object of that beautiful piece of mechanism termed the *Governor* is to enable the engine to regulate the supply of steam admitted to the cylinder, or in other words to adapt the force it has to transmit to the resistance it has to overcome. In this apparatus, two balls rotate round a common axis, with a velocity depending on that of the fly-wheel; if this velocity is great, the balls diverge by virtue of the centrifugal force, and this divergence is a means of partially closing a valve, and lessening the amount of steam which enters the cylinder. From different causes the marine engine and the locomotive do not require governors.

A museum of steam-engines would display some of the highest results of human ingenuity ever manifested. Among the toys or curiosities of such a museum might be placed the tiny steam-engine, made by a mechanic of Saddleworth, for the Great Exhibition, and weighing only three-quarters of an ounce.

STEAM-HAMMER. The steam-hammer introduced by Mr. Nasmyth, economises time and labour in a remarkable degree. It is the most efficient and practical machine yet invented for dealing heavy blows rapidly and steadily. In anchor-making, in iron-forging, and in pile-driving, its application is particularly valuable. The mode of applying this powerful machine to the purposes here indicated, is briefly adverted to under ANCHOR, IRON MANUFACTURE, and PILE ENGINE. An American patent has more recently been obtained by Mr. Kirk for another steam hammer, in which the hammer has a long handle something like the beam of a steam engine, with a fulcrum at the centre, and the hammer head at one end; but we do not know whether this invention has been practically worked.

A medium between a steam hammer and a sledge hammer has been devised for the use of blacksmiths, and called by the fanciful name of the *Blacksmith's Apprentice*. The *foot* of the blacksmith works the sledge hammer instead of the apprentice or subordinate who assists him. The foot presses on a treadle, the other end of which has a chain which coils round a horizontal barrel, to which barrel the sledge hammer is attached; the sizes of the different parts are so regulated, that when the foot presses down the treadle, the hammer is whirled round with considerable force upon the anvil, leaving the hands of the workman free to conduct subsidiary operations.

STEAM VESSEL. Papin proposed a kind of steam-boat, but made no attempt to construct one; and after his time several plans for propelling boats by other means than oars or sails were proposed and tried. At length, in 1774, the Comte d'Auxiron, a French nobleman of scientific attainments, constructed a steam-boat, and tried it on the Seine, near Paris. It appears that the engine had not sufficient power to move the wheels efficiently; an error which was also observable in contrivances brought forward shortly afterwards by Perier and others. The Marquis de Jouffroy tried a steam-boat of considerable dimensions on the Saône, in 1782: it had a single paddle-wheel on each side, and the machinery appears to have been constructed with some skill, though it was not sufficiently strong. M. des Blancs in 1796 formed a boat which was propelled by means of paddles or float-boards attached to an endless chain stretched over two wheels projecting from each side of the vessel. In America an inventor named Fitch succeeded as early as 1783 in moving a boat on the Delaware by means of paddles (not paddle-wheels) set in motion by a steam-engine. In 1787 Rumsey made some short voyages on the Potomac, with a boat about fifty feet long, propelled by the reaction of a stream of water drawn in at the bow and forced out at the stern by means of a pump worked by a steam-engine.

While Fitch and Rumsey were making their experiments in America, other experiments were in progress in Scotland, which tended, more than any previous trials, to the useful application of steam to the purpose of propelling vessels. Mr. Miller, of Dalswinton, Mr. James Taylor, and Mr. Symington, were the three persons who had most to do with this important improvement. A very small steam-boat was constructed by them in 1788, and one constructed larger in 1789. In 1801 Symington commenced a satisfactory series of experiments on steam navigation, under the auspices of Lord Dundas. The object immediately aimed at was the introduction of tug-boats instead of horses for drawing boats upon canals. After several minor trials, one of the boats built on this occasion by Symington drew, on the Forth and Clyde Canal, in 1802, two loaded vessels, each of seventy tons burden.

Among the numerous individuals who inspected Symington's vessel with interest was Fulton. After various minor attempts, Fulton procured, in conjunction with Mr. Livingstone, a patent in America for steam navigation, about the year 1805. He built a steam-vessel at New York, and launched it in the spring of 1807. It made its first voyage from New York to Albany, 145 miles, at the rate of five miles an hour. The dimensions of the boat, which was of 160 tons burden, were 133 feet long, 18 feet wide, and 7 feet deep. Her cylinder was two feet in diameter, and of four feet stroke; and the paddle-wheels were fifteen feet in diameter, with paddles four feet long, dipping two feet into the water. Meanwhile Mr. Stevens, of Hoboken, near New York, introduced steam-boats on the Delaware, and made such improvements in the form of the vessels as to enable him to obtain a speed of thirteen miles an hour. Steam navigation thus became finally established in America.

Henry Bell, of Helensburgh, on the Clyde, was the individual by whom steam-vessels were first used in Britain for commercial purposes. He built a small steam-vessel called the Comet, of forty feet keel and ten and a half feet beam; and of about twenty-five tons burden, and three-horse power. The boiler was placed on one side of the vessel, and the funnel or chimney, was bent so as to rise in the centre of the vessel, where it served the purpose of a mast for carrying sail. A single cylinder was used impelling a cranked axle which carried a large toothed wheel; and this wheel, working into two others fixed upon the axles of the paddles, caused them to revolve. Two paddle-wheels, or rather two sets of revolving paddles, each consisting of four paddles of a form resembling malt-shovels, were used on each side of the vessel. The Comet began to run regularly between Glasgow and Helensburgh, in January, 1812, and continued to ply successfully during the following summer; her rate of motion was about five miles an hour. Improvements were soon found advisable, and Bell soon abandoned the peculiar arrangement of paddles by which his first experiment was distinguished, and adopted complete paddle-wheels. This interesting little steamer is further noticed under Clyde. From that time to the present numerous experiments and an uninterrupted succession of improvements have brought steam-navigation to its present high state of perfection.

The proportions of steam-vessels were, originally, like those of sailing-vessels, short and full, their length being only about three or four times their breadth; while now the proportion of six breadths to the length is common in the best sea-going steam-vessels, and many of the fast river boats are still longer, ranging in length from seven to ten times their width. In America the proportion of length to breadth is sometimes made even greater than as ten to one; and boats have been built, the length of which is twelve times their breadth. In larger steamers, the depth of the hull bears a greater ratio to the width than in smaller vessels. Different steam-vessel builders adopt very different forms, according as they wish to obtain a *roomy*, a *safe*, or a *swift* boat; at the present day swiftness is regarded as almost an indispensable quality.

One of the important questions which has of late years attracted much attention in connection with steam navigation, is that of the comparative advantages of iron and wood as materials for steam-vessels. Small vessels of iron have for many years past been used for river and canal navigation; and recently steam vessels of considerable size have been built of the same material. Although different opinions prevail as to the relative advantages of the two materials, it is certain that, owing to the superior strength of iron, and its power of bearing strain in any direction, an iron vessel may be made much lighter than one of wood of equal strength; the saving of weight being sometimes estimated at one-half. Another great advantage of iron consists in the facility with which it may be formed into any shape. An iron hull is also superior to one of wood in its security from fire and its greater cleanliness. Steam-vessels may be greatly strengthened by means of water tight bulk heads or transverse partitions in the hull, the adoption of which is becoming very general in large steamers.

As an ample supply of cold water can always be commanded for the purpose of condensation, there is not much inducement for the use of high-pressure steam in marine engines; and this circumstance, with the unfavourable opinion generally entertained as to the safety of high-pressure boilers, has led to the almost universal adoption of low-pressure, or condensing engines, in European steam-vessels; although many of the steamers of North America are worked at a pressure of 140 lbs. to an inch, or even more. The kind of marine engine most commonly used in this country, is the sde-lever engine, where two distinct engines work separate cranks upon the same axle; but the *steeple-engine*, and other forms, are occasionally employed. The means adopted for condensing the steam is a matter of great importance in sea-going steamers. The most effectual method of condensation is by the injection of cold water into the condenser, or by causing it to fall in a thin sheet, to which the steam is exposed. When sea water is used for this purpose, an incrustation of salt forms inside the boiler, productive of much mischief. This evil can only be avoided by the use of fresh water in the boilers and condenser, and allowing the salt water to act only on the outside of the condenser. Hall's Condenser and Howard's Vapour-Engine are two methods of attaining this object; but neither of them has fully realised its intended purpose.

Notwithstanding the defects commonly imputed to it, and the great number of contrivances which have been devised for avoiding them, the common *Paddle Wheel* continues to be the chief means of propulsion used. It consists of a number of flat boards, called float-boards or paddles, bolted to the radii or arms of a light but strong iron wheel, which is fixed securely upon the crank axis of the engine; and it should be so placed that the lowest float-board is entirely immersed in the water. Several improvements upon the common paddle-wheel have been introduced, which tend to diminish the defects attributed to it.

The substitution of the *screw* for the *paddle wheel*, is noticed under SCREW PROPELLER.

Sub-marine Steam Navigation has more than once attracted the attention of inventors. Dr. Payerne, whose contrivances in relation to sub-marine descent, are noticed under DIVING BELL, has lately (1851) formed a screw steamer which (according to the account given) will work at any depth down to 150 feet below the surface of the water; while the contained air is rendered respirable by chemical means. The invention is said to be under examination by some of the savans of France; if there is anything important or valuable in it, we shall soon hear more concerning it in England.

The steam ships of Great Britain now amount to a formidable number. Those which were registered at all the ports in the United Kingdom on Dec. 31, 1850, were:—

	Vessels.	Tons.
Under 50 tons	520 ..	12,885
50 tons and above .	658 ..	154,327

The steam vessels that left and entered British ports, to and from foreign ports, in 1850, were as follow:—

	Inwards.	Outwards.
England......	10,782 ..	10,447
Scotland......	4,467 ..	4,603
Ireland	4,340 ..	4,534
Isle of Man...	225 ..	172
	19,814	19,756

These numbers include the repeated voyages of each vessel. Besides the above, 399 steamers arrived from, and 369 started for, the British colonies in the same year. Eighteen timber steamers, and fifty iron steamers, were built and registered at British ports during the same year.

STEARIC ACID; STEARIN. Stearic acid is procured from stearin by the action of potash and hydrochloric acid. It has the form of brilliant white scaly crystals; it is inodorous, tasteless, insoluble in water. It melts at about 158° of Fahrenheit, and on cooling it forms a crystalline mass. It is volatile, and may be distilled unaltered in close vessels. In the air it burns like wax. Stearic Acid, besides its use in the manufacture of soap, is now very largely employed in the making of candles. *Stearin* is the harder portion of animal fats; *Olein*, or *Elain*, being the softer part. Stearin has a pearly lustre, is soft to the touch, but not greasy; it melts at about 140° to 145° Fahrenheit; and, on cooling, solidifies into a mass like wax, which is not crystalline in its texture, and is reducible to powder. Stearin is the chief and most important ingredient of the harder kinds of fat, and the harder they are the more they contain. It is separable into two different principles, namely, *stearic acid* and *glycerin*.

STEEL ENGRAVING. The comparative softness of copper occasions copper plates to wear so rapidly in the process of printing, that the beauty of the engraving is very soon impaired, and it is impossible to produce from a single plate, a sufficient number of impressions for the illustration of books of large circulation. The use of steel plates for diminishing this inconvenience, although not extensively resorted to until within the last thirty years, is a measure of which the possibility was conceived at an early period, but which was first put into practice about thirty years ago, in the attempts to protect the Bank of England notes from forgery.

In Messrs. Perkins and Heath's method of steel engraving (which has been the basis of all recent modes of producing large numbers of copies), the engraving is executed upon a plate or block of cast steel, the surface of which has been decarbonised or softened by a careful application of heat. On the plate thus softened the engraving is effected with facility; and, when it is completed, the hardness of the surface is restored by exposing the plate for some hours to a red heat, the surface being thickly covered with animal charcoal, formed of burnt leather or bones, and the whole being, as before, enclosed in a cast iron box. The plate is afterwards cooled and retempered in a very careful manner. From this hardened plate the engraving is transferred to a softened steel roller, of small diameter, which is pressed against the plate with such force that its surface becomes embossed with a perfect transfer or impression of the engraved device. The roller or cylinder is then hardened in a similar manner to the original plate, and is afterwards made to transfer the devices from its surface to any required number of softened or decarbonised plates, which are then hardened for printing from. This beautiful process is not only applicable to transferring engravings from one plate to another; but, in cases where one ornament has to be repeated several times on one plate, the device may, by being once engraved, be impressed as often as necessary upon different parts of the same plate. The power of multiplication is, for all practical purposes, unlimited. It is by such a process that the postage stamps are produced, millions of impressions being obtained from only one originally engraved plate. The perfection which has been reached is almost beyond conception; the finest writing, and the most minute and intricate patterns, being transferred from plate to plate with such precision that the keenest scrutiny cannot detect a difference between the original and the transfer. The plan has been much used for country bank-notes and similar purposes.

The application of steel engraving to works of fine art is, in a great measure, due to the late Mr. Charles Warren. In this method, the steel is softened to receive the graver, and is printed from in this softened state. The surface of a steel plate is not polished very highly, and in applying etching ground to it, the plate is not heated quite so much as is usual with copper. In the application of steel engraving to matters of fine art, the accomplishment of mezzotinting upon steel plates is one of the most important points, as the wear of copper plates engraved in this manner is very rapid.

The cost of engraving upon steel is considerably greater than that of engraving upon copper; yet, as steel plates afford so many more impressions than copper, they enable the publisher, by calculating his returns upon a large instead of a small number, to issue works of art at so low a price as to ensure a very wide circulation.

STEEL MANUFACTURE. Iron possesses many qualities which render it applicable to innumerable purposes in the arts; but there are some uses for which it is not sufficiently hard, and this defect is supplied by converting it into steel. Steel is an intimate compound of iron and charcoal or carbon. There is carbon in soft iron, but in steel it appears to be in more intimate union with the metal.

Hitherto Swedish and Russian bar-iron have been exclusively employed in the manufacture of the best steel. The preference given to this iron is decided, though from what cause it arises has not been satisfactorily made out. We may however remark, that the foreign iron used is made from magnetic iron ore with charcoal; while British iron is obtained mostly from the impure carbonate of iron, or from peroxide of iron, and both of these are reduced by employing coal or coke. *Bar-steel* is made, with few exceptions, from the Swedish and Russian iron, the bars of which are marked *Hoop L*, *G L*, and *Double Bullet*, which are the best kinds. Iron of lower quality is also used, both Russian and Swedish, each kind having its peculiar mark. These steel irons are imported almost exclusively by English merchants residing in Hull. The limited quantity of the fine iron allowed to be produced from the mines of Danemora in Sweden accounts in some degree for the high price at which they are sold. The quantity of iron imported into this country for the manufacture of steel is estimated at 12,000 to 15,000 tons annually, of which at least 9000 come from Sweden.

The usual operation in manufacturing steel is first to cut the bar iron into certain lengths, leaving room in the vessels for the expansion of the iron. The closed vessels in which the bars are heated are usually twelve feet in length, and divided into two pots or troughs, on the bottom of which the workman strews charcoal to the thickness of about an inch, and upon this he places on their flat side a layer of bars; then about three fourths of an inch more of charcoal is added, and upon this he places another layer of bars, and so on till the troughs are filled; these are then covered with a ferruginous earth coming from the Sheffield grinding stones, called *wheelswharf*, to the thickness of about eight inches. All the apertures of the furnace are closed with loose bricks and plastered over with fire-clay. The fire is then lighted, and in four days and nights the furnace is at its full heat, at which it is kept for several days, according to the degree of hardness required. In order to be able to test the progress of the carbonisation, a hole is left in one of the pots near the centre, and three or four bars are placed in the furnace in such a manner, that the ends come through this opening, and after the sixth day one is pulled out. If the iron be then not sufficiently carbonised, the heating is continued from two to four days longer; a bar is drawn every two days, and when the iron is completely converted, the fire is heaped up with small coal, and the furnace is left to burn out and it requires from this period fourteen days' time to cool sufficiently to allow a person to go in and discharge the steel. A *converting furnace*, as it is called, contains generally fifteen tons of iron; and there are some large enough to hold eighteen to twenty tons. The bar-steel, when discharged from the furnace, is partially covered with small raised portions of the metal; and from the resemblance of these to blisters, the steel is called *blistered steel*. The degree of conversion produced depends upon the purpose to which the steel is to be applied.

Bar steel as it comes from the converting furnace is used for various purposes without refining. Those parts which are free from flaws and blisters are broken out and hammered or rolled to the sizes required by the manufacturer for files, edge tools, table knives and forks, coach-springs, and a great variety of common agricultural implements. It is also manufactured into what is called *sheer steel*, which is more homogeneous, tougher, and capable of receiving a finer edge, than bar steel, which is converted into sheer steel by repeated heating, hammering, and welding.

The *cast steel* is comparatively a recent invention; but it is gradually superseding the use of bar and sheer steel, on account of the equality of its temper, and the superior quality as well as beauty of the articles which are made of it. The process adopted is that of taking bar steel converted to a certain degree of hardness, and breaking it into pieces of about a pound each; a crucible charged with these is placed in a melting-furnace, similar to those which are used by brass founders. The furnaces are 20 inches long by 16 inches wide, and 3 feet deep. The most intense heat is kept up for two or three hours, coke being used as fuel. When the furnace requires feeding, the workman takes the opportunity of lifting the lid of each crucible and judging how long the charge of each will be before it is completely melted. All the crucibles are usually ready about the same time. They are taken out of the furnace, and the liquid steel is poured into ingots of the shape and size required. This is considered, we believe, the most fearful process which British manufactures present, in respect to the fierce heat to which the workmen are exposed: the steel is in a perfectly liquid state in the crucibles. The crucibles are immediately returned into the furnace; and when the contents of all have been poured into the moulds, the crucibles are again charged. They are used three times, and then rejected as useless. The ingots are taken to the forge tilt or rolling mill, and hammered into bars or rolled into sheets as may be required. The celebrated *Wootz*, or Indian steel, is cast steel; but it is frequently so imperfect as to resemble cast iron rather than cast steel. It is however made of iron obtained, as the Swedish is, from the magnetic ore. Wootz is made by the natives from malleable iron, packed in small bits with wood in crucibles, which are then covered with some green leaves and clay: about two dozen of these crucibles are packed in one furnace; they are covered with fuel, and a blast given for about two hours and a half, which terminates the operation. When the crucibles are cold, they are broken, and small cakes of steel are obtained in the form in which it is brought to England.

Steel is of a lighter gray colour than iron, so characteristic as to be described as a *steel-gray*. It is susceptible of receiving a very high polish, and this is greater as the grain is finer. Steel is about eight times as heavy as water. When steel is heated to redness and slowly cooled, it is scarcely harder than iron; but by very rapid cooling it becomes hard, and so brittle as to be readily broken. The fracture of steel is usually fine grained; in ductility and malleability it is much inferior to iron, but exceeds it greatly in elasticity and sonorousness. It may be subjected to a full red heat, or 2786° Fahr., without melting, and is therefore less fusible than cast iron, but much more so than wrought iron. Pieces of steel which have not been cast may be readily welded together or with iron: but after casting the operation is more difficult. Steel does not acquire magnetic polarity so readily as iron, but retains it much longer; by exposure however to a moderate degree of heat this power is lost.

In order to give to steel the different degrees of hardness required for the various purposes to which it is applied, it is subjected to the process of what is called *Tempering*. It is found that the higher the temperature to which it is raised, and the more sudden the cooling, the greater is the hardness produced. The steel is usually immersed in a bath of mercury or of oil, having a temperature varying from 430° to 600°. Captain Kater found that 212°, or the heat of boiling water, was the exact point at which the knife edges attached to a pendulum were properly tempered. *Case-hardening* is the operation by which articles made of malleable iron or cast iron are superficially converted into steel by heating them with charcoal in a crucible.

With respect to the composition of steel and the nature of the admixture requisite to constitute it, differences of opinion have long existed, and the question even now is considered by some as hardly decided, whether carbon is indispensably necessary to its formation, and whether certain substances or metals, especially silicon, may not give rise to it. All steel contains a little silicon and phosphorus as well as carbon. Mr. Faraday and Mr. Stodart published in the 'Phil. Trans.' for 1822 a valuable series of experiments on alloys of steel, from which it appears that by combining steel with other metals its quality is improved. A very minute addition was found sufficient to produce a good effect: thus one 500th of silver gave an alloy harder than cast steel; one 100th of nickel gave a very hard alloy, susceptible of a fine polish: alloys of rhodium and platinum were also formed; and these, with the alloys of iridium, osmium, and palladium, formed the most valuable compounds.

STEELYARD. The most common kind of steelyard, which is often called the Roman Balance, is used by suspending the article to be weighed from the end of the shorter arm, or placing it in a scale-dish from thence suspended, and sliding a determinate weight along the longer arm until the instrument remains in equlibrium in an horizontal position; the weight of the substance attached to the short arm of the lever being indicated by observing the position of the moveable balance weight with respect to a graduated scale marked upon the long arm of the steelyard. Many steelyards are supplied with a second fulcrum, the two being placed at different distances from the point to which the hook or scale is attached, and having their respective pointers and suspending hooks on opposite sides of the lever; one is used for light weights and one for heavy.

Various modifications of the steelyard have been contrived for delicate scientific purposes, or for adapting it to the purpose of weighing very heavy bodies. Several ingenious bent-lever balances have been contrived, some of which, from the circumstance of the levers being of unequal arms, resemble the steelyard in principle. These, and the steelyard weighing machines for ascertaining the weight of loaded carriages, are noticed under WEIGHING MACHINE. The balance known as the Danish or Swedish steelyard differs from that above described in having the weight fixed at one extremity of the lever, while the fulcrum itself is moveable. The portable weighing machine, called the spring or pocket steelyard is noticed under SPRING BALANCE.

STENCILLING. [PAPER HANGING.]

STEREOTYPE. Stereotype Printing is printing from cast plates of type-metal instead of moveable letters or types. It was first adopted by William Ged, a goldsmith of Edinburgh, about 1725; but his method fell into disuse. About the year 1780, Mr. Tilloch and Mr. Foulis introduced further improvements. Towards the latter end of the 18th century, many projects were brought forward in France for multiplying engraved blocks or forms of type by processes more or less resembling that of stereotyping, under the names of polytype, stereotype, &c. In some of these the form was imitated by striking upon a mass of soft metal, in the way described under CLICHÉE. Some of the early experiments of Senefelder, the inventor of lithography, were directed to the discovery of a means of stereotyping by which he might be enabled to print his own works with a very small stock of type. He formed a composition of clay, fine sand, flour, and pulverised charcoal, mixed with a little water, and kneaded as stiff as possible; and with this paste he made a mould from a page of type, which became, in a quarter of an hour, so hard that he could take a very perfect cast from it in melted sealing-wax, by means of a hand-press. He states that, by mixing a little pulverised plaster of paris with the sealing wax, the stereotype plates thus produced were much harder than the common type metal of lead and antimony. Professor Wilson, of Glasgow, in 1797, devised a method of multiplying engraved blocks or plates by stereotype or rather polytype impressions in glass or enamel, which, it was anticipated, would prove very durable, and might be applied with advantage to the prevention of forgery. The revival and introduction into common use of the stereotyping process is in a great measure, due to the exertions of the late Earl Stanhope, about the commencement of the present century; the earl assisted with his counsel and purse many of those who were at that time engaged on the subject; and stereotype printing became firmly established about 1809.

In setting up a form intended for stereotyping from, the *spaces*, or short pieces of metal by which the words are separated from each other, and the *quadrats*, or larger spaces by which blank lines are filled up, are cast higher than usual. The types are set up and formed into pages in the usual manner, with the illustrative wood cuts, if there be any; but instead of these pages being arranged into a form of sufficient size to print a whole sheet, each page, if large, or every two or four pages, if small, is separately locked up in a small frame or *chase;* the pages being surrounded by fillets of wood or metal, which serve in the cast to form a border for attaching the plate to its mount. The face of the types is then moistened with oil, to prevent the mould from adhering to them. A brass frame rather larger than the page is laid upon the chase, in order to retain the plaster while in a fluid state, and to regulate the thickness of the mould. The plaster is then poured on the types, and it soon sets into a solid mass, which must be removed from the types with great care, and trimmed on the edges with a knife. The plaster moulds are, in the next place, baked in an oven heated to about 400° Fahr., until they are thoroughly dry and hard. They are placed upright in a rack, and are usually dried in about two hours. Great care is required in this process, especially when the moulds are large, to prevent them from warping.

After being baked, the mould is placed, with its face downwards, upon a smooth plate of iron, called a *floating plate*, which lies at the bottom of a cast iron box rather larger than the mould. The box is then covered in by a lid, the under surface of which is made perfectly flat, and which has the corners cut off to allow the melted metal to enter the box. The cover is firmly held down by a screw, which is attached to an apparatus by which the box is suspended from a crane. It should be observed that the casting box and plate are heated to the same temperature as the mould before it is inserted. The box is then swung by the crane over the metal pit, which is an open iron vessel containing a large quantity of melted metal, resembling in its composition that used for casting types; and it is lowered into the metal in a nearly horizontal position, being a very little inclined, to facilitate the escape of air from the mould and box. The melted metal runs in at the corners of the box; and by its greater specific gravity, floats up the plate with the mould, forcing the latter tightly against the lid of the box. By this contrivance the metal is forced by hydrostatic pressure into every part of the mould, in the margin of which notches are cut to allow free passage for the metal between it and the floating plate. After remaining immersed in the metal for about ten minutes, the box is gently raised, and removed by the crane to a trough in which its lower part is rapidly cooled by contact with cold water. While the box is cooling, the caster pours in a little metal at the corners, to fill the space left by the contraction of the metal, and so to keep up the necessary pressure upon the cast. When cold, the contents of the box are removed in a mass, from which the superfluous metal is broken off by blows from a mallet. The plaster mould is then broken away from the cast, the face of which is a fac-simile of the types and engravings from which the mould was taken. As the mould is destroyed by this process, it is necessary, when several stereotype plates of the same page are required, to take a distinct plaster mould for each.

The above is the mode of casting usually practised in England; but various modifications of the processes have been brought into use in Edinburgh and elsewhere.

Stereotype plates need careful examination and *picking*, to remove the imperfections in the casting. Small hollows, such as the loops of an a, an e, or an o, are liable to be filled up with metal, owing to blebs of air in the mould, and the fine white lines in wood-engravings are sometimes filled up. Such matters should be corrected by the picker, who should also cut down, with suitable tools, such blank spaces as might be liable to soil in printing. Before printing also, defective letters or words which cannot be corrected by the picker should be cut away, and types inserted in their place. These types are soldered into holes drilled through the plate; their stems being sawn off flush with the back.

Although the plates are cast of as equal a thickness as possible, they require, before printing from, to be accurately flattened at the back by means of a peculiar kind of lathe, in which a steel cutter, or *knife*, mounted in a slide-rest, shaves off the metal from the back of the plate in concentric circles, until it is made perfectly even. They are then mounted upon blocks of wood or metal, to raise them to the same height as common types. The tendency of wood to warp when exposed to changes of temperature, or to occasional wetting, has led to many projects for mounting stereotype plates upon blocks of cement or upon metallic mounts which might be applicable to plates of various sizes. When wooden blocks are used, the plates are usually secured to them by clips at the edges, and sometimes by screws.

The process of stereotyping is one of the most important means by which the production of cheap books has been facilitated of late years. For a work of limited and temporary demand it is unnecessary; but where the demand is very great, and likely to last for several years, it is all-important, since it enables the publisher not only to provide for the regular sales, but also to meet, on short notice, extraordinary demands for the work caused by peculiar circumstances, without the expense of having a very large edition printed at once. In most cases where the demand is uncertain, and in almost all where the demand is sure to be large, it is desirable to resort to stereotyping, because, although it increases the first cost of production, it enables the publisher to avoid, on the one hand, the risk of printing a great number of copies which may prove unsaleable, and, on the other, the outlay necessary for the recomposition of the types, in case the demand should exceed the number of copies first printed.

STILL. [DISTILLATION.]

STIRLINGSHIRE. That part of this county which skirts the Lennox Hills to the south and east, belongs to the coal district of Central Scotland, and yields coal, ironstone, freestone, and limestone, in considerable quantity. The Great Canal, which connects the Forth and the Clyde, has part of its course in this county; by this canal the manufactures of Glasgow are conveyed to the eastern parts of the island, and goods of various kinds conveyed back. The Edinburgh and Glasgow Union Canal, the Edinburgh and Glasgow Railway, and the Scottish Central Railway cross the county, giving access to it from all sides.

In the highland district there are above 4000 acres of natural woods or plantations, the latter being chiefly of oak and larch. The eastern part of the county is the most fertile, and, in an agricultural point of view, the most important. It comprehends the carse or valley of the Forth below Stirling, the soil of which consists principally of a bluish clay mixed with sand. There is here comparatively little waste land; the soil is almost wholly occupied in tillage or in plantations; and the greater facility for obtaining manure which the navigation of the Forth affords has tended to the improvement of agriculture.

Stirlingshire contains several manufacturing towns. *Alva* has manufactures of tartans and blankets. Near *Balfron* is a large cotton-manufactory. *Carronshore* is near the Carron Iron Works, which are among the largest in Europe. There are 4 or 5 blast or smelting furnaces, 4 or 5 cupola furnaces, and about 20 air furnaces; besides mills for grinding fire-clay, boring cylinders, grinding and polishing the metal, &c. The goods manufactured are machinery, agricultural instruments, and warlike implements, as cannon, carronades (which take their name from this place), mortars, shot, and shells. There is abundance of coal in the neighbourhood, but the ironstone and limestone are chiefly brought from a distance. Vessels of 150 tons burthen come up to the village. About 2000 persons are employed at the iron works. *Falkirk* is chiefly indebted for its prosperity to an extensive inland trade, and to the iron works, canals, and collieries, in the neighbourhood. At *Grangemouth* the Grand Canal terminates, in a basin and harbour, and two extensive wood ponds. The basin and harbour admit large vessels, and smaller vessels can proceed by the canal, the traffic on which is considerable. Great efforts have been made of late years to improve the port by the construction of a vast sea-loch, the formation of a wet dock, and the deepening of the river Carron. At *Kilsyth* the manufactures consist almost entirely of handloom weaving to supply orders from Glasgow. *St. Ninians* has manufactures of tartans, shawls, leather, and nails. The county town, *Stirling*, has manufactures of tartan and tartan shawls, yarns, cotton goods, malt, leather, soap, and candles. There are dye-houses for yarns, home-made cloths, and silks, rope yards and breweries. Considerable trade is carried on in corn, wood, coals, bricks, tiles, lime, and wool. About 100 vessels are engaged in the trade up the Forth to Stirling; and there is constant communication by steam with Newhaven, near Edinburgh, and the intermediate places on the Forth.

STOCKHOLM, the capital of Sweden, is the most industrious and commercial town of that country. There are manufactures of cloth, cotton, calico, silk, ribands, sugar, tobacco, leather, cast iron, and soap. Nearly the whole of the superfluous produce of the countries north and west of Stockholm is brought here to be exported to foreign countries; it is mostly shipped in Swedish vessels. The value of the iron exported is as great or greater than the total amount of the other exports, of which the chief are timber, tar, pitch, copper, cobalt, ready built vessels, linseed oil and oil cakes, tobacco, steel, bricks, and a few manufactured articles. The most active commerce is carried on with England, the United States of North America, Denmark, France, Prussia, Portugal, the Netherlands, and Italy. The most important articles of import are sugar, coffee, wine and brandy, rum, woollen and cotton manufactured goods, silk, linens, china and crockery, hemp, cotton, cheese, potash, hides and skins, tallow and candles, train oil, dyeing woods, raisins, almonds, pepper, cinnamon and cassia, tea, butter, and wool.

STOCKINGS. [HOSIERY MANUFACTURE.]

STOCKPORT is one of the principal seats of the cotton manufacture. Orrell's cotton mill, in this town, is one of the finest and largest in the kingdom. The building is nearly 300 feet long, and has about 600 windows. There are six ranges or stories, the lowest of which is 230 feet from front to back. There are four steam engines for working the machines, which consume twenty tons of coal per day. Besides the spinning machinery there are 1,300 power looms.

To the cotton manufacture, which is the staple trade of the town, may be added the manufacture of silk goods, thread, hats, brushes, spindles, and shuttles. There are several iron and brass foundries in the town, and bricks are extensively made in the neighbourhood.

STONE FOR BUILDING. Stone fit for building must in general be freestone firm enough to sustain great pressure, and yet so aggregated as to admit of being worked with facility by ordinary tools, and of receiving correct surfaces in any direction. It must in general yield masses of great dimensions. In the great variety of limestones and sandstones which are adapted for building purposes, we remark, by the aid of the microscope, three principal modes of molecular aggregation: mixtures of grains; segregated concretions of grains; and compacted crystallisations. Mixtures of very unequal or very dissimilar parts, as millstone-grit; concretions which have earthy textures in their interstices, as some oolitic limestones; crystallisations which do not produce compactness, as in some magnesian limestones,—are not in general durable.

The commissioners (Mr. Barry, Sir H. de la Beche, and Dr. W. Smith) who reported on the choice of stone for the construction of the New Houses of Parliament, made valuable experiments as to the hardness, closeness, density, colour, and durability of many varieties of stone. The strength of several sorts of stone, as measured by the weight necessary to be applied for breaking and crushing them, appears below:

	Resistance to fracture.	Resistance to crushing.	Name of Stone.
Sandstones	60	111	Craigleith.
	88	106	Darley Dale.
	56	107	Park Spring.
	48	70	Kenton.
	38	71	Binnie.
Oolites	50	127	Ketton Rag.
	30	55	Portland.
	22	57	Hamhill.
	24	33	Ancaster.
	16	25	Barnack.
	18	21	Box.
Limestones	70	117	Bolsover.
	36	74	Mansfield.
	34	61	Huddlestone.
	24	55	Roche.
	20	23	Cadeby.

Of sixteen specimens selected, the stone most absorbent of water was proved to be the Bath oolite from Box; that most injured by Brard's artificial process of disintegration was the Barnack stone: and that which was most easily crushed was the Bath oolite from Box. Generally speaking, sandstones were least absorbent, magnesian limestones least disintegrating; sandstones appeared to be strongest, though choice magnesian limestones (as that of Bolsover, finally recommended by the Commissioners) were fully equal in this respect, and were almost as little absorbent.

Stones of uniform texture commonly decay by disintegration at the surface, losing grain by grain in proportion to time and exposure. Stones composed of parts unequally mixed suffer unequal waste in different parts. Shells, corals, concretions, and crystallised masses, thus appear prominent from earthy limestones, and indicate the general fact that, in proportion to the force of molecular aggregation in the stone, is the resistance which it offers to decay. It is not the amount but the kind of exposure which governs the decay of stone: the southern and western parts of our cathedrals give way more than the northern and eastern.

STONE WORKING. There are three aspects under which the working in stone presents itself to our notice—quarrying, shaping and preparing the stones, and masonry properly so called.

All statuary marble and all building stone are extracted from the rocks by quarrying. Egypt, Greece, and Italy possessed the quarries from which the great works of the ancients in sculpture and architecture were produced; and nearly every country possesses quarries more or less extensive. The British isles abound with stone of nearly every different kind that can be employed with advantage in architecture and engineering. The *granites* of Aberdeenshire, of Devon and Cornwall, and of Ireland; the *sandstones* of Yorkshire, Lancashire, Derbyshire, and other counties; the *millstone grit* of Yorkshire; the *slate-stones* of Wales, Cumberland, Cornwall, and Ireland; the *limestones* of Portland, Purbeck, Bath, and other counties; the *claystones* of Gloucestershire and Yorkshire; the *ragstone* of Kent—all are plentiful.

In quarrying stone the works are chiefly horizontal or vertical, according as the stone is far below or near the surface. Stone of inferior kind has generally to be removed before the good stone can be reached. The huge masses are often loosened by blasting with gunpowder; but as this shatters the blocks, a slower but less wasteful plan is usually adopted. Most stones present natural layers or places of *cleavage*, which enable it to separate into parallel strata; and the quarry-men employ their picks and jumper-chisels in such a way as to take advantage of this cleavage. After the blocks have been severed from the mass, they are reduced as nearly as possible to a rectangular form; this is done by means of a tool called a *kevel*, pointed at one end and flat at the other, with which the irregular parts are knocked off. The blocks are then usually raised upon low carriages, and drawn on iron railways to the quays or wharfs where the stone is put on shipboard.

The working of stone is similar in principle to that of marble, but does not necessitate so much care. In the common mode of sawing a stone, a man works to and fro a framed saw or cutter, which gradually cuts its way through the stone; the instrument is not really a saw, for it has no teeth; but by the use of sand and water an abrading action is produced which wears a cut in the stone. In the large marble and stone works, of which a fine example has been established at Pimlico, several stone-saws are framed together in parallel array, and worked by a steam-engine; a block of marble or stone is thus quickly cut up into slabs. Slabs are cut up into smaller pieces by hand-saws, or more expeditiously by circular saws fixed upon a revolving axis—the saws, as in the former case, being in fact blunt knives. By bending these blunt knives into a circular or cylindrical form, and fixing them at the bottom of a vertical revolving shaft, circular pieces of stone are cut. Pillars and hollow cylinders or pipes of stone are shaped by similar means. If, instead of a saw, the horizontal axis be furnished with iron wheels shaped with mouldings on their edges, the forms of architectural mouldings may be wrought on long slabs of stone.

The smoothing and polishing of stone and marble are effected by the friction either of a smooth iron surface, or of another piece of stone, plentifully wetted during the process.

Masonry is a most important branch of art, as connected both with architecture and with common building, but especially the former. Owing to its expense, masonry is comparatively rarely employed in England, except for public or other buildings of the highest class: the mason's work being in other cases restricted to such parts as door-steps, string courses, facias, plain cornices, pavements, and stairs. Walls which are not of solid masonry throughout, but are built either of brick or inferior stone and rubble, with only an external facing of squared stone laid in courses, are termed *ashler* or *ashlering*.

STONES, METEORIC. If the materials of which these remarkable precipitated bodies consist had become applicable to any useful end, or if their fall illustrated any practical subject, we would touch upon the phenomena here; but they still remain exclusively within the domain of science. The aerolites are chiefly composed of iron, nickel, silica, magnesia, and sulphur, with smaller portions of alumina, lime, manganese, chrome, cobalt, carbon, and soda. It is remarkable that no new substance, nothing with which we were not already acquainted, has ever been discovered in their composition.

STOP. [ORGAN.]

STOP-COCK. [COCK.]

STOVES. Several kinds of fire-places or stoves give out heat by *conduction* chiefly, others do so mainly by *radiation*. Open fire-places are of the latter kind, and a considerable loss of heating-power results from the arrangement. The burning coals radiate heat into the room, and another portion of heat is reflected from the metallic portions of the grate; but the heated air, which ought to contribute to the desired effect, is mainly allowed to escape up the chimney with the smoke and other results of combustion. Dr. Arnott, in his "Treatise on Warming and Ventilation," enumerates about a dozen evils which are more or less inseparable from open fires. Among these are waste of fuel, unequal heating, a stratum of cold air near the floor, the production of smoke and dust, loss of time in attendance, danger to person and property. Many contrivances have been brought forward to obviate one or other of these inconveniences. Count Rumford suggested the "register-stove," the peculiarity of which consists in narrowing the throat of the chimney by a plate which can be moved to vary the size of the aperture; by this means, particularly if the opening be near the fire, the very hot air directly from the fire enters before it can mix with much colder air from the room, and thus the draught is increased so as to lessen the chance of smoking. But there is a great waste of heat in this as in all other open fire-places.

The common *Dutch stove* is one of the simplest examples of a close stove. It generally consists of a cylindrical case of sheet-iron, within and near the bottom of which is a grating for containing the fuel. There is an ash-pit beneath the grating, and three openings to the interior—one to the ash-pit, one for introducing the fuel above, and one leading to a flue or chimney. In this form of stove the heated iron case warms the air, which thus becomes much more nearly equalised in temperature than it is by a common fire. There is also great economy of fuel, and an absence of smoke and dust; but the air of the room acquires a dry, sulphureous, and unhealthy condition. In *Russian stoves*, earthenware and brickwork are largely used, instead of metal, as a means of making the heat less intense near the stove, and of keeping up a reservoir of heat after the fire is extinguished. The stove is built in a massive style, and consists of a series of chambers, of which the lowest serves as the fire-place, and the upper ones as flues, and being composed almost entirely of brick and porcelain, the outer surface remains at a moderate temperature for a very long period.

Dr. Arnott has the merit of having devised means to prevent the too intense heating of the air near close metallic stoves, by the use of the stove which bears his name. [ARNOTT'S STOVE.] Numerous varieties of the close stove, bearing more or less on the above construction, have been brought forward since the publication of Dr. Arnott's book. Each professes to possess some peculiar merit; but all present these features in common—that the air-hole by which the combustion is fed is very small, and capable of adjustment; that there is a body of air to be warmed, external to the grate or fire-box itself, but confined within an outer case; that the consumption of fuel is much smaller than in any variety of open fire-places; and that the flue for carrying off the smoke and gases is small in diameter, and capable of being carried in any direction. In the different forms of "kitchen-ranges" the open fire-place is combined with what may be deemed a close stove; for the "oven" and "hot-closet" are representatives of the heated space within the outer case of a close stove. The "gas-stoves" and "steam-kitchens" of modern inventors may in like manner be included in the same category, for they are in effect close stoves heated by agents different from common coal.

In the arrangements above described, the stove is in the room which is to be warmed, and its heating effects are calculated with respect to that room alone; but in many factories and other large establishments the fire is in an outer or lower apartment, and the heated air is conveyed thence in a pipe to the apartment to be heated.

In Cundy's patent stove, recently introduced, the air is warmed by passing through channels made of artificial stone; it is intended for use in churches, schools, and other large rooms, and is charged for according to the number of cubic feet of air which it will warm in a given time.

One of the greatest improvements in stoves of recent manufacture is the adoption of such a form in the iron or steel work immediately contiguous to the fire as to reflect out into the room as much as possible of the heat, instead of allowing it to waste by ascending the chimney. In one of these forms, Jobson's patent stove-grate, the reflecting surface entirely surrounds the fire, not only above and at the sides, but also beneath; the ash-pit being so ingeniously arranged as not to interfere with the lower part of the reflector.

Other details relating to heating by stoves, by gas, and by other means, will be found under COOKING APPARATUS, and WARMING and VENTILATION.

STRASBOURG. This large and important city derives so much fame from its exquisite Cathedral, that its industrial features are almost eclipsed thereby. Yet it is a busy place. The trade of the town is very considerable: its manufactures include jewellery, metal buttons, starch, alum, soap, watches and clocks, chemical products, steel, cutlery, pins, combs, cast-iron goods, earthenware, porcelain, enamel, oil from seeds, morocco and other leather, hats, woollen and cotton stuffs, cotton yarn, hosiery, printed flannels, sail-cloth, oil-cloth, thread, carpeting, furs, paper-hangings, playing-cards, &c. There are bleach-grounds, dye-houses, rope-walks, tan-yards, breweries; chicory, mustard, and madder-mills; printing-offices, plaster-kilns, tile-yards, an iron-forge, a type-foundry, sugar-refineries, a snuff-manufactory, &c. There is a considerable trade carried on with Holland, Germany, Switzerland, and Italy; and much business is done in the produce of the surrounding territory, which includes corn, wine, tobacco, madder, hemp, hops, saffron, &c.

STRAW-PLAT MANUFACTURE. It is not known when the manufacture of hats or bonnets of platted straw first became important in Italy, where it has long formed one of the leading pursuits of the agricultural population; but it does not appear to have been followed in England more than seventy or eighty years.

The large size of the wheat-straw used in this country for platting prevented the home manufacture from entering into competition with that of Italy in articles of fine quality; the straw grown for the purpose in Tuscany being much smaller, as well as superior in colour. This difficulty was in some degree overcome by the expedient adopted in England towards the end of the last century, of splitting the straw, and using the narrow *Splints*, or slips of straw, in lieu of whole straws. The operation of splitting is performed by small cutting instruments called *machines*, which have a number of sharp edges so fixed as to divide the straw, by a motion in the direction of its length, into four, five, six, or more equal parts. Before machines were invented, straws were occasionally split with knives by hand. But greatly as the British straw-plat manufacture had been encouraged by the use of split straw, by improvements in bleaching, and by increased care in the selection of straws of uniform size and colour, it was found, when the re-establishment of peace allowed the free importation of Italian straw bonnets, that the home manufacture was unable to compete with the foreign, notwithstanding the heavy protecting duty levied upon hats or bonnets of straw imported from other countries. The Society of Arts therefore, for a long series of years, offered encouragement to attempts for the improvement of the British straw manufacture, which called forth many interesting communications, and led to great improvement.

In plat made of split straw, unless two splints are laid together, with their inside surfaces towards each other, as in the plat called Patent Dunstable, it necessarily happens that the face of the plat exhibits alternately the outer and inner surfaces of the straw, which differ from each other in colour and gloss. Articles made of split straw are also inferior to those of whole straw of equal fineness, in pliability and durability. Another circumstance which greatly increases the beauty of Leghorn plat is the mode of joining it, so as to form, by the combination of several narrow strips, an extended sheet of platted work. British plat is usually joined by making the several rows of plat overlap each other a little, and then stitching through the overlapping with a needle and thread. The surface of a hat or bonnet formed in this manner consists of a series of ridges; and part of each row of plat is concealed by that next above it, so that an unnecessarily large quantity of plat is required to form a given extent of surface. Leghorn plat is formed in such a manner that it may be joined without this loss; the edge of one row of plat being, as it were, knitted into the edge of the other, in such a way that the patterns may appear uninterrupted, and the line of junction may be almost invisible.

The Society of Arts has encouraged the growing of straw similar to that of Leghorn, the platting of the Leghorn straw in England, and every other device which might seem likely to increase the home manufacture. Mr. Parry in 1822 received the Society's large silver medal for his method of manufacturing Leghorn plat from straw imported from Italy. In this method the ears are cut off with a knife, and the straws are then carefully sorted to obtain uniformity in length, thickness, and colour. Thirteen straws are tied together at one end, and then divided into two portions; six straws being towards the left side, and seven to the right, so that the two portions of straw may form a right angle. These are platted over and under each other, so as to form a platted band, about three-eighths of an inch in width. Several of these bands are adjusted in spiral coils, with their adjacent edges knitted together, so as to form the large circular pieces of plat which, under the name of hats, or *flats*, are so extensively exported from the north of Italy.

The straw used in Tuscany is that of *Triticum turgidum*, a variety of bearded wheat, which seems to differ in no respect from the spring wheat grown in the vale of Evesham and in other parts of England. It is grown in Tuscany solely for the straw, and not for the grain; and the upper joint of the straw is that chiefly used for platting. The straw is pulled while the ear is in a soft milky state; the corn having been sown very close, and consequently produced in a thin, short, and dwindling condition. It is then dried by spreading it thinly upon the ground in fine hot weather, and afterwards tied up in bundles and stacked, for the purpose of enabling the heat of the mow to drive off any remaining moisture. After remaining in the mow for about a month, it is spread out in a meadow, and exposed to the action of dew, sun, and air, in order to bleach it. The straw is frequently turned during this operation; and after it is completed, the lower joint of the straw is pulled off, leaving the upper joint, with the ear attached to it, for use. This part is then subjected to the action of steam, and to fumigation with sulphur, in order to complete the bleaching, after which it is ready for use. It is tied up in bundles, and imported to England in this state.

Bleaching the straw with sulphur fumes is commonly practised in this country, and Dr. Ure states that a solution of chloride of lime may be used for the purpose. Straw may be dyed, for ornamental purposes, of many different colours.

The splints, or pieces of split straw, being curved in a way which would impede the operation of platting, require to be flattened between rollers. These, as well as the whole straws used in other kinds of plat, are moistened with water to render them easy to work. It need hardly be observed that cleanliness is indispensable to the beauty of the plat.

In the kind of straw-platting above described, the plat is formed into a narrow strip or riband, which must be formed into a spiral coil, or united edge to edge, to form a hat or bonnet; but in 1834 Mr. T. B. Smith, of St. Alban's, devised a mode of applying Brazilian plat to the manufacture of hats and bonnets of split straw. This kind of plat is not formed in strips, but is at once platted or woven into the required form and size. One advantage claimed for the method is that either the glossy or the dull surface of the split straw may be placed entirely on one side of the plat.

The British straw plat district comprises Bedfordshire, Hertfordshire, and Buckinghamshire; these counties being the most favourable for the production of the wheat-straw commonly used for English plat. The manufacture is also followed in a few places in Essex and Suffolk; but very little in other counties. The principal markets are Luton, Dunstable, and St. Albans.

In 1847, 1,376 lbs. weight of chip hats were imported, and 7,117 lbs. of straw hats; together with 35,530 lbs. of chip-plat, and 13,420 lbs. of straw-plat, for making hats and bonnets; and 892 cwts. of straw-platting.

STRING-COURSE, is a projecting course of masonry forming a string or horizontal line on the face of a wall, and consisting of a series of mouldings, as in Gothic, or a flat surface (either plain or enriched), as in Italian architecture. The string-course itself consists sometimes of only a few narrow and plain mouldings, at others of a variety of them separated by one or more considerable hollows. In Italian architecture, the string-course is either quite plain, or more or less decorated according to the character of the floor to which it belongs.

STRO'NTIUM. This peculiar metal was formerly supposed to be identical with Barytes, but Dr. Hope in 1792 proved them to be distinct bodies. It has not a very high lustre, is fusible with difficulty, and is not volatile. When exposed to the air it attracts oxygen, and becomes converted into *Strontia.* When thrown into water, it decomposes it with great violence, producing hydrogen gas, and forming with the water a solution of strontia.

The salts of strontia are occasionally used in chemical investigations, and in giving a purple flame to fire-works.

STUCCO, is a plaster of any kind used as a coating for walls, and to give them a finished surface. *Stuccatura*, or stucco-work, is the term employed for all interior ornamental plaster work in imitation of carved stone, such as the cornices and mouldings of rooms, and the enrichments of ceilings. Stucco was very much employed by the ancients, and not merely for coating columns, &c., constructed of brick, but in many instances for covering stone, or even marble: for which last purpose it was applied so sparingly as to be no more than a very thin incrustation, for the purpose, it is now supposed, of being painted upon.

The stucco used for internal decorative purposes, such as those above mentioned, is a composition of very fine sand, pulverised marble, and gypsum, mixed with water till it is of a proper consistency. Within a short time after being first applied, it begins to set, or gradually harden, in which state it is moulded, and may at length be finished up with metal tools.

The stucco employed for external work is of a coarser kind, and variously prepared, being now manufactured wholesale as an article of commerce, ready for use; and of which the different sorts are generally distinguished by the name of *cements. Adam's* or *Liardet's Cement* is an oil-cement, of which the chief ingredients are fine whiting and calcined oyster-shells, well mixed and ground up in a mill with oil. *Parker's* or *Roman Cement*, that now most in use, consists chiefly of a preparation of argillaceous limestone found on the coast of Essex and Kent, and in the Isle of Sheppey. Of *Bailey's Cement* lime and sharp sand are the principal ingredients. *Mastic Cement*, or *Hamelin's Cement*, is composed of peroxide of lead and oil. *Keene's Cement* is one of recent invention, and of very superior quality, taking a surface and polish almost equal to that of the finest marble; it is in fact a species of scagliola; consequently it is employed, like that, only for interior decoration. Almost every year produces some new kind of stucco.

If perfectly well executed, stucco will be nearly equal in appearance to stone, and even superior to that of stone of inferior quality. There are some who protest against the use of stucco externally, as a spurious and meretricious mode of building with sham material; but it is certain that most of Palladio's edifices, and of what are spoken of as the 'marble palaces' of Venice and Rome, are merely faced with stucco.

STUTTGART, the capital of the kingdom of Würtemberg, has manufactures of linen and woollen cloths, silk, cotton, gloves, carpets, shawls, &c., and is noted for its beautiful works in gold, silver, and bronze; mathematical, philosophical, optical, and musical instruments; cabinet furniture, lackered ware, and carriages. The bark trade is extremely flourishing. The navigation of the Neckar gives Stuttgart water-communication with the Rhine. Lines of railway, partially in operation and rapidly approaching completion, connect it with the Bavarian and Rhine railroads.

STYRIA. The great wealth of this province of Austria consists in its mines, which are confined to the mountainous portion of the country. The most important minerals are—silver, copper, lead, iron (540,000 cwt. a year), alum, cobalt, sulphur, salt, marble, and coal. The most important manufacture is iron. The iron-mines in the Erzberg, in the north of Styria, were well known to the Romans; this mountain does not contain the ore in veins or strata, but presents a solid mass of iron-ore, which has been worked without interruption for eleven centuries. There are a few manufactories of linen, cotton, woollens, and silk, but none of considerable importance. There is a very brisk trade between Upper and Lower Styria: the latter supplies the former with corn, wine, and tobacco, and receives in return iron, timber, and salt. The exports consist of the metals above-named, and of scythes, sickles, steel and iron wares, including razors, and several millions of Jews'-harps. The imports consist of fine cloths, linens, cottons, silks, and jewellery, and colonial produce. The transit trade between Italy and Germany, from Vienna to Trieste, is very important. This trade is greatly facilitated by good common roads, and by the Vienna-Trieste railway now open from Vienna to Laybach.

SUBMARINE DESCENT. A few details on this subject will be found under DIVING BELL.

SU'CCINUM is a bituminous substance of a peculiar kind, procured from amber. It is not now used in the crude state in medicine, but is employed to yield the *Oleum Succini*, or *Oil of Amber*. Volatile oil of amber probably contains a large portion of creasote. One part of rectified oil of amber, and three parts of moderately strong nitric acid, form *Artificial Musk*.

SUET. There are several kinds of suet, according to the species of animal from which it is procured, such as that of the hart, the goat, the ox, and the sheep. When recent, it is white, easily broken, translucent if thin, and almost without smell; it soon becomes yellow and rancid by exposure to the air. The preponderance of stearin renders suet the most solid of animal fats. It liquifies with a gentle heat, and the prepared suet of the Pharmacopœia is obtained by melting it over a slow fire, and straining it to separate the membraneous portion. It is used as an ingredient in cerates, plasters, and ointments. By pouring it when melted over various articles, such as potted char, from which it thoroughly excludes the air, it assists greatly in preserving them.

SUFFOLK produces scarcely any minerals of value. Chalk and Shell-Marl from the crag formation are dug from manures. This county forms one of the best cultivated districts in the southern part of Great Britain. The greater part of the land is under the plough; there being now scarcely such a thing to be seen as a common field. There is no part of England where the implements of husbandry are more perfect than in Suffolk, or where new implements are tried with more readiness and with less prejudice; nowhere is so great a variety of farm-machines used for saving labour.

Suffolk is far from being a manufacturing county; yet it has a few busy and flourishing towns. At *Bungay* a considerable trade is carried on in grain and other articles of provision by means of the Waveney, which is navigable up to Bungay for small barges. At *Ipswich* the manufactures of the town consist chiefly in the spinning of woollen yarn, shipbuilding, sail-making, &c. Its commerce arises from the exportation of corn, malt, and other produce of the surrounding country. There is, however, one notable establishment, that of Messrs. Ransomes and May, where machinery and agricultural implements are manufactured on a large scale. *Lowestoft* has lately risen into importance on account of the excellent harbour formed there, in connection with the Norfolk railway. Mail steamers have just commenced (April 1851) to run from

Lowestoft to Denmark, under circumstances which promise to be very beneficial to the town. From *Stowmarket* a considerable quantity of corn and malt are sent in river-craft down to Ipswich to be shipped there: timber and deals, coals and slate, are brought up from Ipswich for the supply of the neighbourhood.

SUGAR. Although this valuable commodity is obtainable from various sources, the *sugar cane* is that which yields by far the largest supply. This cane grows in the warm districts both of the old and the new world.

Culture.—The stems vary in height from eight feet up even to twenty feet, and are divided by prominent annular joints into short lengths. The outer part of the cane is hard and brittle; but the inner consists of a soft pith, which contains the sweet juice, and this juice is elaborated separately in each joint. The canes are usually propagated by slips or cuttings, which are planted either in holes dug by hand, or in trenches formed by a plough, about eight to twelve inches deep. The planting usually takes place from August to November, and the cutting in March or April. The maturity of the cane is indicated by the skin becoming dry, smooth and brittle; by the cane becoming heavy; the pith gray, approaching to brown; and the juice sweet and glutinous. The canes which grow immediately from the planted slips are called *plant-canes;* but it is usual, in the West Indies, to raise several crops in successive years from the same roots; the canes which sprout up from the old roots, or *stoles*, being called *rattoons.* The rattoons are not so vigorous as the original plant-canes; but they afford better sugar, and that with less trouble in clarifying and concentrating the juice. The canes are cut as near the ground as possible, because the richest juice is found in the lower joints; and, after cutting them, it is considered well to cut the stumps down a few inches below the surface of the ground, and to cover them up with mould. One or two of the top joints of the cane are cut off, and the remainder is divided into pieces about a yard long, tied up in bundles, and carried immediately to the sugar-mill. The upper branches of the cane are used as food for cattle; and the remainder of the waste forms a valuable manure, for which purpose the *trash*, or waste from the mill, is admirably suited, though much of it is usually consumed as fuel.

Manufacture.—The manufacture of sugar is that train of operations by which the juice is extracted from the canes, and brought to a granulated state. In the West India sugar-mills employed for crushing the canes, a negro applies the canes in a regular layer or sheet to the interval between two rollers, which seize and compress them violently as they pass between them. The ends of the canes are then turned, either by another negro on the opposite side to the feeder, or by a framework of wood called a *dumb returner*, so that they may pass back again between two other rollers placed closer together. Channels are made to receive the liquor expressed from the canes, and to conduct it to the vessels in which it is to undergo the succeeding operations. Improved sugar mills have been lately brought into use.

Cane-juice as expressed by the mill, is an opaque slightly viscid fluid, of a dull gray, olive, or olive-green colour, and of a sweet balmy taste. The juice is so exceedingly fermentable that in the climate of the West Indies it would often run into the acetous fermentation in twenty minutes after leaving the mill, if the process of clarifying were not immediately commenced.

The processes followed in the West Indies for separating the sugar from the juice are as follows. The juice is conducted by channels from the mill to large flat bottomed *clarifiers*, which contain from three hundred to a thousand gallons each. When the clarifier is filled with juice, a little slaked lime is added to it; and when the liquor in the clarifier becomes hot by a fire underneath, the solid portions of the cane-juice coagulate, and are thrown up in the form of scum. The clarified juice, which is bright, clear, and of a yellow wine-colour, is transferred to the largest of a series of evaporating coppers, or pans, three or more in number, in which it is reduced in bulk by boiling; it is transferred from one pan to another, and heated until the sugar is brought to the state of a soft mass of crystals, imbedded in molasses, a thick, viscid, and uncrystallisable fluid. The soft concrete sugar is removed from the coolers into a range of casks, in which the molasses gradually drains from the crystalline portion, percolating through spongy plantain-stalks placed in a hole at the bottom of each cask, which act as so many drains to convey the liquid to a large cistern beneath. With sugar of average quality three or four weeks is sufficient for this purpose. The liquid portion constitutes *molasses*, which is employed to make rum. The crystallised portion is packed in hogsheads for shipment as *Raw*, *Brown*, or *Muscovado Sugar;* and in this state it is commonly exported from our West Indian colonies. The sugar loses usually about 12 per cent. in weight by the drainage of the remaining molasses from it while on ship-board.

Refining.—The refining of sugar is mainly a bleaching process, conducted on a large scale in England. There are two varieties produced by this bleaching, viz. *clayed* and *loaf* sugar. For clayed sugar, the sugar is removed from the coolers into conical earthen moulds called *formes*, each of which has a small hole at the apex. These holes being stopped up the formes are placed, apex downwards, in other earthen vessels. The syrup, after being stirred round, is left for from fifteen to twenty hours to crystallise. The plugs are then withdrawn, to let out the uncrystallised syrup; and, the base of the crystallised loaf being removed, the forme is filled up with pulverised white sugar. This is well pressed down, and then a quantity of clay, mixed with water is placed upon the sugar, the formes being put into fresh empty pots. The moisture from the clay, filtering through the sugar, carries with it a portion of the colouring matter, which is more soluble than the crystals themselves. By a repetition of this process the sugar attains nearly a white colour, and is then dried and crushed for sale.

But *loaf sugar* is the kind most usually produced by the refining processes. The brown sugar is dissolved with hot water, and then filtered through canvas bags,from which it exudes as a clear, transparent though reddish syrup. The removal of this red tinge is effected by filtering the syrup through a mass of powdered charcoal; and we have then a perfectly transparent and colourless liquid. In the evaporation or concentration of the clarified syrup, which forms the next part of the refining process, the boiling is effected (under the admirable system introduced by Mr. Howard) in a vacuum, at a temperature of about 140° Fahr. The sugar-pan is a large copper vessel, with arrangements for extracting the air, admitting the syrup, admitting steam pipes, and draining off the sugar when concentrated. In using the pan, a quantity of syrup is admitted; and an air-pump is set to work, to extract all the air from the pan, in order that the contents may boil at a low temperature. The evaporation proceeds; and, when completed, the evaporated syrup flows out of the pan through a pipe into an open vessel beneath, called the *granulating vessel*, around which steam circulates, and within which the syrup is brought to a partially crystallised state. From the granulators the syrup or sugar is transferred into moulds of a conical form, which were formerly made of coarse pottery, but are now usually of iron; in these moulds the sugar crystallises and whitens, the remaining uncrystallised syrup flowing out at an opening at the bottom of the moulds. This syrup is re-boiled with raw sugar, so as to yield an inferior quality of sugar; and when all the crystallisable matter has been extracted from it, the remainder is sold as *treacle*. The loaves of sugar, after a few finishing processes, are ready for sale.

The improvements introduced into the processes of sugar-refining allow loaf sugar to be now sold at a price so little exceeding that of raw sugar, that the manufacture has lately vastly increased.

Sugar-Candy is a kind of crystallised sugar made in China and India. The crystals are formed around small strings or twigs, from which they are afterwards broken off. When heated to 365° Fahr. sugar melts into a viscid colourless liquid which when cooled suddenly, becomes *barley-sugar*.

Beet Root Sugar is briefly described under BEET. The manufacture is not in a flourishing state, as it cannot well compete commercially with that from the sugar-cane. There is a project at present on foot for establishing the beet-sugar manufacture in Ireland. It is proposed to establish a Company with a capital of half a million sterling; and to buy Irish beet root with a view of extracting sugar from it by processes which have recently been patented, and the patents for which are to be held by the Company. The projectors start upon the basis that the climate, soil, and labour-supply of Ireland are highly favourable to the culture; and that the patent processes are calculated to perform the extraction of sugar well and cheaply. It remains to be shewn how far these anticipations are capable of being borne out; if commercially advantageous at all, Ireland must unquestionably be benefited by it. The Company's calculations give 400 tons of sugar and 100 tons of molasses for 6000 tons of beet-root; and shadow forth a flattering rate of prospective dividend. So do the calculations of the Irish Peat Company; and we can only at present express a *wish* that the anticipations may be realised. (April 1851.)

It has just been announced that there are now 303 Beet-Sugar Manufactories in France; and that the produce of French Beet-Sugar in 1850 was 74,628,607 kilogrammes — about 160,917,900 lb.

Sugar Trade. — Before the discovery of America, sugar was a costly luxury used only on rare occasions. About 1459 Margaret Paston, writing to her husband, who was a gentleman and land-owner in Norfolk, begs that he will 'vouchsafe' to buy her a pound of sugar. The consumption has gradually but steadily increased throughout the world.

The sugar trade of 1849 and 1850 exhibited the following results. The importation of sugar amounted to the quantities here stated:

	1849		1850
From West Indies	2,839,912	cwts.	2,584,162
From Mauritius	897,814	„	1,003,312
From East Indies	1,474,474	„	1,346,081
Foreign	1,725,149	„	1,352,476
Refined	304,392	„	355,387
Molasses	1,311,435	„	1,249,796
	8,553,176	cwts.	7,891,214

The total quantities of all kinds of sugar and molasses re-exported in the same two years, together with the exports of sugar refined in England, were

	1849		1850
Re-exports	761,286	cwts.	466,219
British refined......	223,273	„	209,235
	984,559	cwts.	675,454

The gross amount of duty received on the imported sugar was 4,139,999*l.* in 1849, and 4,130,819*l.* in 1850.

The duties on the importation of sugar into this country have varied very considerably. Between the years 1661 and 1815 the duty was gradually raised from 1*s.* 6*d.* to 30*s.* per cwt. on British plantation sugar. From 1815 to 1844 it varied from 24*s.* to 30*s.* East India sugar paid a higher duty than West India until 1836, when the two were assimilated. Foreign sugar paid a duty of 60*s.* to 63*s.* per cwt. until the recent legislative changes. In 1844 a change was made, whereby sugar from certain foreign countries, under certain defined circumstances, might be admitted at 34*s.* instead of 63*s.* duty. In 1845 another act fixed the duty on sugar, from either the East Indies or West Indies, at sums varying from 14*s.* to 21*s.*, according to the quality. By an act passed in 1846, there was to be a gradual reduction of duties from 1846 to 1851, at the expiration of which period the duty on foreign sugar was to be the same as that on East or West India sugar. By another act passed in 1848 this principle of gradual reduction is to extend until July, 1854, after which time sugars from all countries will be placed on the same footing. They will all pay at that time the following import duties per cwt.;

	s.	*d.*
Refined sugar	13	4
White clayed	11	8
Brown clayed	10	0
Brown raw	10	0
Molasses	3	9

SULPHUR, or *Brimstone*, is a solid elementary non-metallic body, which has been known from the remotest antiquity. It is met with pure, and in various states of combination. Sulphur, both crystallised and massive, occurs in beds and veins in Swabia, Hungary, and Switzerland. Volcanic sulphur is found in immense quantities in Italy and Sicily. The volcanic sulphur brought to this country is purified for use. What is called *refined sulphur* is purified by distillation in a large cast-iron still, and it is condensed in an iron receiver kept cool by water; when melted and cast into wooden moulds, it is called *roll* or *stick sulphur;* and when the vaporised sulphur is condensed in a large chamber, it has the form of powder, and is called *sublimed sulphur*, or *flowers of sulphur*.

Sulphur is of a bright yellow colour, resinous lustre, slight odour, and nearly opaque. It is insoluble in water, but dissolves in alcohol and in boiling oil of turpentine. It is very volatile. When sulphur is heated it begins to vaporise before it fuses: at 555° to 600° it is rapidly volatilised, and in close vessels is condensed without change. Some metals when heated in it burn vividly. The fusing-point of sulphur is 232°, and between this and 280° it possesses the highest degree of fluidity: at 320° it begins to thicken, and at 482° is so tenacious that it will not flow from an inverted vessel: from this to 600°, which is its boiling point, it again becomes liquid, but not so perfectly so as at 280°; when boiled in close vessels, an orange-coloured vapour is formed. When poured into water in a fluid state, at about the temperature of 428°, it becomes a brown pasty mass, which readily receives and retains any form given to it, and hence it is employed in taking casts.

The compounds of sulphur with other bodies are of almost incalculable importance. With oxygen it forms *sulphurous acid gas*, which has powerful bleaching properties. With a further portion of oxygen, it forms *sulphuric acid*, so largely employed in the manufacturing arts. With hydrogen it forms *sulphuretted hydrogen gas*, the powerful constituent of Harrogate and other mineral waters. When sulphur has been brought to the state of sulphuric acid by combining with oxygen, it becomes still more valuable than in any of the above named forms; for it then constitutes the well-known *sulphates*, by combining with various oxides; we thus have the sulphates of soda, potash, ammonia, iron, copper, barytes, lime, magnesia, &c., the practical uses of which are so numerous.

Sulphur Trade.—Although sulphur exists in Iceland, Teneriffe, St. Vincent's, and some other places, the expense of obtaining it is so great, that Sicily alone has furnished the supply required. From 1833 to 1838 England took 49 per cent. of the whole quantity of sulphur exported from Sicily, and France 43 per cent., leaving only 8 per cent. for all other countries; and part of this was shipped for Malta, and eventually reached England. The Sicilian sulphur mines are the property of individuals, and from fifteen to twenty English firms settled in Sicily are engaged in the trade. In 1836 M. Taix, a Frenchman, laid before the Sicilian government a project for establishing a company which was to have the exclusive right during ten years of purchasing Sicilian sulphur at fixed prices, on condition of spending 10,000*l.* a year in constructing roads, and exporting one-third of the quantity produced in Sicilian vessels. The British merchants becoming alarmed, the Sicilian government, in reply to the British ambassador, stated that no such project would be adopted. It would have been in direct contravention to certain commercial treaties between the two governments. The Sicilian government did, however, enter into a contract with M. Taix, and on the 4th of July, 1838, notice was given at Palermo that the monopoly would come into operation on the 1st of August ensuing. The negociations respecting this monopoly were conducted with great secrecy, and it came into operation so suddenly, that twenty-four vessels lost their cargoes. The British lessees of mines, and all others, were compelled to produce only a fixed quantity of sulphur; prices rose more than twofold, contracts could not be completed, the supply became inadequate to the English demand, and other quarters were looked to for a supply. At length the British government took very decided steps to put an end to a monopoly established in the face of commercial treaties; and the trade was then restored to its former footing.

The imports of sulphur during the last three years have been as follows:—

1848................668,392 cwts.
1849................845,388 „
1850................664,630 „

SULPHURATION, or SULPHURING, is the process of bleaching employed to give whiteness to silk and woollens by exposing them to the fumes of burning sulphur. For this process a detached chamber, without a chimney, is made use of, so constructed, that, when required, a current of air may be passed through it. Straw-plat work is also bleached by sulphuring.

SULPHURIC ACID MANUFACTURE. The manufacture of this important acid involves arrangements of great magnitude and interest. At the chemical works of Glasgow, Newcastle, and a few other large towns, the production of sulphuric acid is carried on upon a vast scale. The process consists mainly in bringing sulphur in contact with the air and combining the fumes thus produced with water. As the fumes are very deleterious to the workmen, and as both the fumes and the liquid exert a corrosive action on the vessels which contain them, the apparatus requires to be of a very peculiar kind.

In the first place the Sicilian sulphur is placed in a series of close-fitting iron furnaces, where it is kindled; it combines with oxygen in the act of burning, and produces *sulphurous acid gas*, which gas finds an exit into a hollow wall behind the row of furnaces. The gas passes from thence into vessels which are among the largest known in any department of manufactures. At the Felling chemical works near Newcastle, there are two sulphurous acid chambers, each 200 feet long, 20 wide, and 20 high; and four others about half this length; they are formed of sheet lead, framed strongly together.

In the leaden chambers a conversion takes place of *sulphurous acid* into *sulphuric acid*, and from a gas to a liquid. While the sulphur has been burning in the furnaces, such other ingredients as will yield a little nitrous acid vapour are also heated in the furnace; the nitrous acid vapour accompanies the sulphurous acid gas into the chamber: steam is also admitted into the chamber, and a curious chemical result follows. The acid gas, moistened by the steam, abstracts oxygen from the nitrous acid vapour, and becomes thereby changed from sulphur*ous* into sulphur*ic* acid; and this sulphuric acid, combining with the water of the condensed steam in the bottom of the chamber, becomes a liquid, and then constitutes the sulphuric acid, or *oil of vitriol* of the shops. In order to concentrate the acid for some purposes, it requires to be distilled; but such is its corroding nature, that few materials will resist its action; and hence the costly metal *platinum* is used for the stills for distilling this acid. At the Felling works a platinum still was provided some years ago, which cost one thousand guineas, its weight being about one thousand ounces; it therefore cost about four times its weight in pure silver! Platinum has, however, become less costly in recent years.

SUMACH, or SHUMAC, is a tanning and dye drug procured from the genus of *Rhus* plants. The chief species, *Rhus cotinus*, grows extensively in warm climates. It is made use of, like many other species, for tanning in Italy, where it is called *scotino;* the wood is used by the modern Greeks for dyeing wool of a beautiful rich yellow colour. The *Rhus coriaria* is extensively used for tanning; and it is said that all the leather made in

Turkey is tanned with the bark of this species.

Besides the dye and tan ingredient, many species of sumach tree yield a varnish or japan. The well-known *gum-copal* of commerce, from which *copal varnish* is made, is believed to be procured from the *Rhus copallina.* The celebrated *japan varnish* is produced from the *Rhus vernicifera*, or *varnish-bearing sumach.* The varnish is obtained from those branches of the plant which are about two or three years old, by incision; it is at first white, and of the consistence of cream, but it thickens and blackens after a little exposure; it is exceedingly transparent, and when used a dark surface of finely powdered charcoal is placed underneath it. The Japanese use this varnish, which is very hard, on their doorposts, windows, household furniture, and nearly all their wood-work.

The sumach used by the tanners of Bermondsey, is the powder of the leaves and young branches of the *Rhus coriaria;* it has a fine yellow colour, and is imported from Sicily in cloth bags containing about one cwt. each. For the mode of using it in tanning goat-skins, see LEATHER MANUFACTURE. No less than 12,929 tons of sumach were imported in 1850.

SUMATRA. This is one of the most fertile and important islands in the eastern hemisphere. Rice is cultivated in the lowest plains and in the elevated valleys of the mountain range. The most common esculent vegetables are different kinds of yams, both red and white; the St. Helena yam; sweet potatoes, common potatoes only in the more elevated districts; bredy, a kind of spinach; lobuck, or the Spanish radish; the large purple brinjall, or egg-plant; and many different sorts of beans, with white and green peas, and onions. The peas and onions are articles of export from the north-eastern coast to Penang and Singapore. Chili or capsicum, turmeric, ginger, coriander, and cummin seed, are raised, especially on the western coast. Hemp is extensively cultivated, but only for smoking with tobacco. Tobacco is also grown, and is an article of export from the harbours on the north-eastern coast. Melons are raised on the plains, and sometimes attain an extraordinary size. Sesamum is cultivated for its oil; and the Palma Christi, from which castor-oil is obtained, grows wild. The sugar-cane is only cultivated for chewing; no sugar is manufactured, but it is imported from Java. The plantations of betel-vines are extensive. Indigo and cotton are raised for domestic use only. The fruits are abundant, and include the cocoa-nut, plantains, banana, the bread-fruit tree, jack-tree, mangusteens, durians, mango, different kinds of orange and lemon trees, especially the shaddock: the pine-apple, the jambo, the guava, the papaya, the custard-apple, the pomegranate, and the tamarind The pepper-plant is more abundant in Sumatra than in any other part of the globe. Coffee, sago, cloves, and nutmegs are grown. The forests supply an inexhaustible variety of timber.

Sumatra was once noted for its gold, and a considerable quantity is still exported. Tin occurs in several places on the great plain, but is very little worked, as large quantities are obtained in the Island of Banca, where it is got with less labour. Copper is found between 2° and 3° N. lat., where it occurs in great abundance in an extensive tract. Sumatra contains gold, but it is not much worked. Iron, sulphur, saltpetre, coal, and salt, occur in small quantities.

Nothing perhaps shows more clearly the advanced state of civilization of the inhabitants of Sumatra than their manufacturing industry. The most important manufactures are those of iron and steel, which are carried to a considerable degree of perfection in Menangcabau, where iron has been worked from time immemorial. Silk and cotton fabrics, earthenware, and various works in metal, are among the best of the manufactures.

SUN-DIAL. Up to a comparatively recent period the science of constructing sun-dials, under the name of gnomonics, was an important part of practical science. As long as watches were scarce, and clocks not very common, the dial, which is now only a toy, was in actual use as a timekeeper. Of the mathematical works of the 17th century which are found on book-stalls, none are so common as those on dialling. A sun-dial consists of two parts: the *style*, usually supplied by the edge of a plate of metal, always made parallel to the earth's axis, and therefore pointing towards the north; and the *dial*, which is another plate of metal, horizontal or not, on which are marked the directions of the shadow for the several hours, their halves and quarters, and sometimes smaller subdivisions.

The varieties of sun-dial are numerous; but as the instrument is now little in use, it is unnecessary to describe them.

SUNDERLAND, with its northern suburb of *Monk Wearmouth*, constitutes the busy commercial mouth of the Wear. This river is crossed by an iron bridge of one arch, erected near the close of the last century. The abutments are piers of nearly solid masonry, 24 feet in thickness. The arch is of iron, and forms the segment of a large circle, having a span of 236 feet; the height above low water is 60 feet to the spring, and 94 feet to the centre of the arch, so that ships of 300 tons pass under it very readily by lowering their top-gallant masts. The superstructure is of timber planked over, with flagged footpaths and iron balustrades. This was for many years the most remarkable iron bridge in England.

The preservation and improvement of the port and harbour of Sunderland are entirely owing to the exertions of commissioners who have been appointed under successive acts of parliament for levying certain dues and applying them to the cleansing and improving of the harbour. These works, and particularly the construction of piers on both sides of the mouth of the river, have had so great an effect in improving the port, that ships drawing from 15 to 18 feet of water can now enter and depart from the harbour with great safety. There is a wet-dock comprising nearly 8 acres, with a tidal basin attached to it, on the north side of the river near the entrance of the harbour. In July, 1850, a very large wet-dock was opened on the south side of the river. The works extend from the river to Hendon Bay. First is the tidal harbour of 2½ acres opening from the river; next the half-tide basin (2½ acres), leading from it to the great dock of 20 acres, near the south end of which are the two jetties, one already occupied by four staiths for the shipment of coals, the rest of the accommodation being intended for general traffic. The widths of the entrances between the tidal harbour and the half-tide basin are respectively 45 and 60 feet, and that between the half-tide basin and the great dock 60 feet. In the great dock the depth in the middle at high water of ordinary spring tides is 24 feet, and at neap tides 20 feet 6 inches. Besides the site recovered from the sea, now forming the dock, an area of upwards of 25 acres of land has in like manner been gained from the sea to the eastward of the dock, which will be found exceedingly valuable and available for many useful purposes. The coal traffic is brought by the branch railway to the staiths on the jetties. The access to the dock for other traffic is from the foot of the High Street along the western side of the docks, and to the eastern side by moveable pontoons over the two entrances from the tidal harbour to the half-tide basin. The dock is considered to be the cheapest, as well as one of the best, that has ever been constructed.

The principal manufactures of Sunderland are of bottle and flint glass, anchors, chain-cables, and other iron goods for ships, and cordage. Ship building is carried on to a greater extent than in any other seaport of the British empire. On December 31, 1849, there were 90 ships building, the aggregate burthen of which was 29,210 tons. 5000 tons of shipping more were built in 1849 than in 1848, and 10,000 more in 1850 than in 1849. The number of ships belonging to the port in 1849 was 155 (44,333 tons). About 140 firms are engaged in business in connection with ship-building, as chain-cable manufacturers, sail-cloth manufacturers, anchor and ship-smiths, rope, sail, mast, block, or pump makers; besides ship-owners, brokers, and chandlers. Some of the ropewalks are on a very large scale. Brick-making, coal-mining, and the quarrying of grindstones, are carried on in the neighbourhood; and there are copperas-works, brass-foundries, potteries, hat-manufactories, lime-works, timber-yards, saw-mills, flour-mills, tan-yards, and breweries. The town is, however, more important from its commerce than its manufactures. In shipping coal it is exceeded only by the port of Newcastle, and recently perhaps by Stockton.

The export of lime is another principal branch of trade; also the export of glass and grindstones. The imports are timber and iron from the Baltic; butter, cheese, and flax from Holland; and a variety of goods brought coastwise. A considerable fishery is carried on.

SURREY. The agriculture of this county has immediate reference to the wants of the vast metropolis. The soil varies greatly in different districts; the richest is that which lies along the banks of the rivers, consisting chiefly of a deep alluvial loam. On this soil, in the neighbourhood of London, are some of those extremely productive and highly cultivated market-gardens which supply the metropolis with fruit and vegetables. The immense quantity of manure which is annually laid on the land so occupied, and the deep trenching and digging which are repeated at short intervals, have converted the whole surface, to the depth of three feet or more, into a rich black vegetable mould. On this soil are raised the best and earliest culinary vegetables, which so rapidly succeed each other that five or six different crops are sometimes gathered from the same ground in one year. The well-known hop-grounds in the neighbourhood of Farnham are mostly on a mixed soil of loam and calcareous earth. The greater value of Farnham hops in the market is probably owing partly to the soil being peculiarly suited to this plant, and partly to the greater care with which it is cultivated.

Numerous and attractive as are the towns and villages in Surrey, they owe their importance either to the villa residences which stud them, or to the agricultural markets of which they are the centres; very few of them present a manufacturing character.

SURVEYING is the art of determining the form and dimensions of tracts of ground, the plans of towns and single houses, the courses of roads and rivers, with the boundaries of estates, fields, &c.

Since the measurement of the distance between two objects by means of a rod or chain is very laborious and inaccurate when that distance is considerable, particularly if the ground has many inequalities of level, and is much intersected by walls, hedges, and streams of water, it will seldom be possible to execute even an ordinary survey by such means alone, and instruments for taking angles must be employed, together with the chain, in every operation of importance. A base line of moderate length is measured, and angular observations taken from its two extremities, to determine the relative position of objects.

The surveying instruments are few in number; and the processes are of too mathematical a character to call for description here.

SUSPENSION BRIDGE is a bridge in which the weight of the roadway, instead of resting upon arches of masonry, or on a rigid framework of wood or iron, is supported by the tension of ropes, chains, or rods.

We have no account of the existence of iron suspension-bridges in Europe before the middle of the last century. The earliest appears to have been a small one built across the river Tees, at an elevation of about 60 feet, two miles above Middleton, for foot passengers only. The first iron suspension bridge built in America was that constructed in 1796, by Mr. Finlay, across Jacob's Creek, on the road between Union Town and Greenburgh, the length of which was about 70 feet. Mr. Finlay subsequently, in 1801, obtained a patent for the construction of such bridges, and built several in the United States; one of which, over the Schuylkill, was 306 feet long. In 1807 a scheme was proposed by M. Belu, a French engineer, for crossing the Rhine, between Wesel and Ruderich, by a bridge about 820 feet long, to be supported by a network of wrought-iron chains. In 1814 a bridge of similar construction was proposed for crossing the Mersey at Runcorn Gap, so as to form a direct communication between Runcorn in Cheshire and Liverpool. In 1816 a suspension-bridge was built across Gala Water, made of thin wires, at a cost of only about 40*l.*, although its span was about 111 feet. Another wire bridge of about the same length was built in 1817 across the Tweed, at King's Meadows, at an expense of 160*l.* Sir Samuel Brown soon afterwards introduced an improved method of constructing chains for suspending the roadway. Chains of the ordinary form, with short links, are very defective in strength; and several difficulties, among which is the great extent of surface exposed to oxidation, attend the use of cables consisting of small rods or wires. The plan adopted by Sir S. Brown was to form chains of round or flat bars of iron, several feet long, having either welded eyes or drilled holes at each end, and being connected together by short links and bolt-pins. The first extensive bridge erected upon this plan was the Union Bridge across the Tweed, near Berwick, opened for use in 1820. The length is 449 feet, and the deflection is about 30 feet. There are twelve suspending chains, arranged in pairs side by side, and in three tiers, one above the other; each chain being formed of round rods, 15 feet long, and 2 inches in diameter. The suspension-rods are round, an inch in diameter, and are attached alternately to each of the three tiers of chains. In 1821 Brown commenced the Trinity suspension-pier at Newhaven, near Edinburgh, which consists of three spans of 209 feet each, with 14 feet deflection. In 1818 the Holyhead Road Commissioners applied to Telford for his opinion respecting the erection of an iron suspension-bridge at the Menai. A brief account of this beautiful bridge, and of the yet more extraordinary Britannia Tubular Bridge, recently erected near it by Mr. Robert Stephenson, will be found under MENAI BRIDGES.

While the Menai Bridge was in progress Sir S. Brown constructed the suspension-pier at Brighton, which consists of four openings of 255 feet each, with a deflection of 18 feet; and Mr. W. Tierney Clark commenced in 1824 the Hammersmith suspension-bridge, the first erected in the vicinity of London. The central opening of the Hammersmith Bridge has a chord-line of 422 feet, with a deflection of about 30 feet. The width of the bridge is about 30 feet, there being a carriage-way of 20 feet, and two side foot-paths of 5 feet each. There are eight chains, arranged in four double lines, or in two vertical tiers. The Hungerford suspension-bridge, opened April 18th, 1845, is for foot passengers only; the chains are borne by two towers in the river, 22 feet square and 80 feet high, the height of the roadway above high-water mark being 32 feet. The span of the centre between the two towers is 676 feet 6 inches, of each of the side arches 333 feet. The roadway is supported by single suspension rods 12 feet apart on each side. It was built under the direction of Mr. I. K. Brunel.

Some suspension-bridges have been erected in which the main chains, instead of passing over a pier or tower at or near each end of the platform, are supported by a single tower in the centre of the bridge, and form what may be called two semi-catenaries. A bridge of this kind was built in 1823 by Sir M. I. Brunel, in the Isle of Bourbon. The bridge consists of two openings of 122 feet each. A few suspension-bridges have been built in which the chains are suspended below the platform, which is supported by framework built upon instead of hanging from them.

Some small bridges of wire have been alluded to already, and Drewry describes several of large dimensions which were erected on the Continent soon after the introduction of suspension-bridges upon an extensive scale in Great Britain. The first large one erected in France was that of Tournon, across the Rhône, between Tain and Tournon, in 1824-5; it consists of two openings of 278 feet each. Another remarkable wire-bridge is that over the Sarine, at Fribourg in Switzerland, which was completed in 1834, by M. Challey. It has a span, from pier to pier, of 870 feet, and is 167 feet above the level of the river, being much longer and higher than the Menai Bridge. The platform is suspended from four cables, arranged in pairs at the sides of the bridge, with a deflection of 55 feet. The wire of which the bridge is composed is about one-twelfth of an inch in diameter, and each cable consists of fifteen bundles of eighty wires each, packed together in a cylindrical form, and bound round at intervals of two or three feet with annealed wire. The wires are not twisted together like the strands of a rope, but each of them extends straight from end to end of the cable. The two pairs of cables are suspended at a distance of 30 feet from each other, but the width between the lower ends of the suspension rods is only 24 feet, so that their position is not quite vertical. These rods are small cables, consisting of thirty wires similar to those of which the cables are composed. The roadway is formed of fir planks, supported by transverse beams, and stiffened by a strong oak railing, or diagonal truss. The bridge was completed at a cost of 24,000*l.*, and was publicly opened in 1834.

The use of wire instead of bar-chains in the construction of suspension-bridges is favoured by the simplicity of the apparatus necessary for their erection, and the superior strength, bulk for bulk, of small wires over bars of considerable dimensions. In some instances the chain system and the wire system have been combined. There is a chain bridge at Geneva, in which both the long and short links may be called skeins of wire, bound round into a cylindrical form in the centre, and spread out into broad loops at the ends, where they embrace the hollow bolts. The structure is in fact a chain bridge, of which the chain-bars and linking-plates consist of bundles of wire instead of solid bars.

Several suspension-bridges of small span have been constructed upon an ingenious plan which combines the advantages of the opposite principles of tension and compression. The first of these was the Monk Bridge, across the river Aire at Leeds, which was erected in 1827, by Mr. George Leather, of that place. The platform is supported by vertical suspension-rods, the upper ends of which, instead of being attached to catenarian chains, are supported by rigid arches of cast-iron, which rising between the carriage-way and the footpaths, are elevated above the level of the platform. The suspending rods are of malleable iron, and they sustain transverse cast-iron beams upon which the roadway is laid. Timber bridges have been constructed on a similar principle to the above. Drewry mentions one at Eglisau, near Zürich, in Switzerland, consisting of two arches formed of beams 15 feet long, 10 inches broad, and 1 foot deep, with their abutting ends secured by iron straps. The ends of the arches are tied together by horizontal braces, and the weight of the platform is suspended by vertical bars arranged in pairs, which embrace the wooden arch or rib, and are bolted together above it.

Much attention has been excited by the principle of constructing suspension-bridges introduced by Mr. Dredge of Bath, who obtained a patent for his invention in 1836. The leading features of his plan are the adaptation of every part of the chain to the precise amount of strain to which it is exposed, by diminishing the number of plates, and consequently the weight and strength of the chains, from the points of suspension to the lowest or central point of the catenary; and the position of the suspending rods, which, instead of being vertical, are arranged in oblique lines from their points of attachment to the main chains towards the centre of the catenary. The Victoria Bridge over the Avon, at Bath, which was built on this plan in 1836, contains only twenty-one tons of iron, although it is of 150 feet span. The number of bridges since built on this plan is very considerable. An example of them on a very small scale may be seen in the Regent's Park. In 1827-8 a suspension-bridge of *steel* was erected over the Danube at Vienna, by an engineer named Von Mitis; the bridge alluded to at Vienna has a chord-line of 334 English feet, with a deflection of nearly 21½ feet.

Perhaps the finest suspension bridge ever constructed is that built by Mr. Tierney Clark over the Danube at Pesth. In magnitude and in cost it exceeds all others. It was finished in 1849, and was shortly afterwards traversed by the Austrian and Hungarian armies.

Suspension-bridges are well adapted for many situations in which, from the limited traffic, the expense of ordinary stone bridges would prevent their adoption, and also for places in which, from the great span required, the great elevation, the unfavourable nature of the bottom, or the rapidity of the current to be crossed, the erection of any other kind of bridge would be difficult; but they are not applicable to situations of great and constant traffic, since they are much weaker than arch-bridges, and very liable to injury from the vibration occasioned by what might appear slight forces.

SUSSEX. Few persons are now aware that Sussex was once an iron smelting county. It was in the wealden strata of Sussex, when wood was abundant and when charcoal was employed in smelting iron, that the chief iron-works of Sussex were situated, the iron-ore being extracted from the ironstone of the argillaceous beds. Up to the year 1720 Sussex was the principal seat of the iron manufacture in England; but by degrees the furnaces were disused and the manufacture transferred to districts where coal was abundant. The last furnace, at Ashburnham, was blown out in 1827.

The rich marsh-lands, of which there are about 30,000 acres in the county, make an excellent pasture-ground, on which many oxen and sheep are reared and fatted for market. There are also about 50,000 acres of down-land, which produce excellent pasture for the small sheep known as Southdown sheep. Hops are cultivated to a considerable extent in the eastern part of the county; they have been introduced from Kent, and have gradually extended themselves westward. Upwards of 8000 acres are now under cultivation; the produce however is not so much esteemed in the market as that of Kent.

Sussex, like Surrey, has but few of the characteristics of a manufacturing county; its towns are pleasure towns and agricultural towns, rather than manufacturing towns. Of the former class are Bognor, Brighton, Eastbourne, Hastings, and Worthing. There is, however, a small amount of sea and river traffic at Arundel, Newhaven, Rye, and Shoreham.

SWANSEA. This important Welch town contains groups of furnaces and other works connected with the smelting of copper, for which Swansea is celebrated. The ore is imported from Cornwall, Devonshire, and other parts of Great Britain, and also from various foreign places besides Australia. Besides the works for smelting copper, there are iron-works, zinc-works, tin-plate-works, yards for building and repairing ships, roperies, tanneries, and potteries. The traffic with the country is facilitated by several canals and tram-roads. A canal about 17 miles in length runs along the valley of the Tawe into Brecknockshire; another connects the Neath river and canal with Swansea harbour; and a third communicates with collieries on the N.E. of the town. In 1849 the trade of Swansea was as follows:—Foreign vessels—entered inwards with cargoes, 205, bringing 48,000 tons; outwards, with cargoes, 438, taking 50,000 tons; inwards, with ballast, 112; 9000 tons; outwards, with ballast, 16; 3600 tons. Coasting vessels—entered inwards with cargoes, 4000, bringing 263,000 tons; outwards, with cargoes, 6000, taking 355,000 tons. In addition to the above, about 100 vessels arrived in ballast, and about 200 cleared out in ballast. Eighteen out of the 205 (of a burthen of 600 tons each) entering inwards from foreign parts brought copper ore and wool from South Australia.

The copper ore bought at Swansea by the smelters during the last few years has varied from 600,000*l.* to 900,000*l.* annually in value. It is all purchased by about eight or ten large firms, whose smelting works form the most distinguishing features in the neighbourhood of Swansea. When smelted and reduced to the forms of ingot, bar, sheet, &c., it is distributed throughout every part of the United Kingdom, and indeed throughout the known world. Almost all the copper ore smelted in this country is smelted in and near Swansea. For further details on this subject, see Copper.

SWEDEN. The climate and soil are less favourable to the growth of grain in Sweden than in most other parts of Europe. The principal objects of cultivation are rye, barley, oats, peas and wheat. The produce of potatoes increased from about 200,000 qrs. in 1805 to about 2,000,000 qrs. in 1840. Other objects of cultivation are hemp, flax, and tobacco; buckwheat, carraway seed, hops and madder. Cherries, apples, and pears, are abundant only in the southern districts; cranberries and other berries abound in the northern districts. The forests are very large, covering altogether more than one-fourth of the whole of the surface of Sweden. The export of timber, though considerable, is not in proportion to the immense extent of the woods. The forests supply fire-wood, of which a great quantity is consumed, as Sweden has no useful coal. Large quantities of charcoal are also used in the mines and factories. Tar and pitch are extracted chiefly from the roots of pine trees, and are minor articles of export. Several kinds of coniferous trees and birch compose the greater part of these forests. Oak and beech grow only in the southern districts. The seas of Sweden contain abundance of fish. Salmon abounds in almost all the rivers and lakes.

Sweden is rich in minerals. Gold is found on the table-land of Smäland, at Adelforss, but no mines are worked. Silver-mines are worked at Sala, in Westeras Län, and at some other places, and in Falu Län. The annual produce of the copper-mines amounts to nearly 1000 tons; the richest mines are those at Falun in Falu Län and at Otvidaberg in Linköping Län. Lead mines are worked in Westeras and in Falu. Iron-ore is found in nearly every district of Sweden, and there is no part where it is not worked more or less, with the exception of the plain of Scania, where it seems that no iron ore exists; the best iron is obtained from the mines of Dannemora in Upsala Län. The annual produce of all the iron mines of Sweden amounts to more than 67,000 tons of bar iron. In Orebro Län are rich mines of cobalt, which yield annually more than 600 tons; this metal is found in several other parts of Sweden. At some places alum and vitriol are obtained, but only in small quantities. Some bad brown coal is raised near Cape Kullen in Scania. Porphyry is got at Elfvedal, in the upper valley of the Dal-Elf, and marble in the mountains north of Norrköping.

Manufactures have been fostered in Sweden by a system of prohibitions and severe restrictions. The most important industrial establishments are confined to the large towns. Stockholm has large sugar-refineries, cotton and silk factories, tanyards, woollen-cloth mills, &c. Norrköping is the chief centre of the woollen manufactures. Steam machinery and mill-work are manufactured in Motala, Stockholm, and Nyköping, which last has also large iron-foundries. Tobacco is extensively manufactured in most of the large towns. Other products are paper, cotton-yarn, glass, morocco leather, printed cottons and linens, seed-oils, pottery and chinaware, linen, soap, sail-cloth, silk ribands, &c. Göteborg has important breweries, sugar-refineries, and sail-cloth factories. Very few of the articles named are exported from Sweden, and none to any considerable amount; nor of many of the most important items is the supply sufficient for the demand. The Swedish peasant is of necessity himself a handicraftsman and manufacturer; and very few persons, comparatively speaking, are exclusively devoted to technical trades. The most important articles of peasant industry are—the coarse woollen stuffs of Dalecarlia and West Gothland in which the country people are clad; the linen of West Gothland and Helsingland, and the damasks and fine linens of Angermanland; the stockings, pottery, turnery, and woodwork of West Gothland and Schonen; and the wooden clocks of Dalecarlia; all of which enter largely into the internal trade of the country. Breweries and distilleries are to be found in most of the towns; and most of the towns on the coast have ship-building yards.

The internal commerce, which is considerable, in corn, salt, fish, whisky, bricks and tiles, linens, and other manufactured goods is facilitated by good roads and navigable rivers, and in winter by the whole country being covered with snow—a circumstance which renders the conveyance of goods in sledges easy and expeditious. The Swedes are much given to a seafaring life. Their vessels visit most of the countries contiguous to the Atlantic, and they are also employed in the carrying trade between other countries, especially in the Mediterranean, and on the coasts of South America. The imports consist of fish from Norway; butter, tallow, and provisions from Finland; hemp, flax and hemp seed, linseed oil, hides, tallow, and peltry from Russia; corn, wool, cattle, and provisions from Denmark; colonial produce, dye-stuffs, spices, and manufactured goods, from England and the Hanse towns; fruit, cattle, corn, and manufactured articles from Mecklenburg and Prussia; wine, fruits, oil, and silk from France; tropical fruits and salt (an important article, which Sweden does not produce) from Portugal and Spain; colonial produce and dye-stuffs, drugs, hides, tobacco, and rum, from America and the East Indies.

The principal articles of export are—bar and pig iron, nails and other wrought iron; boards, planks, logs and spars, staves, tar; some copper, brass, alum, manganese, paper, and linen and hempen fabrics. The value of the imports in 1844 amounted to 17,487,000 Swedish rix-dollars; the value of the exports in the same year was 21,080,000 rix-dollars. In that year 5445 vessels entered Swedish harbours, 3677 of which were Swedish, and 839 Norwegian; the mercantile marine of Sweden numbered 940 vessels, 738 of which, with 139,990 tons burthen, were engaged in the foreign trade.

In 1850, of Swedish and Norwegian vessels, 1674 entered ports of Great Britain, with an aggregate burthen of 283,061 tons.

The value of the British and Irish produce and manufactures exported to Sweden and Norway in 1849 was 367,363*l*.

SWEEPING MACHINES. Mr. Whitworth's street-sweeping machine deserves to be more extensively adopted than it has yet been; for its operations are more expeditious and more effective than those ordinarily adopted. It was introduced about eight or nine years ago at Manchester. There had before been invented road-scraping machines; but the sweeping machine superseded them. The machine consists of a cart, to the hinder part of which is an endless chain of brushes or brooms, inclining downwards to the ground. The motion of the wheels causes other wheels within the machine to rotate; and these minor wheels act upon the brushes, causing each brush in turn to sweep over the surface of the ground, and to carry up its portion of dirt into the cart. Sloping boards are so adjusted as to facilitate the transfer of the dirt into the cart. The sweepings from 800 to 4000 square yards of street or road suffice to fill the cart, according to the previous state of the ground as to cleanliness. It has been calculated that one of these machines, drawn by two horses, can sweep 24,000 square yards, on an average, per day—a quantity equal to that which twenty men could cleanse in the same time.

Mr. Whitworth patented, in 1849, a new arrangement of the brushes; they are attached to the lower surface of a horizontal disc, which has a revolving motion given to it round a vertical axis, by machinery connected with the ordinary wheels of the cart.

Another street-sweeping machine was patented by Mr. Walker, in 1849. It consists of a cart on four wheels, the front pair of which give motion to two channel brushes, one on each side; while the hinder pair give motion to a large roller brush, as long as the width of the machine. The action of these three brushes is such as to collect the dirt of the street into parallel ridges; and another apparatus then comes into work. This apparatus is something like Whitworth's in respect to sweeping the dirt up a sloping board into a receptacle; but there is also an endless chain of buckets which lifts the dirt from the receptacle into a cart temporarily attached to the machine. The whole contrivance is much more complicated than Whitworth's.

SWITZERLAND. This interesting country does not produce corn enough for its consumption. Flax and hemp are extensively grown; but the chief territorial wealth of the highlands, and indeed of the greater part of Switzerland, consists in its pastures and its cattle. The vine is extensively cultivated in the cantons of Vaud, Geneva, Neufchâtel, Zürich, Schaffhausen, Valais, Ticino, and parts of Aargau, Thurgau, St. Gall, and Basel; but the wine is generally inferior. In the highland cantons cider is made. Kirschwasser is distilled. Mulberry-trees are planted and silk-worms reared in the canton of Ticino and the valleys on the Italian side of the Alps. Chestnut-trees are found in sheltered situations; walnut-trees are more generally diffused; olive-trees grow only in some favoured spots of the canton of Ticino, where also the fig and peach-trees bear abundantly, as well as in some parts of the lower Valais. The highlands abound with timber-trees, especially firs of various kinds, maple, beech, larch, birch, and oak trees. Most of the cottages and farm-houses are built of wood, and the same material is used for fuel, the annual consumption of which is enormous: a great quantity of timber is also exported to France and other countries. Coal-mines are worked in the cantons of Freyberg, Vaud, Basel, and Thurgau, but the coal is mostly of inferior quality. Iron is found in the Jura; and there are furnaces and iron-works of some importance in the cantons of Vaud, Bern, Soleure, Basel, Aargau, and Grisons. In the Grisons there are mines of lead, zinc, and galena. Salt-springs abound, but they are generally neglected, except those of Bex in the canton of Vaud. Switzerland has been a manufacturing country for centuries. In the canton of Zürich the manufacture of silks, taffeta, serges, silk handkerchiefs, and ribands, gives employment to between 12,000 and 13,000 people. The cotton-manufactures of Zürich employ about 12,000 weavers, 5000 spinners, besides 4000 persons engaged in other trades connected with the cotton manufacture. The cantons of St. Gall and Appenzall have important manufactures of cotton cloths, fine muslins, cotton prints, leather, linen, glass, and jewellery. The city of Basel forms another emporium of trade and manufactures, principally of silk ribands, silk thread, taffeta, and satins. Schaffhausen has a manufactory of steel and files, which is in great repute; one of cotton-spinning, and one of cotton prints. It has also a good transit trade with Germany. At the opposite extremity of Switzerland, Geneva is a great mart of trade and industry. The manufactures of Geneva consist chiefly of watches, jewellery, and musical boxes; but include also cabinet work, saddlery, lithography and engraving, cutlery, fire-arms, enamels, &c. The chief industrial occupations in the canton of Neufchâtel are—cotton printing, lace-making, and more especially watch-making, which prevails greatly among the highlands of the Jura, giving employment to about 20,000 persons, who manufacture and export yearly above 120,000 gold and silver watches. The cantons of Thurgau, Glarus, and Aargau manufacture cotton cloth, prints, and muslins of all descriptions, hosiery, silks, and ribands; in Aargau linen and cutlery are also made. The rest of the cantons of Switzerland manufacture merely what is required to supply their own wants. The manufactures find a vent in distant countries by passing through Germany and the Sardinian States to the harbours of Holland and the Mediterranean.

The Great Exhibition affords gratifying proof that the industrial products of Switzerland are varied, ingenious, and valuable.

SWORD MANUFACTURE. Several countries have been celebrated for the excellence of the swords manufactured by the inhabitants. The swords of Toledo were famed even as far back as the time of the Romans. The Milan swords have likewise had a high reputation. But the Damascus swords have had the widest celebrity; though no such manufacture is now carried on in that city, as the Damascus swords now existing are of old date.

About the year 1689 an attempt was made to improve and extend the sword manufacture of England by the incorporation of a company of sword-cutlers for making hollow sword-blades in Cumberland and the adjacent counties. The company was empowered to purchase lands, to erect mills, and to employ a great number of German artificers; yet the project failed. Owing apparently to the parsimony of the manufacturers, which led them to use inferior materials, and to employ unskilful workmen, English sword-blades fell into very ill repute during the 18th century; so much so, indeed, that an English officer would not trust his life to the hazard of the probable failure of a sword of native manufacture. Attention having been drawn to this subject, the late Mr. Gill, of Birmingham, entered into competition with the German sword-cutlers, and produced swords even superior to those of the German makers. The tendency of recent years has been to bring the chief European nations nearly to a level in this manufacture.

The process of manufacturing swords at Birmingham is as follows:—The material of which the blade is wrought should be cast-steel of the very best quality, and wrought with the greatest care. Of this material, besides the quantity prepared at Birmingham, much is obtained from Sheffield in the form of bars, called *sword-moulds.* These bars are heated in the fire, and drawn out upon an anvil by two workmen with hammers, giving alternate strokes. When the blade is required to be concave upon the sides, or to have a reeded back, or some similar ornament, it is hammered between steel bosses or *swages.* The blade is then hardened by heating it in the fire until it becomes worm-red, and is then dipped, point downwards, in a tub of cold water. It is tempered by drawing it through the fire several times until the surface exhibits a bluish oxidation, which takes place at a temperature of about 550° Fahr. The sword is then *set* to the required shape by placing it on a sort of fork upon the anvil, and wrenching it by means of tongs in the direction required to correct any degree of warping which it may have contracted during the hardening. The grinding is performed upon a stone with either a flat or fluted surface, according to the kind of blade; and as the uniformity of the temper is impaired by this process, it is subsequently restored by a slight heating, after which the blade is glazed with emery, and, if the instrument be a fine one, with crocus martis, after the manner of a razor-blade. The sword is then ready for the hilt or handle, the variety of which it is needless to enumerate.

Among the tests to which sword-blades are subjected in order to prove their flexibility and elasticity, is that of bending them into a curve by pressing the side of the blade against six or eight pegs or stout nails driven into a board, in such a manner that, when in contact with all the pegs, the middle of the blade may be bent six or seven inches from a straight line drawn between the point and the hilt. A further test is applied by an apparatus consisting of a vertical pillar rising from a board. The point of the sabre is placed upon the board at the foot of the upright pillar, and the hilt is then pressed down until the middle of the blade bends away from the upright piece to the required degree; the amount of curvature being shown by a peg which projects horizontally from the pillar, about midway between the top and the bottom. The temper is also proved by striking the blade smartly upon a table on both sides, and by severe strokes with the back and edge upon a block. Mr. Inglis, in his 'Spain in 1830,' describes the trials to which sword-blades are subjected at the celebrated manufactory of Toledo. Each sword is there thrust against a plate in the wall, and so bent into an arc forming at least three parts of a circle, and then struck edgeways upon a leaden table with all the force which can be given by a powerful man holding it with both hands. The polishing, according to the same authority, is performed upon a wheel of walnut wood.

The ancient Damascus sword-blades have a peculiar wavy appearance on the surface, which is called *damascene* or *damasking*. [DAMASCENE WORK.] Various modes have been adopted for imitating this appearance; but it is not known whether any of them are identical with the original practice.

SYRIA. In this important region of Western Asia the ordinary farming produce is raised in fair variety and quantity. Cotton, hemp, flax, madder, indigo, and tobacco, are to some extent cultivated. Almost all the fruits both of temperate and of tropical climates are met with in Syria. The forests on the mountains consist of cedars, firs, and pines; those of the table-lands include the oak, walnut, laurel, juniper, scammony, and sumach.

There are no metals found in Syria except iron, which is worked in the Kesrouan in Mar Hanna, west of Beirout, where also coal has been discovered of late years. In the Tyh Beni Israël, and at the southern extremity of the Dead Sea, there are mountains almost entirely composed of rock salt. Bitumen is collected on the western shores of the Dead Sea. In the northern Ghaur pieces of native sulphur are found at a small depth beneath the surface.

Syria is the most manufacturing country in Western Asia. With the exception of hardware and cutlery, there is hardly any manufactured article imported into Syria; but a great variety of goods which are made in Syria are exported to Egypt and Anatolia, and still greater quantities go to the countries farther east, and find their way into Persia, where they meet the articles brought from Hindustan. The most manufacturing town is Damascus. The Phœnicians were probably supplied from Damascus with a great number of manufactured articles for the market of the countries that surround the Mediterranean, and they supplied the manufactures of Damascus with some of the materials used in them. The extent of the manufacturing industry of this town may be conceived from the statement of Schubert, that above 40,000 persons are employed in making silk stuffs, especially satin and silk damasks and brocades; and that caravans frequently go from Damascus to Haleb, which take no other goods but articles of this description. The varieties of manufactures at Damascus are almost countless. Those of Aleppo are considerably smaller, and are mostly limited to cotton and silk stuffs, and gold and silver lace. Some branches of manufacturing industry are carried on in most of the small towns, and even in some villages, such as cotton stuffs for gowns and shirts, the dyeing of cotton, mostly blue and red, tanning leather, and making soap. Such places, however, supply only the neighbourhood, and the Beduins who resort to them for such articles, and they rarely if ever work for a distant market.

The commercial intercourse between Syria and Europe is very small. None of the agricultural products of Europe are in demand in Syria; no kind of grain is imported, with the exception of rice, with which Syria is supplied from Egypt. The manufactured goods of Europe are not in demand, not being adapted to the taste and customs of the East. The only article which is imported to a certain extent is hardware, which is almost exclusively supplied by England: some French cloth is also imported. The chief articles sent from Europe to Syria are supplied by the East and West Indies, and consist of indigo, cochineal, and coffee. The chief exports from Syria to Europe are silk, galls, olive-oil, sponges, fruit, and tobacco. The commerce between Syria and the countries to the east and north of it is very extensive, and is concentrated at Aleppo. Two well-frequented roads lead from Aleppo to Constantinople through Anatolia; and two likewise extend from Aleppo to Persia, which divide at Orfa in Mesopotamia. But the most frequented caravan road between Aleppo and Bagdad lies to the west of the Euphrates, passing by Annah and Hit.

The objects sent from Syria to the Great Exhibition consist of specimens of the manufacture of silk, gold, silver lace and embroidery, native jewellery, Lebanon horns, petrifactions, oils, different sorts of woods, seeds, the apples of Sodom, &c. The Pacha of Jerusalem sends a few specimens of the Bethlehem work in mother-of-pearl, which is brought by the Hadj from Mecca, such as the crucifixion, and other religious subjects. Mr. Consul Finn sends Palestine flowers arranged in a box of olive wood, and some specimens of Jerusalem marbles contained in a box made of one of the stones of Jerusalem. Colonel Rose, her Majesty's consul-general in Syria, sends with the Syrian specimens a few gold antiquities. One of them is a gold mask found in a Greek sarcophagus near Gebal, which was placed on the face of a female corpse, and still retains her features.

SYRINGE, a portable hydraulic instrument of the pump kind, commonly employed for the forcible ejection of fluids. In its simplest form it consists of a cylindrical tube, with a perforated nozzle at one end, and a piston or plunger, to the rod of which a ring or other convenient handle is attached. The tube being held in the left hand, with its nozzle immersed in water, the piston is drawn to the upper end of the tube by the right hand. The pressure of the atmosphere upon the surface of the water causes it to follow the piston, so that the syringe becomes filled with water. The instrument is then removed from the vessel of water, and, by pushing the piston back towards the nozzle, its contents may be ejected with a force proportionate to the power applied to the piston. Syringes of various sorts are extensively used for surgical, horticultural, and other purposes. The fire-engine, the garden-engine, the air-pump, the stomach-pump, and the school-boy's squirt, are all examples of syringes.

SYRUPS are medicinal solutions of sugar, either in water alone, as in simple syrup, or in liquids charged with some peculiar principle of an active kind, such as senna or buckthorn, or merely grateful from its colour or fragrance, or both, such as syrup of violets. These must be of a proper consistence, either by having a suitable quantity of sugar added to the water first, or by subsequent evaporation of the superfluous water. The former is the preferable mode, as the syrup keeps better. The purest and most thoroughly refined sugar should be employed, and generally in the proportion of two parts of sugar to one of fluid.

The variety of syrups is very considerable. Syrups of buckthorn, cochineal, coltsfoot, gum, ginger, horehound, ipecacuanha, lemon, marshmallow, mulberry, orange peel, poppy, rhubarb, rose, rue, saffron, sarsaparilla, senna, squills, tolu, violets—these are some of the many kinds of syrups prepared by druggists.

T

TACHOMETER. This is the name of an apparatus patented by Messrs. Napier, in 1848, for ascertaining the speed with which vessels pass through the water. It consists of a horizontal spindle, moving freely on pivots attached to the side of the vessel beneath the water line, and enclosed in a case open at both ends. The spindle is fitted with vanes, the pitch or angle of which is so regulated, that ten revolutions of the spindle shall equal one fathom. Other wheel-work connects this spindle with a dial and index, so as to measure the number of nautical miles which the apparatus, and consequently the ship itself, has passed through the water.

Messrs. Penn, the engineers of Greenwich, patented in the same year a tachometer of a very ingenious and peculiar kind. It is to be attached to an auxiliary steam ship; that is, a ship which *sails* only under ordinary circumstances, but which has also facilities for *steaming* in ordinary weather. (Such an auxiliary moving power is described under SCREW PROPELLER.) Messrs. Penn's apparatus is intended, not only to measure the speed of such a vessel through the water, but to strengthen or weaken the steam force according as the sailing force is weak or strong. It is self-acting, like the governor and valve of a steam engine: it feeds itself with steam power, according to its wants. There is a small horizontal paddle-wheel attached to the side of the ship, and the shaft of this wheel is connected, by intervening apparatus, with the steam pipe; as the vessel advances this little wheel rotates, and according as the rotation is fast or slow (depending on the greater or less speed), the steam pipe becomes opened less or more widely.

TALBOTYPE. [CALOTYPE; PHOTOGRAPHY.]

TALC. This remarkable mineral, which consists chiefly of silica and magnesia, presents itself in various forms. It is sometimes crystalline, sometimes laminated in thin plates, and sometimes in greenish gray masses of talc-slate. It is found in beds of clay slate and mica slate, in various parts of Scotland and the Alps. It is used as an ingredient in rouge, as a polisher for soft alabaster, as an ingredient in porcelain paste, and in the manufacture of crayons.

TALLOW is animal fat melted and separated from the membranous matter which is naturally mixed with it. When pure, tallow is white, and nearly tasteless; but the tallow of commerce usually has a yellow tinge.

A very large proportion of the tallow used for making soap and candles in this country is of home production, and is fitted for use by the *renderer*, who chops into pieces the fat and suet received from the butchers, and boils it in water, by which operation the greater part of the fat is melted out from the membranes, and floats to the top, whence it is removed by skimming. The remaining fat is subsequently squeezed from the membranes by a powerful press, leaving the membranous matter in the form of a cake or block, of a dark colour, which is called *graves*, and which, when macerated in warm water, softens and swells, and becomes a wholesome and palatable article of food for poultry, dogs, and other domestic animals. It is extensively used in fattening poultry for the market.

Almost all our imported tallow is brought from Russia, where this article is produced in enormous quantities. 250,000,000 lbs. are annually exported from Russia to various countries, mostly furnished from the steppes of Southern Russia. The cattle are bought by thousands, driven to the Salgans, or tallow factories, and there fattened and slaughtered. After the animals are slaughtered and skinned, a little of the flesh and the intestines are removed, and the rest of the carcass, cut into pieces, is thrown into the boilers, of which there are from four to six in every salgan, each large enough to contain the flesh of ten or fifteen oxen. During the boiling, the fat, as it collects at the top, is skimmed off with large ladles, and before it is quite cold it is poured into the casks in which it is afterwards shipped. The first fat which comes off is the best, and is quite white, while that which follows has a yellowish tinge; and a still coarser tallow is obtained by squeezing the bones and flesh in presses.

An ox in good condition will yield from seven to eight poods (250 to 290 lbs.) of tallow, which is generally worth from eleven to fifteen rubles a pood—about 1½*d.* to 2*d.* per lb. The merchants of St. Petersburg divide the tallow which they receive from the interior into white and yellow candle tallow, and common and Siberian soap-tallow; the latter, which is considered the best tallow for soap-making, being brought by water transit from Siberia. Yellow candle-tallow, when good, should be clean, dry, hard when broken, and of a fine yellow colour throughout. The white candle-tallow, when good, is white, brittle, hard, dry, and clean. The best white tallow is brought from Woronesch.

The chief uses of tallow are noticed under CANDLE and SOAP. Palm-oil has recently come extensively into use as a substitute for tallow in candle-making.

The tallow imported during the last three years amounted to the following quantities:—

1848	1,498,359 cwts.
1849	1,465,629 „
1850	1,241,781 „

Russia, as has been stated, is the great source whence the supply is obtained; but Australia now sends large cargoes of tallow to the mother country.

TAMARINDS. Of the two species of the genus *Tamarindus* the fruit is much larger in the East Indian than the West Indian. The shell being removed, there remains the flat square hard seed, imbedded in a pulp, with membranous fibres running through it. In the East Indies the pulp is either dried in the sun, and used for home consumption, or with salt added it is dried in copper ovens; this kind is sent to Europe. This sort, called natural tamarinds, is much darker and drier than the West Indian, which are called prepared tamarinds.

The West Indian Tamarinds reach maturity in June, July, and August, when they are collected, and the shell being removed, they are put into jars, either with layers of sugar put between them, or boiling syrup poured over them, which penetrates to the bottom. Prepared tamarinds therefore contain much more saccharine matter than the others.

The timber of the East Indian tamarind tree is very firm, hard, and heavy, and is applied to many useful purposes in building.

TAMPING. In mining operations, where the process of blasting with gunpowder is necessary for loosening masses of rock or ore, the powder is pressed in a cavity prepared for its reception by a careful process of ramming; this is called *tamping*. [MINING.]

TANKS. The importance of collecting rain-water for domestic purposes, especially in districts where springs are deficient or lie at a great depth, has been much overlooked in this country. Mr. Waistell urges the importance of placing spouts round all the buildings of a farm to collect the rain-water which falls upon them into a tank or tanks; observing that, besides the value of the supply of water thus obtained, the buildings will be benefited by the walls and foundations being kept drier than when the water from the roof is suffered to fall upon them. He states that the quantity of water that falls annually upon every hundred superficial feet or square of building (in Great Britain) is about 1400 imperial gallons. If, therefore, the external surfaces of roofs were adapted to the collection of the rain water which falls upon them, and means were provided for conveying it to covered tanks, in which it might be preserved from evaporation, and kept free from any admixture of impurities, almost every house might be readily and cheaply supplied with a quantity of wholesome water sufficient for the ordinary wants of its inhabitants. The extensive roofs of churches and other public buildings might be employed in like way to collect water for the supply of ponds or tanks for public use. In some cases even the drainage of lands might also be made available, as the water may be submitted to any required process of filtration before it is allowed to enter the tank.

Tanks or cisterns to hold water for domestic purposes may be conveniently situated beneath the surface of the ground, so that, being paved over, they occupy no valuable space. They are formed of stone slabs grooved into each other and set in cement; of Welsh slate; of large paving-tiles bedded in cement; of brick-work; of plates of cast iron; or of thick wooden planks, protected by charring and pitching, or lined with sheet lead. The brick tanks described by Waistell are circular, the sides being built like a well, with bottoms of an inverted dome-shape, of very slight convexity. The top is also dome-shaped, and has an opening in the centre large enough to receive a man, in order that the tank may be thoroughly cleaned out when necessary. This opening which may be upon the surface of the ground, or a little above it, should be covered with an oak flap pierced with a number of holes, or with an iron grating.

TAPESTRY. This name is commonly applied to the textile fabrics usually composed of wool or silk, and sometimes enriched with gold and silver, woven or embroidered with figures, landscapes, or ornamental devices, and used as a lining or covering for the walls of apartments. It is probable that many of the early tapestries were embroidered by hand or worked with the needle. This kind of work, of which the Bayeux tapestry is a celebrated example, was continued long after the practice of weaving tapestry in the loom had become common

The 16th century, which was an age of general improvement in France, gave a new impulse to the production of tapestry. Francis I. founded the manufactures of Fontainebleau, in which threads of gold and silver were skilfully introduced into the work. It was, we are informed, with this new impulse that the practice was commenced of weaving tapestry in a single piece, instead of composing it, as before, of several small pieces joined together. Francis spared no pains in the encouragement of this department of the fine arts. He engaged Flemish workmen, whom he supplied with silk, wool, and other materials, and paid liberally for their labour; and documents exist to prove that he also patronized the tapestry-makers of Paris. Henry II., the son and successor of Francis, continued to encourage the manufactory at Fontainebleau, and established a manufacture of tapestry on the premises of the Hôpital de la Trinité, which attained its highest celebrity in the reign of Henry IV., and produced many fine tapestries. In 1594 Du Bourg, the most eminent artist connected with this establishment, made there the celebrated tapestries of St. Meri, which were in existence until a recent period; and these pleased Henry IV. so much, that he determined to re-establish the manufacture of tapestry at Paris, where it had been interrupted by the disorders of the preceding reigns. This he did in 1597, bringing Italian workers in gold and silk to assist in the work. In 1605 were laid the foundations of new edifices for the tapestry-weavers, in the horse-market at Paris; and at that time, or a little later, Flemish workmen were engaged to superintend the manufacture. The establishment languished, if it did not become quite extinct, after the death of Henry IV.; but when the royal palaces, especially the Louvre and the Tuileries, were receiving their rich decorations, in the reign of Louis XIV., his minister Colbert revived it, and from that time the celebrated royal tapestry manufactory of the Gobelins dates its origin. Foreign artists and workmen were engaged, laws were drawn up for the protection and government of the manufactory, and everything was done to render it, what it has continued to be, the finest establishment of the kind in the world. Le Brun, when chief director of the establishment, made many designs for working after; and M. de Louvois caused tapestry to be made from some of the finest designs of Raphael, Julio Romano, and other Italian painters. The manufacture declined greatly at the Revolution, but was revived under the government of Napoleon, and has ever since been carried on successfully, though by no means to the same extent as formerly.

The introduction of tapestry-weaving into England is usually attributed to a gentleman named Sheldon, late in the reign of Henry VIII. At Burcheston were worked in tapestry, on a large scale, maps of Oxfordshire, Worcestershire, Warwickshire, and Gloucestershire, some fragments of which were, it is stated, in Walpole's collection at Strawberry Hill. Little more is known of this establishment. James I. endeavoured to revive the manufacture of tapestry by encouraging and assisting in the formation of an establishment at Mortlake, about 1619, under the management of Sir Francis Crane. James I. gave 2000*l*. towards the formation of this establishment. After the Restoration, Charles II. endeavoured to revive the manufacture, and employed Verrio to make designs for it, but the attempt was unsuccessful. During its period of prosperity, this manufacture produced the most superb hangings, after the designs of celebrated painters, with which the palaces of Windsor Castle, Hampton Court, Whitehall, St. James's, Nonsuch, Greenwich, &c., and many of the mansions of the nobility, were adorned.

In the primitive method of working tapestry with the needle, the wool was usually applied to a kind of canvas, and the effect produced was coarse and very defective; but some finer kinds of tapestry were embroidered upon a silken fabric. The process of weaving by the loom, after the manner known as the *haute lisse*, or high warp, was practised in the tapestries of Flanders as early as the 14th and 15th centuries; the only essential difference between these and the productions of modern times being that previously noticed, the comparative size of the pieces woven in the loom. The weaving of tapestry, both by the 'haute lisse' and the 'basse lisse,' appears to be of Oriental invention; and the difference between the two methods may be briefly described. In the 'haute lisse' the loom, or rather the frame with the warp threads, is placed in a perpendicular position, and the weaver works standing; while in the 'basse lisse' the frame with the warp is laid horizontally, and the weaver works in a sitting position. In weaving with the 'basse lisse,' which is now relinquished, the painting to be copied is laid beneath the threads of the warp, which are stretched in a manner resembling that of common weaving, the pattern being supported by a number of transverse threads stretched beneath it. The weaver, sitting before the loom, and leaning over the beam, carefully separates the threads of the warp with his fingers, so that he may see his pattern between them. He then takes in his other hand a kind of shuttle, called a *flûte*, charged with silk or wool of the colour required, and passes it between the threads, after separating them in the usual way by means of treddles worked by the feet. The thread of woof or shoot thus inserted is finally driven close up to the finished portion of the work by means of a reed or comb formed of box-wood or ivory, the teeth of which are inserted between the threads of the warp. In this process the face of the tapestry is downwards, so that the weaver cannot examine his work until the piece is completed and removed from the loom. The frame of the 'haute lisse' loom consists of two upright side-pieces, with large rollers placed horizontally between them. The threads of the warp, which usually consist of twisted wool, are wound round the upper roller, and the finished web is coiled round the lower one. The cartoon, or design to be copied, is placed perpendicularly behind the back or wrong side of the warp, and then the principal outlines of the pattern are drawn upon the front of the warp, the threads of which are sufficiently open to allow the artist to see the design between them. The cartoon is then removed so far back from the warp that the weaver may place himself between them with his back towards the former, so that he must turn round whenever he wishes to look at it. Attached to the upright side-pieces of the frame are contrivances for separating the threads of the warp, so as to allow the *flûte* or broach, which carries the woof, to pass between them. Like the weaver with the 'basse lisse,' the operator works, as it were, blindfolded; but by walking round to the front of the loom he may see the progress of his work, and may adjust any threads which have not been forced into their right position by the reed or comb, with a large needle, called an *aiguille à presser*. The process of working with the 'haute lisse' is much slower than the other, and is indeed almost as slow as that of working with the needle. Lady Wilton, in describing the productions of the Hôtel Royal des Gobelins, observes that 'not the least interesting part of the process was that performed by the *rentrayeurs*, or fine-drawers, who so unite the breadths of the tapestry into one picture, that no seam is discernible, but the whole appears like one design.' Now, however, the pieces are woven so wide that joining is very seldom resorted to, even for the largest pieces.

TAPIOCA. [MANDIOC.]

TAR is obtained from wood or coal by distillation in close vessels, or in piles from which the air is excluded. *Pitch* is obtained by boiling tar until all the volatile matters are driven off. Tar is a viscid brown semi-fluid mass, which long preserves its softness. If it be mixed with water, the water acquires a yellow colour and the taste of tar, with slightly acid properties. This solution is well known by the name of tar-water, and has been used in medicine. Tar is soluble in alcohol, in æther, and in the fixed and volatile oils. Oil of tar, creasote, and many other valuable substances, are obtained from tar.

Tar is extensively manufactured from the roots and branches of pines and firs in Norway, Sweden, Germany, Russia, North America, and other countries in which those trees abound; but that made in the north of Europe is considered far superior to what is produced in the United States. A conical cavity is made in the ground (generally in the side of a bank or sloping hill), and the roots of the fir, together with logs and billets of the same, being neatly trussed in a stack of the same conical shape, are let into this cavity. The whole is then covered with turf, which is well beaten down. The stack of billets is kindled, and a slow combustion of the fir takes place, without flame, as in making charcoal. During this combustion the tar exudes; and a cast-iron pan being at the bottom of the funnel, with a spout which projects through the side of the bank, barrels are placed beneath this spout to collect the fluid as it comes away. As fast as the barrels are filled, they are bunged, and made ready for exportation.

In some parts of France and Switzerland tar is extracted in a kind of oven or kiln, built of stone or brick in the form of an egg, with its smaller end downwards.

As England requires a large quantity of tar for the navy, the supply from foreign countries is an important matter. At different periods the high price of Swedish tar has led to the encouragement by government of the making of tar in the British American colonies. During the American war, attention was paid to the establishment of the manufacture of tar from pitcoal, an object which had been previously attempted; but the manufacture of coal-tar has not proved so important as was at one time anticipated, although for some purposes it is deemed superior to that made from wood. Tar is produced in large quantities in the manufacture of coal-gas; but in some districts its value is considered so trifling that it is mixed with the fuel by which the retorts are heated. It is usually separated from the gas by condensation.

The tar imported in the last three years amounted to the following quantities:

1848	12,609 lasts.
1849	15,206 „
1850	12,096 „

This last named quantity is equivalent to about 5,000,000 gallons. Tar is free from import duty.

TARTARIC ACID was first obtained in a separate state by Scheele; it exists in several vegetable products, but principally in bitartrate of potash, which is usually called *cream of tartar*, a salt which is deposited from wine.

Tartaric acid is colourless, inodorous, and very sour; it occurs in crystals of a considerable size, the primary form of which is an oblique, rhombic prism; it suffers no change by exposure to the air; water at 60° dissolves about one-fifth of its weight, and at 212° twice its weight. It combines readily with alkalies, earths, and metallic oxides; and these salts are called *tartrates:* many of them are usefully applied in the arts.

Tartaric acid is largely employed as a discharge in calico printing, and for making what are called sodaic powders, which are imitations of soda-water.

Tartaric acid is entirely confined to the vegetable kingdom, and is found free or uncombined in tamarinds, in the unripe grape, and in pepper; and in combination in tamarinds, ripe grapes, gooseberries, mulberries, squill, dandelion, chenopodium vulvaria, in various species of pines, and as tartrate of lime in the fruit of the *Rhus typhina.*

TEA. Though now so extensively employed, the introduction of tea into Europe is of comparatively recent origin. Pepys in his 'Diary,' writes, Sept., 25, 1661, 'I sent for a cup of tea (a Chinese drink), of which I had never drank before.' The Dutch East India Company probably first introduced it into Europe, and from Amsterdam it was brought to London.

The species of the genus *Thea* are few in number. Some botanists are of opinion that even these are varieties of a single species called *Thea Chinesis;* but there are usually said to be two species yielding green and black tea respectively. The Asam tea-plant, which has lately attracted so much attention, seems to partake of the characters of both of the foregoing, and is regarded by some botanists as a distinct species. Tea is cultivated in China over a great extent of territory. Dr. Wallich mentions it as being cultivated in Cochin-China, in 17° N. lat. We know it is cultivated in the southern provinces of Yunnan and of Canton. If we proceed north we find the principal cultivation of teas for the foreign trade is between 27° and 31° N. Lat.; but tea is said to be produced in several places to the northward of 31°; even in 36°, and also in the Japanese Islands, which extend from 30° to 41° N. lat.

The culture of the tea-plant in China seems simple enough. The plants are raised from seeds, sown in the places where they are to remain. Several are dropped into holes four or five inches deep and three or four feet apart, shortly after they ripen; or in November and December, as they do not preserve well, from their oiliness. The plants rise up in a cluster when the rain comes on, and require little further care, except that of removing weeds, till they are three years old, when they yield their first crop of leaves. They are seldom transplanted, but sometimes four to six plants are put close together, so as to form a fine bush. After growing seven or ten years they are cut down in order that the numerous young shoots which then spring out may afford a more abundant supply of leaves. In some districts the bushes grow unrestrained, in others they are regularly pruned, to keep them low. The gathering of the leaves is performed with great care: they are usually gathered singly, first in March or May (according to the district), when the young leaves are scarcely expanded; the second about two months later, or May and June; and the third in August, or about six weeks after the second; but the times necessarily differ in different districts, as well as the number of crops which are obtained, some avoiding the third for fear of injuring the bushes. When the leaves are gathered they are dried in houses which contain small furnaces, on each of which there is a flat iron pan, and upon this, when heated, the leaves, partially dried by exposure to the sun, are thrown; the leaves require frequent shifting and turning. When all are properly dried, they are quickly removed either by the hand or with a shovel, and either thrown upon a mat or into baskets which are kept ready to receive them. They are then removed to a table where they are rolled and cooled, and the process is repeated; after which they are sifted and sorted into several varieties.

The most difficult part of this question is to determine whether the green and black teas are produced by one or two distinct species of plants, as the statements of apparently equally well qualified judges are not only contradictory, but directly the reverse of each other. The Chinese tea-makers in Asam and those in Java alike state that the black and green trees may be prepared from the same plant.

Tea having become so extensive an article of commerce, and a source of considerable revenue, various attempts have been made to introduce it into other countries; but the climates are very different in which the several experiments have been made, as in Rio Janeiro and the warm part of Brazil, and latterly in the hilly parts of Java and Brazil, in Penang, Asam, and the Himalayas. Favourable reports are given of the teas grown in the East Indies, but as yet only small quantities are brought into the European markets. [ASAM.]

The first importation by the English East India Company took place in 1669 from the Company's factory at Bantam. The directors ordered their servants to 'send home by their ships one hundred pounds weight of the best *Tey* they could get.' In 1678 were imported 4713 lbs., but in the six following years the entire imports amounted to no more than 410 lbs. According to Milburn ('Oriental Commerce'), the consumption in 1711 was 141,995 lbs.; 120,695 lbs. in 1715; and 237,904 lbs. in 1720. In 1745 the amount was 730,729 lbs. In 1844 it was 41,363,770 lbs. The tea consumed in the United Kingdom, and the revenue which it yielded, in 1848, 1849, and 1850, were as follows:—

1848	48,347,789 lbs.	5,329,992*l.*
1849	50,021,576 lbs.	5,471,422*l.*
1850	51,178,215 lbs.	5,597,707*l.*

There have been great changes in the taxes levied on tea. In 1835 the excise duty on tea was repealed from and after July 1, 1836, when a customs' duty of 2*s.* 1*d.* per lb. was levied on all sorts of tea, which, with 5 per cent. added in 1845, makes the duty now paid 2*s.* 2¼*d.* per lb.

For above a century and a half the sole object of the East India Company's trade with China was to provide tea for the consumption of the United Kingdom. The Company had an exclusive trade, and were bound to send orders for tea, and to provide ships to import the same, and always to have a year's consumption in their warehouses. The teas were disposed of in London, where only they could be imported, at quarterly sales. The act of 1834 opened the trade to China. The importation of tea is no longer confined to the port of London, and the trade has increased both in the quantity and variety of the exports to China.

The tea-duty produces about one-twelfth of the total revenue. In 1801 it was 1,423,660*l.*, in 1844, 4,524,193*l.* The amount in later years is stated above. As it was foreseen that on the opening of the tea trade there would be a considerable reduction in price, so that an *ad valorem* duty would not, even with the increased consumption, be so productive as formerly, a fixed duty was imposed. Up to 1836, each of the hundred thousand tea-dealers in the United Kingdom was visited once a month by the officers of excise, who took an account of his stock; and no quantity exceeding 6 lbs. could be sent from his premises without a permit, of which above 800,000 were required in a year. Tea is now sold by the importing merchants by public auction and private sales.

The duty on tea is still too high, and it is certain that an increased consumption would follow a diminution of the duty.

Russia is supplied with about 7,000,000 lbs. of tea annually through Kiakhta; France requires about 2,000,000 lbs.; and Holland about 3,000,000 lbs. With the exception of China no other country consumes so much tea as England. The tea-trade of the United States is, however, rapidly increasing. In 1850 there were 173,317 chests of green tea and 91,017 of black tea exported from Canton to America; these quantities with a further portion purchased from England, made a total of about 23,000,000 lbs. of tea which crossed the Atlantic in 1850.

Tea, like many other commodities is too frequently adulterated with various substances, —tests for detecting which are pointed out by Dr. Normandy. The same authority tells us that the much advertised *veno beno*, for 'improving' the flavour of tea, is nothing more than a mixture of catechu with broken tea leaves.

TEA, PARAGUAY, or MATÉ, is the produce of a plant belonging to the family *Aquifoliaceæ*, which is a shrub attaining the size of the orange tree. The leaves of this shrub are in great repute amongst the inhabitants of South America, and are used in infusion in a similar manner to the tea of China. Upwards of 5,000,000 lbs. of the leaves of this tree are annually collected in Paraguay, and are sent to Chili and Buenos Ayres. After the branches have been cut away, the ground is heated by means of a fire, and the leaves, being laid upon the heated ground, are dried, and afterwards they are beaten and pressed into bags, in which state they come into the market. The plant when used is steeped in boiling water, to which a little sugar and sometimes lemon-juice is added. It is drunk out of a vessel called *Maté*, which has a spout perforated with holes for the purpose of preventing the powdered herb from passing out with the fluid. The Creoles are passionately fond of this infusion, and rarely partake of a meal without it. The properties of this plant are sedative and stimulant.

TEAK. The teak-tree is a native of different parts of India, as well as of Birma, chiefly along the banks of the Irawaddy, and of the islands from Ceylon to the Moluccas. The teak-tree grows to an immense size, and is remarkable for its very large leaves, which are from 12 to 24 inches long and from 8 to 16 broad, and are compared by Oriental writers to the ears of the elephant.

From extensive experience teak timber has been found the most valuable timber for ship-building, and has been called the oak of the East. The wood is light, brownish-coloured, easily worked, but at the same time strong and durable. It is soon seasoned, and, from containing a resinous oil, resists the action of water, as well as insects of all kinds.

Some interesting details have lately been published concerning the export of teak-timber from Moulmein in India. Teak is the principal article of export from that province, both in quantity and value. During the year 1849 upwards of 25,000 tons were shipped to various parts of the world, all properly converted, by hand or machinery, of a value estimated in the rough at 100,000*l*. The teak of these provinces and the surrounding foreign states, which finds its way into Moulmein, is of a very superior quality, and unequalled for ship-building purposes by any other wood in the world. The annual supply is more than the demand, in consequence of this port being but little known to the English ship-owners and builders. There is almost an unlimited extent of teak forests in the neighbouring states, of superior quality, and easily worked. The price of first-rate converted squares and planks is 3*l*. per ton of 50 cubic feet, of lengths ranging from 25 feet to 50 feet, and from 10×10 to 24×24 inches square. A vessel arriving here at any time of the year can always procure a cargo, provided she is supplied with funds, or a credit on a good Calcutta house. The time calculated for loading is ten working days for every 100 tons, although a vessel of a large size generally loads much quicker on account of the stowage being easier. In consequence of the abundance of teak to be had at this port, it is likely to become the first building port in India. It has already turned out some of the finest ships now afloat, and as strength and durability are much sought after, this place is most advantageously situated for building good vessels.

TEAZLE (*Dipsacus Fullonum*) is a plant which grows wild in the hedges, but an improved variety is carefully cultivated in those districts of England where cloth is manufactured. It is used for the purpose of forming a species of brush with which the finer hairs of the woollen fabric are drawn to the surface, where they produce what is usually called the *nap* of the cloth. The teazle has a fine hooked awn, which very readily insinuates itself into the woollen web, and draws out with it some of the fine fibres of the wool; these are afterwards shorn smooth, and leave the cloth with the fine velvet-like nap which is its peculiar appearance.

Teazles will grow in any soil; but they grow strongest and best in a stiff loam. The wild teazle which grows in hedges appears at first sight to be the same as the cultivated variety; but it is of no use to the cloth-worker, from the weakness of the awns, which break off, instead of drawing the wool out of the surface of the web. The growing of teazles is a peculiar trade, and a kind of speculation, for the crop is very precarious. The teazle-grower hires a piece of ground suited to his purpose from the farmer for two years, and pays a considerable rent.

The dressing of a piece of cloth consumes a great number of teazles; as many as 1,500 to 2,000 being required to do the work properly. The teazles are made up in bundles for sale to the clothiers, containing 9,000 or 10,000 each. The price is affected by so many circumstances, that it varies from 4*l.* to 20*l.* per pack or bundle; but when the home price exceeds about 8*l.* the clothier can import more cheaply from abroad.

TELEGRAPH. We may class these useful contrivances in two groups—the *Mechanical* and the *Electro-Mechanical Telegraphs*:—Most of the older telegraphs consisted of boards or wooden arms, which according to the positions assumed, signified the letters of the alphabet. The kind generally used in France at the end of the last century was the T telegraph of M. Chappe. Four arms shaped something like a T were moved on three joints at the upper angles. M. Chappe communicated his intelligence letter by letter, and simplified the movements by using an alphabet of only sixteen letters. Such telegraphs were first erected on a line commencing at the Louvre, in Paris, and proceeding by Montmartre and other elevated points to Lisle, in order to communicate between the Committee of Public Safety and the combined armies in the low countries.

The advantages of such extraordinary celerity of communication were so obvious that, in England and other countries, many plans were immediately brought forward, some of which differed materially from that which had been successfully put in practice in France. These plans are mostly separable into two classes: shutters which open or close certain apertures made to receive them; or arms moveable on pivots. A shutter-apparatus, submitted to the Admiralty in 1795, by Lord George Murray, was adopted in the first government line of telegraphs established in England, in 1796, between London and Dover. It was employed by the Admiralty until 1816.

In 1816 it was determined to change the Admiralty telegraphs into semaphores constructed on the principle of those used in France, with the improvements suggested by Sir Home Popham. These semaphores had been introduced on the French coast in 1803. They consisted of upright posts with two or three moveable arms. Sir Home Popham's telegraph had two arms on one post; but as they were mounted upon separate pivots, each of them could assume six different positions, and the two together were capable of affording 48 signals. This kind of telegraph continued to be used at the government stations till the introduction of the electric telegraph.

Several modes of telegraphic communication without machinery, or with something which may be held in the hands, have been devised, especially for the purpose of directing military operations, or of conveying speedy intelligence in time of war, where no line of ordinary telegraphs can be established. One such method was by circular discs of wood held by men in particular positions; another by a white handkerchief varied in position; another by two small flags; and another by stationing a few men in pre-arranged positions, &c.

Marine telegraphic communication is an object of even greater importance than that on land, since there are many circumstances which render communication between vessels at sea impracticable by any other means than by signals, and that sometimes in cases of the greatest emergency. But, although naval signals have been necessarily long used, and flags of various forms and colours have been extensively employed for the purpose of making them, it was not till within a comparatively recent period that they were reduced to anything like an efficient telegraphic system. Lord Howe proposed a system of numbering the flags used as signals, and also prepared a signal-book which was long used by the Admiralty. An improved code of signals, suggested by Sir Home Popham, was afterwards adopted. A very useful system of flag telegraphing was introduced a few years ago by Mr. Watson, for the use of commercial shipping, and for maintaining communication between a vessel at sea and any of the stations on the coasts of the British islands, whence communication might be made by telegraph inland.

Electric Telegraphs.—It is chiefly to the joint labours of Messrs. W. F. Cooke and Professor Wheatstone that electric telegraphs owe their practical application. Their telegraph, which was patented in 1837, acted upon principles founded on Oersted's celebrated discovery, that a magnetic or compass needle may, through the agency of a voltaic current, be invested with an artificial polarity. The first line was laid down upon the London and

Blackwall Railway; the second from London to West Drayton; and the third (in 1849) from London to Gosport.

In Messrs. Cooke and Wheatstone's first apparatus there were five needles, arranged with their axes in a horizontal line. The needles when at rest hung vertically, by reason of a slight preponderance given to their lower ends. Each electro-magnetic coil was connected with one of the long conducting wires at one end, and was united at the other with a common rod of metal, which joined together the similar ends of all the coils. The current was transmitted from the opposite end of the wires (where an appropriate set of five pairs of finger-keys, for making the connections with the battery, was placed) through two of the wires at once. In accordance with the keys which were pressed down, the needles assumed various positions with respect to each other; and these were made to indicate signals according to the entries in a signal book. The instruments at the two stations were always rendered reciprocating; that is, at each end of the line were placed an instrument, a set of finger-keys, and a voltaic battery, so that either station could transmit or receive a signal. By a beautiful arrangement, a bell or alarum could be rung, when the attention of the clerk at the distant terminus was required. In 1838 Mr. Cooke obtained a patent for some further improvements of this apparatus.

Dr. Steinheil constructed an electric telegraph between Munich and Bogenhausen in 1837. In his telegraph he availed himself of the conducting power of the earth, whereby he was enabled to reduce the cost of erection. The earth in fact occupied the place of the return wire. All that is necessary to enable this to be effected, is that the wire which connects the two ends of the metallic conductor with the earth, shall be carried to a sufficient depth below the surface to be always in contact with moist earth or with water; and that it shall be at this point attached to a plate or piece of metal, of about two or three feet superficial. The electric telegraph invented by Professor Morse, of America, in 1837, was essentially a registering instrument, the various signals being traced on a strip of paper. An electro-magnet was so placed as to be within attracting distance of an armature fixed to the shorter arm of a lever, of which the longer end carried a pencil projecting sideways from it, and pressed lightly against a sheet of paper. This paper was made to travel slowly beneath the pencil. So long as no attractive power was exerted by the electro-magnet, the pencil would continue to trace a straight line as the paper moved onwards; but on momentarily making the circuit with the battery, the armature was drawn to the electro-magnet, and the pencil, carried by the arm of the lever upwards, made an angular mark, like the letter V reversed, on the paper. These angles might either be joined in groups, by rapidly succeeding completions of the circuit, or they might be separated by longer or shorter spaces of straight line. In the telegraph constructed by Morse in 1844, between Baltimore and Washington, a different mode of recording the signals was adopted. The use of the pencil was found objectionable, from its so frequently requiring fresh pointing, and from the risk of breakage. The same arrangements were retained in regard to the paper, but it was made in its course to pass under a roller having a groove around it. The long arm of the lever carried a blunt steel point, standing out from its upper surface, vertically under the groove in the roller. When therefore the arm of the lever was elevated, by the attraction of the magnet upon the armature, the steel point pressed the paper into the groove and produced an indentation. If the attraction were momentary, a depressed point was produced; but if the action were continued for a longer time, a lengthened depression was the result, as the paper was drawn on. The combinations of these two kinds of marks denoted the various letters and figures.

In the year 1837 Mr. Davy of London obtained a patent for an electric telegraph, the chief peculiarity of which consisted in the method of registering or recording the various communications, by causing the current of a supplementary battery to pass through a riband steeped in a solution of iodide of potassium and starch. The salt being decomposed by the current, a blue spot was produced by the combination of the iodide with the starch, and the position of one or more of these spots across the breadth of the riband determined the nature of the signal transmitted.

In 1840 Professor Wheatstone patented his electro-magnetic telegraph, in which the indicating power was the magnetisation of soft iron by the electric current, instead of the employment of a real or permanent magnet. One part of the apparatus is the Communicator, a wheel or disc, on the edge of which are alternately arranged pieces of iron and of ivory, the one a conductor and the other a non-conductor of electricity. A metal spring presses on this edge while the wheel revolves, and is connected also with the galvanic apparatus, in such a way that when the spring is in contact with the iron, a galvanic circuit is completed, but when in contact with the ivory the circuit becomes broken. Thus alternations of action are produced, which by ingenious mechanism are made the means of transmitting impulses or symbols through the telegraphic wire. This telegraph requires only a single wire for its use, the return of the current being provided by the earth. One application to which Professor Wheatstone found his invention suitable was that of an *Electric Clock*, by adapting his wheel and galvanic apparatus to the action of the escapement wheel of a common clock.

In 1840 Mr. Bain, in conjunction with Mr. Barwise, patented a clock which was to be set in motion by electricity; and in the next following year he brought forward a new electric printing telegraph. The essential principles of this telegraph are two. First, the employment of type, mounted on the periphery of a disc or wheel, capable of revolving with its edge carrying the type very near to a cylinder covered with white paper, between which and the type-wheel a piece of transferring paper or riband is placed; the cylinder has a small movement in a spiral direction communicated to it, after each impression of a signal. The second principle is that of the use of two clocks at the two communicating stations, to rotate the type-wheels with a uniform motion. These clocks, having heen adjusted to exactly the same rate, and being started from the same signal, would bring continually, at each station, similar type opposite to the paper cylinders at the same moment. A hand or index revolving on a dial in front of the machine, at the same rate as the type-wheel, indicates to the operator the signals which are successively in a position ready for printing in his own instrument, and therefore, if the clocks go accurately together, in a similar position in his correspondent's instrument.

In 1842 Mr. Bain patented his proposed plan for working an electric telegraph with a peculiar form of battery. At one end of the line he buried in moist earth a large plate of zinc, and at the other end a plate of copper, iron, or other substance, such as coke or charcoal, which might act the part of a negative plate to the zinc. Then on connecting these distant plates with a wire insulated from the earth, a current of electricity would constantly pass from the one plate to the other. This system has been found insufficient at long distances.

In 1843 Mr. Cooke specified his patent for the mode of insulating the wires by suspending them in the air upon posts or standards of wood or iron; the wires not coming in actual contact with any part of the standard, but passing through rings of porcelain or earthenware. The standards are usually fixed at from forty to sixty yards asunder, and at each quarter of a mile a stouter post is placed, to bear the winding or straining apparatus. The intermediate posts within each quarter of a mile merely supported the wire, without reference to its tension, which depended solely on the winding posts. Instead of the copper wires hitherto employed, iron wires of a larger size were then used. Before this period the wires had been placed in iron tubes buried beneath the ground; but this new form of arrangement was deemed an improvement, and has since been generally acted on in this country.

Since the year last named, the progress of the electro-telegraphic system has been exceedingly rapid. In 1846 an Electric Telegraph Company was formed, by whom the patent rights of Messrs. Cooke and Wheatstone, and some of those of Mr. Bain, were purchased. It is this company which has carried out the greatest part of what has been recently effected in Great Britain. Nearly all the principal railways, except the Great Western, have had lines of telegraphic wire laid by it. A modification of Cooke and Wheatstone's arrangements is generally employed; but the company also possesses a remarkable printing or rather registering telegraph invented by Mr. Bain. A long strip of paper has small holes stamped in it by means of a machine, each hole or group of holes representing a particular letter. This paper is coiled on a wooden roller, from whence it passes to a metal roller, where metallic points act upon it. The arrangement of the mechanism is such, that when the metallic points touch the metal of the roller, through the holes in the paper, a galvanic circuit is completed; but when the points touch the paper itself, the circuit is stopped; and this rapid alternation is made to indicate signals. There is also a recipient apparatus, in which the strip of paper employed has been first soaked in diluted sulphuric acid, and then in a solution of prussiate of potash. Two metallic points press on this paper; and when a galvanic current is passing through these points, they discolour the chemically-prepared paper, and leave a number of dark spots upon it; but when no current is passing, no discolouration is produced. By an ingenious arrangment of mechanism, the recipient apparatus at the end of the telegraphic wire marks with its dark spots the signals which are conveyed by the transmitting apparatus at the other end.

In the form which the English telegraphic system has now assumed, all the stations are placed in connection with the central office in Lothbury. At this office are departments for transmitting messages to and receiving messages from almost all parts of the kingdom. There are several rooms, each of which has its own electric clock, showing Greenwich time, and its own electro-telegraphic machine. Wires pass from the machines to the great hall, and from the hall to the outside of the building, whence they pass under the pavements of the London streets to the great railway termini at Euston Square, Shoreditch, London Bridge, Waterloo Road, &c., as well as to the Admiralty and one or two other Government establishments. Along the lines of railway the telegraphic wires and apparatus are so arranged as to be available both for the railway company's own purposes, and for commercial purposes in general; and a system has been formed whereby information of a commercial character is regularly transmitted to and from the great centres of industry and commerce.

Mr. Whishaw, in a paper communicated to the British Association in 1849, gave an account of the telegraphic systems followed in three countries, Great Britain, Prussia, and the United States. In Great Britain the wires are suspended on poles. The length of railway to which the system had been applied down to July 1849, was about 2000 miles; and the cost was about 150*l.* per mile. In Prussia the telegraphic wires were suspended on the English system until the year 1844, since which date a new plan has been followed. The wires are coated with gutta percha, and laid along under ground, at a distance of about two feet beneath the surface, not only under railways, but under turnpike roads and towing paths. There are at each principal station two telegraphic machines, one colloquial and one printing. The length of Prussian telegraph to July 1849, was about 1500 miles, at a cost of about 40l. per mile. In the United States the telegraphic line is formed by a single iron wire supported from post to post. It is carried not only along railways, but across the open country. There were in July 1849, about 10,500 miles of American telegraph, at a cost of about 20l. per mile.

Various improvements in electro-telegraphic machines have been patented from time to time by Messrs. Brett and Little, and other inventors; but those which seem most likely to be attended with important results relate to Submarine Telegraphs. It has been proved that wires may be so coated with gutta percha and other materials as to act under water. A tube so constructed has been carried under the sea between Dover and Calais; and the first communication by electric telegraph was made from Cape Grisnez to Dover on August 28, 1850. The length from Dover to Cape Grisnez is 21 miles. The copper wire was $\frac{1}{16}$th of an inch in thickness, and was enclosed in a solid cylinder of gutta percha, $\frac{1}{2}$ of an inch in diameter. The entire length of wire was 25 miles, and its weight was 1 ton 2 cwt. 1 quarter 10½ lbs. The weight of the gutta percha was 4 tons 7 cwts. 1 quarter 9 lbs.

Wherever the railway system has extended, there does the electro-telegraphic system find more or less of encouragement; and in the United States the telegraphic wires extend also over vast tracts of country where no railways are yet laid down. In respect to our own country, the contrivances of Messrs. Cooke and Wheatstone have hitherto been those most generally adopted; but there is at the present time (May 1851) an attempt being made to form a new telegraphic company; and if this attempt succeed, we shall probably see many new and efficient mechanical arrangements adopted.

One of the most recent electro-magnetic instruments, partaking of the nature of the electric telegraph in some of its features, is Mr. Shepherd's ingenious clock at the Industrial Palace.

The experiments made in the British Channel have shewn that the submarine Telegraph is practicable; and we shall probably see, ere long, the adoption of the system between England and France, and between England and Ireland. The proposed oceanic telegraph between England and America may well afford to wait till the fruition of the less gigantic schemes.

TELESCOPE. Such telescopes as are constructed with glass lenses only are called *dioptric*, or *refracting* telescopes; whereas those which have a reflecting speculum are the *catoptric*, or *reflecting* telescopes. By these instruments objects even in the remotest depths of space are rendered accessible to human vision; and terrestrial objects faintly visible in the distance are brought as it were close to the eye. There is evidence to show that Roger Bacon, who died in 1292, knew that lenses might be so combined as to make objects seen through them appear to be magnified. No further indications of telescopes are met with till after the middle of the 16th century, when Dr. Dee suggested that the commander of an army, who wants to discover the number and arrangement of an enemy's troops, 'may wonderfully help himself by perspective glasses.' In 1609 Galileo constructed a telescope, with which he discovered the four satellites of the planet

Jupiter. Huygens, Dr. James Gregory, Sir Isaac Newton, Dr. Hooke, Dr. Bradley, Sir Wm. Herschel, Mr. Dollond, and Lord Rosse, have since been the persons most distinguished for the improvements which they have respectively made in the construction of telescopes.

To explain the optical principles which govern the action of telescopes would be beyond the scope of the present volume; but we may briefly explain differences of construction.

The telescope invented by Galileo consisted of one convex lens and one concave lens; the distance between them being equal to the difference between the focal lengths of the two lenses. This is the construction of what is called an *Opera Glass;* and the Galilean telescope is now used chiefly for viewing objects within a theatre, or an apartment; since if considerable magnifying power were given to it the extent of the field of view would be very small.

A simple telescope may also be constructed by means of two convex lenses, which are placed at a distance from one another equal to the sum of their focal lengths.

In order to afford a view of objects in the same position as they appear to have when seen by the naked eye, Mr. Dollond employed an eye-tube containing four lenses; whereas in the eye-piece invented by Huyghens, which is used in most astronomical telescopes, there are only two lenses, and objects are seen inverted.

In reflecting telescopes, a speculum at one extremity of the tube serves the purpose of the object-glass in refracting telescopes by forming an image at its focus; and the image so formed is viewed by the eye through intermediate reflectors. The *Newtonian* reflecting telescopes have one concave speculum at the bottom of the tube; and the rays reflected from it fall in a convergent state upon a small plane mirror placed so as to make an angle of 45° with the axis of the telescope: after the second reflection the rays unite and form an image which is viewed through a Huygenian eye-piece fixed in the side of the tube, opposite the plane mirror; that is, near the open end of the tube. In the *Gregorian* reflecting *telescope* the second reflection is given by a second concave mirror, the face of which is towards the observer.

The telescope constructed by the late Sir Wm. Herschel differed from the Newtonian telescope only in having no small mirror. The surface of the great speculum, which was 4 feet in diameter, had a small obliquity to the axis, so that the image formed by reflection from it fell near the lower side of the tube at its open end: at this place there was a sliding apparatus which carried a tube containing the eye-glasses. The observer in viewing was situated at the open end of the tube, with his back to the object, and he looked directly towards the centre of the speculum. The reflecting telescope executed by Lord Rosse in 1842 is 56 feet long, and its speculum is 6 feet in diameter. It is capable of being directed from the zenith to the horizon towards the south, and from the zenith to a position parallel to the earth's axis towards the north; it has also a movement in azimuth of about 8 degrees on each side of the meridian.

The Great Exhibition contains a noble telescope by Mr. Ross, which is, we believe, the largest ever constructed on the *refractive* principle.

TELFORD, THOMAS, was one of those invaluable men whose engineering labours form the best memento of their personal history. He was the son of a shepherd in Eskdale, Dumfriesshire, where he was born in 1757. At the age of fourteen he was apprenticed to a stone-mason in the town of Langholm. In 1780, being then about twenty-three, he went to Edinburgh, where he seems to have devoted much attention both to architecture and drawing. After remaining there about two years, he removed to London, and obtained employment at Somerset House, then erecting by Sir William Chambers. He was employed upon various buildings at Portsmouth dockyard for three years subsequent to 1784; and in 1787 he was employed by Sir William Pulteney to make some alterations at Shrewsbury Castle. He thereupon removed to Shrewsbury, where he was also employed to erect a new gaol, and was subsequently appointed county surveyor, in which office he had to furnish plans for and oversee the construction of bridges and similar works. He erected the iron bridge over the Severn at Buildwas, besides about forty smaller bridges in the same county.

The Ellesmere Canal was the first great work upon which Telford was engaged; and from 1793, in which year the act of parliament for its construction was obtained, his attention was directed almost solely to civil engineering. The aqueduct-bridge over the valley of the Dee, called the Pont-y-Cysylte, is a remarkable work. It consists of a trough of cast-iron plates, securely flanged together, and supported by eighteen piers or pillars of masonry, the elevation of which is 121 feet above the water. These gigantic works were executed between 1795 and 1805. The Caledonian Canal, which was opened throughout in 1823, is another of Telford's principal works. The locks were the largest ever constructed at that time, being 40 feet wide, and from 170 to 180 feet long. Of other canals constructed wholly or partially under Telford's superintendence it is sufficient to mention the Glasgow, Paisley, and Ardrossan; the Macclesfield; the Birmingham and Liverpool Junction; the Gloucester and Berkeley (completed under his direction); the Birmingham, which was completely remodelled, and adapted to the conduct of a very extensive traffic, by him; and the Weaver navigation, in Cheshire. He also constructed a new tunnel, 2,926 yards long, 16 feet high, and 14 feet wide, at Harecastle, on the Trent and Mersey Canal. He also executed many important works connected with the drainage of the fen country, especially of Bedford Level. On the Continent he superintended the construction of the Gotha Canal, in Sweden, a navigation of about 120 miles, of which 55 are artificial canals. For this work a Swedish order of knighthood and other honours were conferred upon him.

The works executed by Telford under the Commissioners of Highland Roads and Bridges were of great importance; and in the improvements of the great road from London to Holyhead, under another parliamentary commission, appointed in 1815, Telford had a further opportunity of carrying into effect his system of road-making. The Menai suspension bridge especially is a noble example of his boldness in designing and practical skill. [MENAI BRIDGES.]

Among other works of Telford are many bridges of considerable size, in which he adopted the important principle of making the spandrils hollow, and supporting the roadway upon slabs laid upon longitudinal walls, instead of filling up the haunches with a mass of loose rubbish, which often proves of serious inconvenience when the masonry of the bridge needs repair.

Telford executed some important harbour works at Aberdeen and Dundee; but his most striking performance of this class is the St. Katherine Docks, London.

In addition to the works which he executed himself, Telford was frequently applied to for his judgment upon important schemes, and in this way he made many reports to parliament. The Russian government frequently applied to him for advice respecting the construction of roads and canals; and the Emperor Alexander acknowledged his sense of his services, in 1808, by sending him a diamond ring with a suitable inscription. He closed his useful life in 1834, and was buried in Westminster Abbey.

TELLU'RIUM, is a metal discovered in 1782 by Müller of Reichenstein. Its colour is silver-white, and it is very brilliant; it is crystalline and brittle, of a lamellar fracture, easily pulverised. Its specific gravity is about 6·13. It is nearly as fusible as antimony, and at a high temperature it boils, and may be distilled. When strongly heated in contact with air, it burns with a lively blue flame, green at the borders, and forms a white vapour, which has an acid odour.

The principal ores of tellurium are *Native Tellurium*, both crystalline and massive, *Graphic* or *Auro-Argentiferous Tellurium*, *Yellow Tellurium*, *Black Tellurium*, *Bismuthic Tellurium* or *Telluret of Bismuth*. But neither the ores nor the various chemical combinations of the metal have yet been applied to many useful purposes.

TEMPERING. [STEEL MANUFACTURE.]

TENACITY. This property is a result of the attractions and repulsions which act within the insensible spaces supposed to exist between the particles of bodies: it is consequently different in different materials, and in the same material it varies with the state of the body with respect to temperature and other circumstances. The particles of liquids adhere to one another, and generally to those of solid bodies, by attractive forces which decrease very rapidly; and, at insensible distances from the supposed places of contact, the adhesion entirely disappears. It is on account of the small distance to which the attraction of the fluid molecules extend, and to the freedom with which the particles move on one another, that fluids appear to have so little tenacity; but from the weight which it supports in glass tubes, Dr. Robison has estimated that the mutual attractions of the particles of water on a surface equal to one square inch must far exceed 190 lbs.

Though, when a piece of metal is fractured, the parts will not by simple adjunction adhere together; yet, in some cases, by hammering them upon one another, so many points on their surfaces may be brought within the limits to which the force of cohesion extends, that they will acquire a tenacity equal to that which the metal had in its natural state.

The tenacity of wood is much greater in the direction of the length of its fibres than in the transverse direction, the fibres being united by a substance having little cohesive power. With respect to metals, the processes of forging and wire drawing increase their tenacity in the longitudinal direction; the augmentation of friction and lateral cohesion, arising from the particles being forced together in the transverse direction, more than compensates for the diminution of the attraction which may result from the particles being forced or drawn farther asunder longitudinally. Copper and iron have their tenacity more than doubled; while gold, silver, brass, and lead have it more than tripled, by those metals being drawn into wire.

TENNESSEE. The industry and commerce of this portion of the American Union are briefly adverted to under UNITED STATES.

TERRA COTTA. This is the Italian for *baked earth*, and is the name applied to the material with which many of the coarser varieties of Italian pottery are made. The Etruscan Vases, whatever may be the devices on the surface, are made of Terra Cotta. [ETRUSCAN WARE.] At the Mediæval Exhibition of 1850 there were many fine specimens of terra cotta ware; and in the Etruscan room at the British Museum the collection is especially fine. There is a church near Bolton, in Lancashire, in which the chief material employed, at least in the ornamental parts, is terra cotta; and terra cotta ware finds a fitting place among the articles of pottery at the Great Exhibition.

TESSELLATED FLOORS. Mr. Ward, in the Introductory Essay to Mr. Owen Jones's beautiful work on Mosaic Pavements, says:—"The materials of the best and costliest pavements at Rome (such, for example, as those still remaining in the Baths of Caracalla) are coloured marbles of various kinds, differing considerably from each other in hardness and durability. The inferior pavements, found scattered through Britain, France, and other parts of Europe, and along the western coast of Africa, are usually made of such coloured stones as the neighbourhood happened to supply; with the exception only of the red tesseræ, which are almost invariably of burnt clay. Thus, in the celebrated Roman pavement which was discovered in 1793, at Woodchester in Gloucestershire, the gray tesseræ are of blue lias, found in the vale of Gloucester; the ash-coloured tesseræ of a similar kind of stone, often found in the same masses with the former; the dark brown of a gritty stone, met with near Bristol, and in the Forest of Dean; the light brown of a hard calcareous stone, occurring at Lypiat (two miles from the site of the pavement); and the red tesseræ (as usual) of burnt brick."

The tesseræ, or small cubic pieces of the Roman pavements, are by no means uniform in shape and size; the fissures between them are wide and irregular; and as these fissures are filled up with cement, a muddy hue is given to the general tints.

In the beginning of the present century, Mr. Wyatt introduced the plan of inlaying stone tesseræ with coloured cements. In later methods, *terra cotta* tesseræ have been inlaid in a similar way. Mr. Blashfield adopted the plan of forming the tesseræ of cements coloured with metallic oxides. Bitumen, coloured with metallic oxides, is another material employed. Mr. Singer introduced a plan of forming tesseræ by cutting pieces of the required form out of thin layers of clay; which pieces are afterwards dried and baked, and united by a peculiar cement. In another plan, adopted at the Worcester porcelain works, tiles of two colours are formed by pressing a device on slabs of clay, and pouring liquid clay of another colour into a sunk device on the surface of the former.

In Mr. Prosser's method, small tesseræ are formed by compressing porcelain powder into moulds with great force, in the manner described under BUTTON MANUFACTURE. The tesseræ may be of any colour—white, black, red, blue, yellow, brown; and of any definite form—triangular, quadrilateral, rhomboidal, hexagonal, &c. In the formation of a floor or pavement with such tesseræ, the pieces are first put together in their proper order, placed downward on a smooth surface; and as soon as a sufficient portion of the design is finished, it is backed with fine Roman cement, which is worked in to fill the crevices between the tesseræ. The pavement is thus formed into smooth flat slabs of convenient size, which are laid down on any properly prepared foundation.

Although it belongs more to inlaying or marquetry than to tessellated pavements, we may say a word or two concerning the beautiful floor of the new Coal Exchange. It is a circular floor 60 feet in diameter, and is formed of 4,000 pieces of wood, arranged into a star-like pattern of great beauty, bearing some resemblance to a mariner's compass. All the wood formed portions of living trees within a short period pefore the floor was made; the pieces having been prepared by the Drying or Dessicating process of Messrs. Davison and Symington. In this respect the floor is an exemplar of a highly useful and important manufacturing invention. The kinds of wood employed are ebony, black oak, red oak, common oak, white holly, mahogany, elm, red walnut, white walnut, and mulberry.

TE'SSERA. The Roman tesseræ were small cubes or squares resembling our dice, which were used by the ancients for various purposes, and formed of different materials, as marble, precious stones, ivory, glass, wood, or mother-of-pearl. Such small tesseræ of different colours were used to form the mosaic floors, or pavements in houses, which were hence called *tesselata pavimenta*. (See the preceding article.) The same kinds of cubes were used by the ancients as dice in the games of hazard, just as in our times.

TESTS, CHEMICAL, or Chemical Reagents, are those substances which are employed to detect the presence of other bodies, by admixture with which they are known to produce certain changes in appearance and properties.

TEXAS. This region—once a portion of Spanish America, then a state of republican Mexico, then an independent republic, and now one of the United States—is still in the infancy of its industrial development. Bituminous coal is said to be abundant in the interior, and iron ore is also plentifully distributed. Building stone is abundant in all parts except the sea coast region. Gold, silver, copper, and lead, have been found in the mountainous parts of the State. Oak, pine, and other large timber trees, are abundant along the courses of the rivers and upon the slopes of the mountains. Texas is stated to have climates and soils suitable for maize, wheat, oats, barley, and rice; for apples, pears, figs, melons, and oranges; for the vine, olives, and mulberries; for the sugar-cane and the cotton plant; and in fact for almost every kind of grain, fruit, and vegetable.

The rise of a great commercial community from these elements has yet to take place.

TEXTILE MANUFACTURES. The spinning and weaving of fibres into a web are the general type or representative of textile manufactures. It is difficult to say whether these or metallic manufactures are the most important; but the textile take the lead in respect to our exports. The amount of these exports, and the nature of the processes, are noticed under the names of the respective goods — such as COTTON, FLAX, FUSTIAN, GAUZE, LACE, LINEN, MUSLIN, RIBBON, SHAWL, SILK, VELVET, WOOLLENS, &c.; while the manufacturing statistics are glanced at under FACTORIES, and under the names of the chief textile manufacturing towns and counties.

THAMES. The navigation of this most busy of English rivers commences at Lechlade, where the river is about 258 feet above low-water mark at London Bridge. The Thames and Severn Canal, which follows the valley of the Churn and the Thames from near Cirencester, opens into the Thames at Lechlade, thus connecting it with the Severn and the western coast of the island. At Oxford the Oxford Canal joins the Thames, and opens a communication with the great canal system of the central counties. At Abingdon the Wilts and Berks Canal joins the Thames and, as well as the Kennet and Avon Canal, which joins the Kennet at Newbury (where the navigation of that river commences, 20 miles above its junction with the Thames), opens a communication with the Somersetshire Avon and by it with the Severn. The Thame is navigable from the town of Thame, about 17 miles above its junction with the Thames. The Wey is navigable from Godalming, about 17 miles from its junction; and is connected with the Wey and Arun Canal, and the Basingstoke Canal, the former of which opens a communication with the river Arun and the Sussex coast. The Grand Junction Canal, which unites with the Oxford Canal at Braunston in Northamptonshire opens into the Thames by the mouth of the Brent, the lower part of which is incorporated with the Canal. Below London Bridge the Lea, which is navigable, chiefly by artificial cuts, for 25 miles, opens into the Thames; and just above the Lea, the Regent's Canal, which encircles the north and east side of the metropolis, and communicates with the Paddington Canal, and so with the Grand Junction Canal, also opens into the river.

The Medway is navigable below Rochester Bridge for sea-borne vessels, and from Penshurst, above 43 miles from its mouth, for river craft.

The navigation of the Thames, in its upper part, is kept up by locks and wears, the lowest of which is at Teddington, which is consequently the limit of the tide. Teddington is about 18 or 19 miles above London Bridge. High-water mark at Teddington is about 1¼ feet higher than at London Bridge, and the time of high water is about two hours later. Low-water surface at Teddington is about 16¾ feet higher than at London Bridge. At ebb tide there is a depth of from 12 to 13 feet water nearly or quite up to London Bridge, and the rise of the tide is about 17 feet, or at the extreme springs about 22 feet.

Vessels of 800 tons get up to the St. Catherine's Docks, and those of 1400 tons to Blackwall, about 6 miles below bridge. No other river in the world equals the Thames in its commercial importance. The river for some 2 miles or more below London Bridge is crowded with vessels, chiefly coasters, steam vessels, and colliers, which moor alongside the quays or in tiers in the stream; others are moored lower down, though not in such numbers; and for larger vessels there are several docks excavated on the banks of the river.

There is a dockyard for the navy (now little used) at Deptford, about 4 miles below London Bridge; one at Woolwich, 9 miles below; one at Sheerness, in the Isle of Sheppy, at the junction of the Thames and Medway; and one at Chatham, the most important of the four, on the Medway. The fortifications at Sheerness defend the entrance to both rivers; the passage of the Thames is further protected by Tilbury Fort, and that of the Medway by Gillingham Fort.

Among many engineering schemes for improving the banks of the Thames within the limits of the metropolis, is the following by Mr. W. H. Smith:—It is proposed that a terrace, about 12 feet above high-water mark, designed exclusively for the public, and without any landing places except for passengers, should be carried along the banks of the Thames. The width of the esplanade is to be 60 feet, having a parapet and open railing on the side next the river; thus offering a clear view of the general traffic, but at the same time, by means of the parapet, securing the operations of commerce beneath. This esplanade is connected immediately by carriage approaches with the bridges and main thoroughfares. Where the width of the river is sufficient to admit the space required, it is proposed there should be lines or colonnades of handsome shops, dwellings, or warehouses, according as the situation might require. The goods' traffic of the river is conveyed by transverse arches beneath, descending to within a foot of high water, which are connected with the property of the wharfs and warehouses on the inner side, the river traffic being thus carried on unimpeded and almost invisibly. Immediately beneath is a railway tunnel, in the base of which the required culverts for pure water, gas, rain water, and sewage, would be formed at about low-water mark. It is proposed that the sewage should be entirely cut off from the river, passed longitudinally under the embankment by means of an iron culvert, and carried into the marshes on the southern side of the river beyond the influence of the tide. The probable expense of this great undertaking, extending from Vauxhall to the West India Docks on the north, and from Vauxhall to Deptford on the south, Mr. Smith estimates at about 3,000,000*l.*

THATCH is a covering of straw, rushes, or reeds, as a substitute for tiles or slates for houses, barns, ricks, stacks, and sheds. We will first describe the mode of thatching hay ricks and corn stacks, as the simplest.

The rick or stack having been formed into a proper shape, either with a roof slanting from a ridge, or conical, ending in a central point, the straw is prepared by moistening it, that it may more easily bend without breaking. It is then forked up in a loose heap, the straws lying in every direction, and somewhat matted. Portions are now drawn out from this heap in handfuls, which lays the straws again in a more parallel order: these are placed in a forked stick, which will hold several of these bundles or handfuls, and are thus carried to the thatcher on the top of the rick or stack. He seizes a handful, and bending one end into a kind of a noose, he inserts this into the hay or straw near the bottom of the roof, at one end if it be a square roof, or at any convenient part if it be a round one. He presses down the straw which he has thus inserted to about half its length, in order to form the eaves, which extend a little beyond the lower part of the roof. When he has thus laid several handfuls side by side so as to cover about a yard in width, that is as far as he can conveniently reach without moving his ladder, he begins another row a little above the place where he began, so that the lower end of the straw now inserted may cover the upper part of the first row, as tiles do each other. Thus he proceeds upwards till he comes to the upper ridge of the roof, or to the point of the cone in a round stack. In the latter case the covering diminishes to a point so as to form a triangle. The ladder is now shifted a yard to one side, and the same operation is performed, care being taken that each fresh handful put on shall be interwoven with that which lies beside it, so that no water can possibly pass between them. Thus the work proceeds until the roof is completed, and it only remains to secure the upper ridge in a square stack, or the point of the cone in a round one. In the first case the highest layer of straw is made to extend beyond the ridge on both sides, and the ends are brought together and stand up like the bristles on a hog. A rope of straw has been prepared, and many small rods, about two feet long, and cut sharp at the point: these are inserted just below the ridge, in a line with it, and about a foot apart; one end of the straw rope is inserted into the stack, and twisted firmly round the projecting end of the first rod; it is then wound once round the next rod, and so on the whole length of the ridge: this is done on both sides. The straws which form the ridge are now cut with shears horizontally, to give it a neat finish, and at each end a kind of ornament is usually made by winding a straw rope round a handful of the projecting straw, forming a kind of knot or bow, according to the taste of the thatcher. Rods and straw ropes twisted round them are inserted near the edge of the slanting side and all along the eaves, which prevent the wind from blowing off the thatch.

The only difference in the thatch of a round rick is, that it is brought to one point, where it is tied with straw rope wound round it, and formed into a kind of bow; the rods are inserted a little below in a circle, and a straw rope twisted round them, and likewise around the circular eaves. Barley is generally put into square stacks, and wheat in round ones. When the outside is neatly trimmed and cut smooth, so that no birds can lodge in it, wheat may be kept for years without danger of injury or loss, much better than in a barn, or even in a granary.

In thatching sheds and buildings which are to last many years, the straw is prepared in the same manner, but the ends of the handfuls, as they are put on a lathed roof, are kept down by means of long rods, which are tied to the laths of the roof by means of strong tar twine. A much thicker coat of straw is put on; and rye-straw, which has a solid stem, is preferred, as more lasting, and less liable to be filled with water than hollow straw. Instead of straw ropes, split willow is used, and the rods which are inserted are much nearer each other and more carefully secured. As this kind of thatching is a peculiar trade, it requires a regular apprenticeship to be master of it.

THEIN is the neutral vegetable principle obtained from common tea, and supposed to be identical in its nature with *caffein*, the peculiar principle of coffee. It forms tufts of white delicate silky needles, which have a bitter taste, melt and lose water when heated, and sublime without decomposition.

THEOBROMA. For the best known products of the theobroma plants, see COCOA and CHOCOLATE.

THEODOLITE is the name generally given to the instrument used for measuring horizontal angles. In its simplest form the theodolite consists of a divided circle, which is to be set parallel with the horizon, and a telescope which has so much motion in a vertical plane as to enable the observer to view any object which he may require above or below the horizon.

THEORBO is a musical instrument of the lute kind, which has long fallen into disuse. The upper and middle strings were attached to the lower head or nut; the lower, or base strings, to an upper or additional one. [LUTE.]

THERMO'METER is an instrument by which the temperatures of bodies are ascertained. It consists of a glass tube with a capillary bore containing in general alcohol or mercury. When the liquid expands or contracts by variations in the temperature of the atmosphere, or by the instrument being immersed in the liquid or gas which is to be examined, the state of the atmosphere, liquid, or gas, with respect to caloric, is indicated by a scale which is either applied to the tube or engraven on its exterior surface.

The end proposed by a thermometer is the measurement of the temperature of any body with relation to the temperature of some other substance, as of water at the point of freezing; but the measure so obtained must not be understood to express the absolute quantity or density of caloric in any body, it being well known that different substances, though exhibiting the same apparent temperature, contain very different quantities of caloric according to their *capacities* for that element.

The thermometer was in use in the beginning of the 17th century, but it is not known precisely to whom the honour of the invention is due. A physician of Padua named Santorio, in his 'Commentaries on Avicenna' (1626), claims it for himself. It may however have happened with this, as with other scientific discoveries, that the idea of the instrument occurred to two persons or more about the same time.

The earliest kind of thermometer consisted of a long glass tube containing air, which was hermetically sealed at the upper end, while the lower was made to enter into a vessel of coloured spirit. By the pressure of the atmosphere the spirit was made to occupy part of the tube; and the variations in the temperature of the atmosphere causing the column of spirit to ascend or descend in the tube, allowed the degree of temperature to be measured by a scale applied to the latter. The defects inseparable from such thermometers are, that the dilatations of the air are not proportional to the increments of heat, and that the length of the column of spirit varies with the temperature of the atmosphere. Thus the indications afforded by the thermometer are rendered erroneous, or require corrections which it is difficult to apply.

About the middle of the 17th century the members of the Academia del Cimento caused thermometers to be constructed in which, instead of air, alcohol, or spirit of wine, was employed. Alcohol dilates and contracts considerably with the variations of temperature to which it may be subject, though not in so great a degree as air. It is also capable of measuring very low temperatures but; as it is brought to a boiling state sooner than any other liquid, it cannot be employed to ascertain a high degree of heat.

The idea of employing mercury for the

purpose of measuring degrees of heat by its expansion is supposed to have first occurred to Dr. Halley. The invention is ascribed to Römer, but it was not till 1724 that such a thermometer was known in this country. The advantages of mercury over alcohol and air, as a measure of temperature, are, that its expansions are more nearly proportional to the increments of caloric than those which take place in either of the other fluids; it is easily deprived of air; and its power to conduct heat being considerable, the changes of its volume by changes of temperature in the surrounding medium take place more rapidly than those of any other fluid except the gases.

The scale which has been in general use in this country since the year 1724, is supposed to have been invented by Fahrenheit. It is quite unknown on what ground he made choice of the fixed points on his scale, or the number of graduations between them; but it is thought that one of the fixed points was that of boiling water, and that the other, which is the zero of the scale, was that at which the top of the column stood when the instrument was exposed to an intense cold in Iceland, in 1709. The extent of the scale between this last point and that of boiling water is divided into 212 parts, and the point of freezing water is at the thirty-second division from the zero point. That which is called Réaumur's scale has the interval between the points of freezing and boiling water determined by experiment, and the distance between them is divided into eighty parts, the zero of the scale being at the freezing point. A third scale, called 'Centigrade,' has been much in use among the philosophers of the Continent within the last fifty years. It was invented by Celsius, a Swede, and it differs from that of Réaumur only in the distance between the points of freezing and boiling water being divided into 100 parts. The length of each degree in this thermometer, as well as in that of Réaumur, is greater than in the scale of Fahrenheit.

According to the experiments of Mr. Dalton, mercury does not boil till it has acquired a temperature equal to 660° of Fahrenheit's scale; and it does not freeze till it is subject to a degree of cold expressed by 39 divisions below the zero of that scale, or 71° below the freezing-point of water. Pure alcohol, on the other hand, has never been frozen, though it has been exposed to a degree of cold exceeding that which is expressed by 91° below the zero of Fahrenheit; and therefore a spirit thermometer is to be preferred to one of mercury when it is intended to ascertain the temperature of the air in high northern or southern latitudes: but since the spirit boils in air with a degree of heat expressed by 175° of Fahrenheit, it is unfit for many of the purposes for which a thermometer is required. For instruments capable of measuring very high temperatures, see PYROMETER.

Register Thermometers.—It is of great importance in meteorology that the observer should be able to ascertain the highest or lowest point of a thermometer scale at which the column of mercury may have stood during his absence; and several contrivances have been adopted by artists in order to obtain this end. Of these, one, which is still preferred, was invented by Mr. Six, whose name the instrument bears; it is described in the 'Philosophical Transactions' for 1782. It consists of a long tube bent so as to form three parallel branches, of which the central branch is an elongated bulb, and the rest of the tube has a capillary bore. The lower portion of the bent tube contains mercury, which rises in the two side branches to certain points, and the bulb is filled with spirit of wine, which passing over a bend at the top descends to the upper extremity of the mercury in one of the branches; the upper end of the other branch is also filled with spirit, and this is hermetically sealed. Two small indices of steel, coated with glass, are introduced in the branches, and are capable of being forced upwards by the rising of the column of mercury in either tube, and they have about them a fine wire or a thread of glass; so that they will remain stationary where they happen to be when the heads of the columns recede from them. Their lower extremities consequently indicate the points at which the ends of the columns may have stood before such recess.

Differential Thermometer.—This instrument, which was invented by M. Sturmius, of Altdorf, before the year 1676, and was revived by Professor Leslie in 1804, consists of two thermometer tubes, terminating, at one extremity of each, in a hollow glass ball, and containing coloured sulphuric acid: the opposite extremities are united by the flame af a blowpipe, and an enlargement of the bore is made, at the place of junction. The tube is then bent so as to form three sides of a rectangle, the two balls, which are of equal diameter forming the upper extremities of two sides; and the instrument is on a stand with the branches of the tube in vertical positions. When the temperature of the air in the two balls is the same, the acid occupies one side and the base, and rises a little way up the other side of the rectangle. To the latter side is attached a graduated scale, with the zero of which the upper extremity of the acid in that branch should coincide. In the event of this adjustment being deranged, it may be restored by causing a small quantity of air to pass from one ball to the other, which is done simply by the warmth of a hand applied to that ball from whence the air is to be driven.

Radiating Thermometer.—[ACTINOMETER.]

THERMOSTAT. This name has been given by Dr. Ure to an apparatus invented by him, for regulating temperature in vaporization, distillation, heating baths or hothouses, ventilating apartments, and other applications of heat. It operates upon this physical principle,—that when two thin metallic bars of different expansibilities are riveted or soldered facewise together, any change of temperatnre in them will cause a sensible movement of flexure in the compound bar, to one side or other; which movement may be made to operate, by the intervention of levers, &c., in any desired degree, upon valves, stop-cocks, stove-registers, air-ventilators, &c. In this way the temperature of the space in which the compound bar is placed may be regulated. Two long rulers, one of steel, and one of hammered brass, answer very well. There are many forms which the apparatus may present, according to the purpose to which it is to be applied.

THIBET. [TIBET.]

THIMBLE. Thimbles are usually formed by means of a stamping machine; but the following method is sometimes practised in France:—Sheet-iron, one twenty-fourth part of an inch thick, after being cut into strips of convenient size, is passed under a punch-press, by which it is cut into circular discs of about two inches diameter. These discs are then made red-hot, and laid in succession upon a series of mandrils, with hollows of successively increasing depth, into which the softened discs are forced by striking them with a round-faced punch, about the size of the finger. After being thus brought to the required shape, the thimble is placed in a lathe, when the inside is polished and the outside is turned and ornamentally finished. Iron rings used in the rigging of ships are in some instances called thimbles.

THRASHING MACHINE. The separation of the grain from the ear in corn is effected in different ways. The finest and ripest grains for seed are extracted by simply beating the corn on a table or flat board. The most usual method is by means of the *flail*, an instrument so formed as to strike a large extent of corn at one time. The flail, by means of its long handle, is swung round the head; and the beating part of it is made to fall horizontally on the straw which is spread on the thrashing floor; and by inserting this part occasionally under the straw, the latter is turned over, and a fresh portion is brought up to be beaten.

In a serene and dry climate, corn may readily be thrashed out in the manner described in the Bible; viz., by levelling a portion of the corn-field, laying the corn in the straw in a large circle, and driving oxen or horses over it till the grain is all trodden out. Such a method as this, however, is not suited for an English climate.

Modern times have seen the introduction of *thrashing machines*, which perform the operation with much rapidity. The general construction may be thus briefly described. A rapid motion is given to a hollow cylinder round a horizontal axis; on the outer surface there are projecting ribs parallel to the axis, at equal distances from each other. Around half the cylinder is a case, the inner surface of which is lined with plates of cast-iron, grooved in the direction of the axis. The ribs or beaters come quite close to these grooves, so that an ear of corn cannot well pass between them without being flattened. The corn is drawn in between two rollers, and the beaters act on the straw so as to beat out most of the corn. The grain falls through the meshes of a sieve, but the straw is retained until removed by rakes.

Many modifications of are adopted by different makers, but the above gives a pretty general idea of the mode of action. Such an apparatus is usually worked by a horse; but there are also hand-machines, which are profitably worked where hand labour is cheap, but where there are no skilful flailmen. There is a peculiar system adopted in some counties, in which a hand-thrashing machine is taken from farm to farm by the owner, who lends and superintends the machine, while the farmer supplies horses and men, a stipulated price being paid to the machine owner, to the mutual advantage of both parties.

The most complete thrashing machines are those which are worked by steam power. In some of the best and largest farms a steam-engine is kept to the thrashing, the chaff-cutter, and other agricultural implements. At the recent agricultural and cattle shows, the thrashing machines made by Garrett, Crosskill, Wedlake, Hensman, &c., have been shewn in great variety; and many such have been sent to the Great Exhibition.

THREAD MANUFACTURE. Sewing-thread, and the various kinds of thread used in the manufacture of bobbin-net, lace, and some other kinds of textile fabric, consist of two or more *yarns*, or simple spun threads, firmly united together by twisting, just as a rope-strand consists of several yarns or distinct cylinders of hemp.

The operation of combining yarns of cotton or linen into thread is performed by a machine called a *doubling* and *twisting frame*, somewhat resembling the throstle of the cotton-spinner. Along the centre of the machine is an elevated creel or frame-work, which supports two parallel rows of cops or bobbins of yarn, one row towards each side of the machine. From the cops the yarns are conducted over horizontal glass rods, which are fixed parallel with the creel, and thence downwards into troughs filled with water or very thin starch-paste, which, by moistening the yarns, facilitates the subsequent process of twisting. After being wetted, the yarns pass over the rounded edge of the trough, which is covered with flannel for the purpose of absorbing the superfluous moisture; and thence under and partly around an iron roller, which is made to revolve with any required velocity by a train of wheel-work. Upon this roller rests another, of box-wood, which revolves solely by contact with the iron roller, its axis playing in vertical slots. In passing under the iron roller, then between it and the wooden roller, and finally over the latter, the yarns required to form the thread are brought together and slightly compressed; and they are finally twisted by apparatus very like that used in throstle spinning. A few details concerning the export of thread are given under the names of the materials employed.

THUNDER-ROD, is a rod of metal attached generally to a side of a building, and extending from below the level of the ground to a point several feet above the highest part of the roof of the building, in order to secure the edifice from the effects of thunder or lightning: the upper extremity of the rod or bar terminating in a point. It is to Dr. Franklin that the world is indebted for the idea of raising pointed rods in order to secure buildings from the effects of atmospherical electricity; and the recommendation was immediately adopted both for edifices on land and ships on the water.

The thunder-rod should be thick enough to carry the electric fluid to the ground without being melted by it; in general a cylindrical rod about half an inch in diameter will be sufficient to prevent this effect from taking place; whether of iron or copper, it should be covered above ground with a coating of paint; and the part under ground is usually formed with two or more branches in order to facilitate the passage of the electric fluid to the earth.

A ship at sea, like an edifice on land, may, when there is an accumulation of electric matter in the upper part of the atmosphere, be struck aloft; or, when the atmosphere is in a contrary state, the lower part of the ship may be struck, the lightning in the latter case ascending along the mast: and ships unfurnished with metallic conductors have frequently suffered serious injury during thunder-storms, while those which have been so provided have generally escaped. The rigid bars of Franklin are considered inapplicable, as conductors, to ships, and instead of them chains of copper have been generally employed; these are attached to the masts at their upper extremities; and, following the standing rigging, they pass down the ship's sides into the water. In 1822 Mr. (now Sir W.) Snow Harris proposed, and subsequently caused to be executed for ships, conductors consisting of slips of copper, of sufficient thickness to prevent them from being fused; these slips are inserted, in two layers, in a groove cut longitudinally along the mast, the joints of one layer being opposite to the middle parts of the other, and they are fastened to the mast by copper screws. The whole line of metal passes down from the copper spindle at the top of the mast-head, and at the junctions of the upper and lower masts the ship is made to join a cylinder of copper which lines each sheave-hole; the lower part of the line is connected with a plate of copper which is fixed on the keelson, at the step, and from thence there is a communication with the water by three copper bolts which pass quite through the keel. This improvement by Sir W. Snow Harris, has proved to be a most valuable one; the safety thereby ensured to the royal shipping, (so far as the effects of lightning are concerned), represents, in money value, a sum which must be immense, however difficult to estimate.

TIA'RA, was a kind of hat, in ancient times worn by the inhabitants of Middle and Western Asia, especially by the Persians, Parthians, Armenians, and Phrygians. There were two kinds of tiaras: the upright tiara was used by kings, priests, and other persons of the highest rank, and the upper part had frequently the shape of a crown; the tiara worn by other people was of a soft and flexible material, so that it hung down on one side, as in the case of the so-called Phrygian bonnet. In modern times the term tiara is applied to the head-dress of the popes, which is worn on solemn occasions, and consists of a triple crown. Hence it is also used in a figurative sense to designate the papal dignity.

TI'BET. Among the minerals of this elevated, but little known region of Asia, are gold, silver, copper, tin; salt, which is taken from the salt-lakes of Jayek and Deng-tsavga; corundum stone, lapis lazuli, turquois, and agate. Besides a great number of grasses which are common in Europe, Tibet produces a kind of barley, grapes, asafœtida, rhubarb, madder, safflower, apples, nuts, apricots, peaches, pomegranates, and figs, in the valleys. The cedar grows in Tibet. Among the animals there are wild oxen with long hair, buffaloes, the buffalo which is called the yak, goats with a very fine fleece, goats with long fine hair, silk-worms, wild cats, tigers, leopards, lynxes, argali with horns of 100 lbs. weight, pigs, white eagles, and swans. Of the industry and commerce of Tibet, we have very little trustworthy information.

TIDE GAUGE. The phenomena of the tides relate too intimately to physicial science to come fittingly under notice in this work; but *tide-gauges*, such as that recently erected at Sunderland, are too important to commerce to be passed over here.

Mr. Meik, the engineer of Sunderland has invented and registered a tide-gauge, for the use of ships entering or leaving a harbour. In a tidal harbour the number of ships which can enter or leave during one tide depends on the time, the depth, and the rapidity of the tidal flow; and Mr. Meik wished to produce some sort of gauge which should indicate these conditions, in a way intelligible to ordinary seamen, at the busy port of Sunderland, by night as well as by day. In conjunction with Mr. Watson, a brass founder at Newcastle, Mr. Meik has carried out his project at Sunderland in the following way.

There is a vertical tube, up which the water rises to a greater or less height according to the state of the tide. A float is borne on the surface of the water; and a copper wire from this float passes upwards to a train of wheels and rollers, which rotate in one or other direction according as the float rises or sinks. A web of wire gauze passes from one roller to another; on this web are painted in large letters the various depths from high to low water; and two fixed pointers also indicate the number of feet and half feet of depth of water, at any hour of the tide, on the bar at the entrance of Sunderland harbour. By day the figures on the web are shown white on a black ground; by night they appear distinctly lighted up, the ground still remaining dark. A white transparent varnish is used for the figures, and an opaque black for the ground.

There are also *tide registering gauges* employed at some ports. There is a vertical tube, into which the water of a river or harbour can enter from beneath, rising to a greater or less height according to the tide. A float is on the surface of the water, and a copper wire passes upwards from the float to a rack which holds a pencil. There is a cylinder, on the surface of which is fastened a sheet of paper, properly ruled for the purpose; and large enough to receive the entries for fourteen days. A time piece gives an equable motion to the cylinder; and as the point of the pencil is in contact with the cylinder, a waving line becomes marked on the paper, passing *round* the cylinder as time progresses, and passing *along* the cylinder according as the tide rises and falls. There thus results a permanent record of the height of the tide at every hour and even minute of the day.

TIFLIS, or TEFLIS, the capital of the Russian province of Georgia, is most favourably situated to be the medium of an extensive transit trade between Europe and Asia; the rich Armenian bankers and merchants of the town have the chief direction of this trade, which however is now carried on mainly through the Turkish port of Trebizond, and thence by caravans to Persia and Bushire. Recent relaxations in the Russian tariff on goods in transit are likely however to turn the course of this trade again through the Georgian port of Redout-Kalé, Tiflis, and the Caspian. The enterprising Armenians of Tiflis trade extensively with Odessa, Trieste, Leipzig, Nishnei-Novgorod, Persia, Bokhara, Thibet, and Cashmere.

TILE MAKING. In the ancient buildings of Greece and Rome, tiles were made of various materials, among which were baked clay, marble, and bronze. They were made flat, or with a raised border along each edge, or semicircular on their lower edges.

The process of making tiles is so similar to that of brick-making [Brick], that it will be sufficient to observe that only the best qualities of brick-earth are fit for the purpose. The roofing tiles used in this country are chiefly of two sorts, *plane-tiles*, which are flat, of a rectangular form; and *pan-tiles*, which also have a rectangular outline, but are bent in such a manner that, when laid on the roof, the greater part of their surface forms a concave channel for the descent of water, while one side forms a narrow convex ridge, which overlaps the edge of the adjoining tile. Tiles of a semi-cylindrical form, laid in mortar with their convex or concave sides uppermost, respectively, are used for covering ridges and gutters. Drain-tiles are most commonly made in the form of an arch, and laid or bedded upon flat tiles called *soles*.

TILT-HAMMER, is a large hammer worked by machinery, impelled either by a water wheel or a steam engine. Such hammers are extensively used in the manufacture of iron and steel; and the name *Tilt-Mill* is sometimes applied to the mechanism of which they form the principal feature. [STEEL MANUFACTURE.]

TIMBER. The name of timber-trees is most usually applied to such trees as oak, ash, and elm, of the age of twenty years and upwards; but there are many other kinds which may fittingly be designated by the same name. The characteristics of these various sorts of timber are described under the several names [ELM; FIR; OAK; &c.]

The preservation of timber from dry rot and other symptoms of injury is a very important feature in connexion with ship-building and civil engineering. A few details on this subject will be found under the headings ANTISEPTICS and DRY ROT.

The timber subject to Customs Duties on importation is designated by various names according to sizes and forms into which it is cut. *Battens, batten ends, boards, deals, deal ends, planks,* and *staves,* are the principal among these names. The following were the imports in 1850, classified according to the custom-house arrangements:—

Battens, batten ends, boards, deals, deal ends, and planks, entered by tale or No., 34 hundred.

Deals, battens, boards, and other sawn or split timber, entered at per load, 796,108 loads.

Staves, 82,588 loads.

All kinds of timber not included in the above enumeration 870,571 loads.

The gross amount of duty received on these imports was 655,232*l.* Measures are now (May 1851) under consideration of parliament, for a reduction in the timber duties.

TIME-KEEPERS; TIME-PIECES. [CHRONOMETERS; CLOCKS and WATCHES.]

TIN. This metal is one of those which were earliest known, though it occurs in comparatively few countries. It is found in England, Saxony, Bohemia, Hungary, the isle of Banca, the peninsula of Malacca, in Chili, and Mexico. Malacca furnishes the purest tin, and Cornwall the largest quantity. It occurs in two states of combination, the *Peroxide of Tin* and the *Double Sulphuret of Tin and Copper:* this last is rather a rare substance, and it is from the former that the metal is almost entirely obtained.

The peroxide is found in Cornwall in combination with other metals, in *Tin-Stone;* and in loose rounded masses called *Stream-Tin.* The former, when reduced to the metallic state, yields *Block-Tin;* while the latter yields *Grain-Tin,* which is the purer of the two. The tin-stone, which contains 77 per cent. of pure tin, occurs in a crystalline form, as well as in masses; but stream-tin is uncrystallised, and has evidently been derived from the destruction of tin veins or lodes, the lighter portions of stony matter having been carried away by the water, which has rounded the fragments of the ore.

This metal is of a silver-white colour, very soft, and so malleable that it may be reduced into leaves 1-1000th of an inch thick, called tin-foil: it suffers but little change by exposure to the air. Its tenacity is but slight, so that a wire of 1-15th of an inch in diameter is capable of supporting only about 31 lbs.: a bar a quarter of an inch in diameter was broken by 296 lbs. weight. Tin is inelastic, but very flexible, and when bent it produces a peculiar crackling noise. When rubbed it imparts to the fingers a peculiar smell, which remains for a considerable time. Its specific gravity is about 7·29: at 442° Fahr. it fuses, and if exposed at the same time to the air, its surface is tarnished by oxidation, and eventually a gray powder is formed. When heated to whiteness it takes fire, and burns with a white flame, and is converted into peroxide of tin. If slowly cooled after fusion, it exhibits a crystalline appearance on solidifying.

The combinations which tin forms with oxygen, chlorine, sulphur, and iodine, and those which the oxide of tin forms with the various acids, are valuable in calico printing and many other of the practical arts.

Most of the malleable metals are rendered brittle by alloying with tin. It combines readily with potassium and sodium, forming brilliant white alloys, which are less fusible than tin. With arsenic it forms a metallic mass which is whiter, harder, and more sonorous, than pure tin. With antimony tin forms a white, hard, and sonorous alloy. Bismuth forms with tin an alloy which is more fusible than either of the metals separately, a mixture of equal weights melting at 212°; this compound is hard and brittle. Copper and tin form alloys which are well known and highly useful—*Bell Metal* and *Bronze.* With mercury tin readily amalgamates, and the compound is used for silvering mirrors. Tin forms with iron white compounds, which are more or less fusible according to the proportion of iron they contain. Tinplate is of all the alloys of tin the most useful, and the preparation of this and of pewter are the most extensive applications of this very valuable metal.

TIN MANUFACTURE. The ores of tin raised in Cornwall and Devonshire are mostly reduced or smelted within those counties. The smelting-works do not generally belong to the proprietors of the mines, but to other parties who purchase the ore from them, their value being determined by a kind of assay. The smelting is effected by two different methods, according as *tin-stone* or *stream-tin* is to be acted on.

In the former process the prepared ore, which is called *schlich*, is mixed with from one-fifth to one-eighth of its weight of powdered anthracite, or culm, to which a little slaked lime or fluor-spar is sometimes added as a flux. The charge (from 12 to 24 cwts.) is spread upon the concave hearth of the furnace, and then the apertures by which it is inserted are closed and luted, and the furnace is gradually heated, and kept hot for six or eight hours, by which time the reduction of the ore is complete. When the fusion or reduction of the ore is considered to be finished, one of the apertures of the furnace is opened, and the scoriæ removed; after which a channel is opened, by which the melted tin flows from the hearth into a large vessel, where it is allowed to rest for some time, in order that the impurities yet remaining with the metal may separate, by their different specific gravities. When it has settled, the tin is ladled into moulds, so as to form it into large blocks or ingots.

The ingots produced by the above process frequently contain portions of other substances, to remove which the tin is exposed to the process of *refining*. The tin is again melted in another furnace; and into the molten metal billets of green wood are plunged. This occasions the disengagement of considerable volumes of gas from the wood, and thus a kind of ebullition is produced in the tin, which causes the lighter impurities to rise to the surface in a frothy form, and the heavier to fall to the bottom. The scum is removed, and the rest is allowed to settle, whereby all the purest tin rises to the top, and the quality deteriorates thence to the bottom; by which means the tin, poured into moulds, presents many different qualities. The moulds are made of granite, and yield blocks of tin weighing about 3 cwts. each: granite having been found well fitted for this purpose. An inferior kind of tin is produced by remelting the scoriæ. The average quality of the tin ore, as prepared for the smelting-furnaces, is such as to yield 62 to 65 per cent. of pure tin; and the quantity of coal required for producing one ton of tin is about a ton and three-quarters.

The smelting of tin by the blast-furnace, with wood-charcoal, is practised on a limited scale for the production of tin of the greatest possible purity, and from *stream-tin* instead of *tin-stone*. No substance is added to the ore and charcoal, unless it be the residuary matter of a previous smelting; and the proportion of charcoal consumed is about one ton and six-tenths for every ton of tin produced. The melted tin runs from the furnace into an open basin, whence it is run off into a large vessel in which it is allowed to settle. The scoriæ which run with the metal are skimmed off, and separated into two portions, one consisting of such as retain tin oxide, and the other of such as have no oxide, but contain tin in a granulated state. In order to convert the blocks of tin produced by the blast-furnace process into the form known as *grain-tin*, they are heated until they become brittle, and made to fall from a considerable height in a semi-fluid state, thus producing an agglomerated mass of elongated grains.

Tin is rarely employed alone in our metalline manufactures, but when laid in a thin coat upon the surface of sheet-iron by the process of *Tinning*, it produces a material of extensive use in the manufacture of culinary and other articles. Most of the tin used in the manufacture of articles composed exclusively of that metal is that which is expanded by rolling and hammering into leaves of *tin-foil;* this is the substance which is laid upon the back of glass mirrors, and there amalgamated with mercury, so as to form what is called the *Silvering*.

The art of *tinning*, or of coating other metals with a thin layer of tin, so as to protect them from oxidation, was known to the ancients, although it does not appear to have been very extensively practised. The tinning of plate-iron is more modern than that of copper vessels, and is supposed to have been invented either in Bohemia or in Germany, whence it spread to France about 1725, and to England about 1730.

The process of tinning depends upon the strong affinity which exists between tin and the metals to which it is applied. The finest bar-iron, called *tin-iron*, is used for making tin-plates. This material is first made into flat bars, or slabs, about thirty inches long, six inches wide, and weighing eighty pounds; and these bars are rolled until the metal assumes the proper degree of thinness, after which the sheets are cut into pieces measuring usually about thirteen inches by ten.

The removal of every particle of oxide or other impurity from the surface of the plates is then effected by the application of muriatic acid and of heat; and any warping is removed by a process of cold-rolling between very hard rollers. The plates are then immersed singly, in a vertical position, in a fermented steep of bran; whence, after 10 or 12 hours, they are transferred to a leaden vessel containing diluted sulphuric acid. They are then removed into pure water, in which they are scoured with hemp and sand, to remove any remaining oxide. They are next dried by rubbing with bran, greased on both surfaces, and plunged into the metallic bath, which contains a mixture of block and grain-tin, covered with a quantity of grease sufficient to form a layer four inches deep, and heated. When the plates have remained in the tin bath an hour or two, they are lifted out with tongs, and placed upon an iron grating, to allow the superfluous tin to drain off; but as there still remains upon them much more than the proper quantity of tin, they are afterwards subjected to a process called *washing*, which consists in dipping them into a pot containing a quantity of pure grain-tin in a melted state, then rubbing them with a peculiar kind of brush made of hemp, plunging them again for a moment into the melted tin in the wash-pot, and then into a pot filled with clean melted tallow, or lard free from salt. Owing to the vertical position of the plates during the preceding operations, a selvage of tin accumulates along their lower edge, which is partially removed by a re-melting and shaking of the edge. The plates are then cleaned from grease by rubbing them, while yet warm, with dry bran; after which they are packed in boxes of wood or sheet-iron.

The tinning of the inner surfaces of cooking utensils and other vessels of capacity is formed by scouring the surface until it is perfectly bright and clean; then heating the vessel, pouring in some melted tin and rolling it about, and rubbing the tin all over the surface with a piece of cloth or a handful of tow: powdered rosin is used to prevent the formation of oxide. Bridle-bits, stirrups, and many other small articles, are tinned by immersing them in fluid tin.

Tin-Plate Working, or the forming sheets of tinned iron into a variety of useful vessels and utensils, is carried on by means of bench and hand-shears, mallets and hammers, steel heads and wooden blocks, soldering-irons and swages. In the formation of a vessel the first operation is to cut the plate to the proper size and form with shears; and when the dimensions of the article require it, to join them together, which is done either by simply laying the edge of one plate over that of the other, and then soldering them together, or by folding the edges together with laps, and then soldering them. Similar joints are required when gores or other pieces are to be inserted, and also at the junction by which a cylinder is closed in. The usual method of forming laps, bends, or folds for this or other purposes is to lay the plate over the edge of the bench, and to bend it by repeated strokes with a hammer; but a machine is sometimes used for this purpose.

After a tin vessel has been rounded upon a block or mandril, by striking it with a wooden mallet, and the seams finished, all its exterior edges are strengthened by bending a thick iron wire into the proper form, applying it to what would otherwise be the raw edges of the metal, and dexterously folding them over it with a hammer. A superior kind of tin-ware, commonly known as *block-tin ware*, is carefully finished by beating or planishing with a polished steel hammer upon a metal stake. The process of *swaging* is resorted to as a ready means of producing grooved or ridged borders or other embossed ornaments. This process consists in striking the metal between two steel dies, or swages, the faces of which bear the desired pattern, and are made counterparts to each other. Many ornamental articles are produced by embossing or stamping tin-plate, in the same manner as other metallic sheets, with a fly-press or other machinery. Cheap coffin-plates are manufactured at Birmingham in this way; and these and similar articles are sometimes lacquered, painted, or japanned. One particular kind of tin plate is described under MOIRÉ.

Tin forms the principal ingredient in various kinds of pewter and other white metallic alloys, which are manufactured into domestic utensils by casting, stamping, and other processes. *Britannia Metal* is a mixture of tin, antimony, copper, and brass; which is melted, cast into slabs, and rolled into sheets. The principal use of this metal is for candlesticks, tea-pots, coffee-biggins, and other vessels for containing liquids. The feet of candlesticks, the bodies of tea-pots, and other articles containing embossed work, are stamped between dies; while articles of a more globular shape are stamped in two or more pieces, which are afterwards soldered together. The sheet metal has a ductility which enables it to be bent into various curved forms, by pressure on a model or core: this process is called *spinning*.

Many small vessels, spoons, and other articles, are cast in an alloy somewhat harder than that which is rolled into sheets. Articles of this metal are cleaned from the oil, resin, and other impurities acquired during their formation, by boiling in water containing sweet soap; after which they are polished, either by hand, or more commonly by the buff and brush set in motion by a steam-engine; then boiled in a solution of pearlash; and finally hand-brushed and hand-polished by an application of soft soap, a little oil, and powdered rotten-stone.

TINCTURES are solutions of the active principles, mostly of vegetables, sometimes of saline medicines, and more rarely of animal matters, in certain solvents. From possessing more or less of colour, they have obtained this name. They are distinguished according to the kind of solvent employed. When alcohol is used, they are termed *alcoholic tinctures*, or more generally simply *tinctures;* when sulphuric æther is used, they are denominated *ætherial tinctures*. When wine is used, though differing little from pure alcohol, the term *medicated wines* is applied to them; and when the process of distillation is employed to aid the extraction, particularly of volatile oils, the result is termed a *spirit*, such as of rosemary. Ammonia is sometimes conjoined, and the proceeds termed an *ammoniated tincture*. *Elixirs* differ only from tinctures in being of a greater consistence: they are not unfrequently turbid from the attractive matter suspended in them. The number and variety of tinctures are numerous.

TITA'NIUM. This metal was first recognised by Mr. Gregor, in 1791, as a distinct substance; he detected it in a black sand found in the bed of a rivulet in Cornwall. The form of the crystals of this metal is the cube; their colour resembles that of bright copper; they are sufficiently hard to scratch rock-crystal. Titanium is acted on by very few acids. For fusion an extremely high temperature is required. The metal and its compounds have yet been applied to very few purposes in the arts.

TOBACCO. *Tobacco* was the name used by the Caribbees for the pipe with which they smoked, but was transferred by the Spaniards to the herb itself. The genus *Nicotiana* contains about 40 species, most of them yielding tobacco for smoking, and many of them cultivated in the gardens of Europe.

The cultivation of tobacco is most extensively carried on in the United States of North America. It requires considerable heat to bring it to perfection; but with care and attention, and by treating it as an exotic, it may be very successfully cultivated in much colder climates. In Holland, of which the climate differs little from that of Great Britain, the tobacco-plant is cultivated to a very great extent, even in very poor soils, by great attention to manuring, and by accelerating the growth of the plant.

The seed is sown in a well prepared seed-bed in March, and protected by mats laid over hoops as long as the nights are cold and frost is dreaded. The ground in which the tobacco is to be transplanted is laid in narrow beds with intervals between them; the plants are taken up carefully with a trowel; they are placed slanting in a shallow basket, and are thus carried to the prepared beds. They are inserted into holes made by a proper instrument, so that the fibres of the roots and the adhering earth may be completely buried up to the bottom of the stem. When the leaves acquire a certain size the lower leaves are pinched off. A few plants are left for seed, and of these the heads are allowed to shoot the full length. Tobacco takes about four months from the time of planting to come to perfection. As soon as the colour of the leaves becomes of a paler green inclined to yellow, they are fit to be gathered. The plants are cut down close to the ground, and are then carefully and gradually dried. When the plants are quite dry, they are removed in moist or foggy weather; for if the air is very dry the leaves would crumble. They are laid in heaps on hurdles and covered over, that they may sweat again, and are examined from time to time to see that they do not heat too much; and, according to the season and whether the plants are more or less filled with sap, they remain so a week or a fortnight. If the leaves were not stripped off at first, which is not the most common practice, they are taken off now and sorted; those which grow on the top of the stem, in the middle, and at the bottom, are laid separately, as being of different qualities. They are tied together in bundles of ten or twelve leaves, and again dried carefully, when they are ranged in casks horizontally, and pressed in by means of a lever or screw.

Tobacco is packed in hogsheads for shipment: it is done with the greatest care; and the pressure applied is so great, that a hogshead 48 inches in length, and 30 or 32 inches in diameter, will contain one thousand pounds weight. Upon the arrival of the tobacco in this country, it is conveyed to bonding-warehouses, examined, charged with duty, and sold to the manufacturers.

The manufacture of the tobacco-leaves into the numerous varieties of tobacco for smoking in pipes is commenced by loosening and opening the bundles, and sprinkling the leaves with water. The stalks are then stripped from the leaves; this is effected by women or boys, who fold the leaf along the middle, and, by means of a small instrument, separate the stalks from the leaves, and lay them aside in different heaps. To prepare them for being cut into shreds, the leaves are pressed together in large numbers. When removed from the press to the cutting-engine, the cake of leaves is as hard as a board; yet it retains a slight degree of clamminess or moisture from the leaves having been previously sprinkled. In cutting the tobacco, the cake of leaves is laid upon an iron bed, which is susceptible of a slow progressive motion by means of a screw which passes beneath it, and is connected with a cog-wheel in such a manner that, while the machine is moving, the bed is constantly urged forward. Another part of the mechanism gives motion to the knife, which has a sharp blade, rather longer than the width of the cake, and is pivoted on a hinge or fulcrum at one end, the other rising and falling with the action of the machinery.

The kind called *pig-tail* tobacco is produced by a process similar to spinning, and requires the simultaneous aid of a man and two boys. A bench several yards in length is made use of, with a spinning-wheel at one end, turned by one of the boys. The other boy arranges a number of damp leaves, with the stalks removed, end to end upon the bench, taking care to lay them smooth and open; and the man immediately follows him, and rolls up the leaves into the form of a cord by a peculiar motion of his hand. As fast as this is done, the finished tail is wound upon the spinning-wheel. It is transferred from the spinning-wheel, by the action of the machinery, to a frame connected with it; and subsequently it is wound or twisted up into a hard close ball.

Other forms into which the plant is manufactured are noticed under CIGAR and SNUFF.

Trade.—For the following years the consumption of tobacco, and the duty thereon, were—

	Consumption.	Duty per lb.
1801	16,514,998 lbs.	1*s.* 7*d.*
1811	14,923,243	2*s.* 2*d.*
1821	12,983,198	4*s.*
1831	15,350,018	3*s.*
1841	16,000,000	3*s.*

Seven-eighths of all the tobacco brought into this country is grown in the United States. The duties payable are 3*s.* 1⅘*d.* per lb. on unmanufactured tobacco; 9*s.* 5⅖*d.* per lb. on cigars and manufactured tobacco; and 6*s.* 3⅗*d.* per lb. on snuff.

The imports in the last two years have been:

	1849.	1850.
Unmanufactured	42,098,126 lbs.	33,894,506 lbs.
Manufactrd. and Snuff	1,913,474 lbs.	1,532,829 lbs.

The home consumption is about 28,000,000 lbs. annually, the rest being re-exported. The gross duty realised in the two years was 4,425,040*l.* and 4,430,134*l.* respectively.

TOBACCO-PIPES are made of clay, white and coloured earths, porcelain, ivory, and various other substances. The tobacco-pipes commonly used in this country are formed of a fine plastic white clay, which is called from this application, *pipe-clay.* It is procured chiefly from Purbeck, in Dorsetshire; and, after being purified and made into a soft state, is cut into small pieces, each enough for one pipe. Each piece is kneaded thoroughly upon a board, and rolled out to nearly the form and size of a pipe, with a projecting bulb at one end for the formation of the bowl. These pieces are laid aside for some time to dry, and when the clay is sufficiently firm, they are subjected to the curious process of boring. The workman takes the roll of clay in his left hand, and with his right inserts the end of an iron needle, previously oiled, in the small end of the roll, and by dexterous management thrusts the needle through the whole length of the roll, without penetrating the surface. The bulb is then bent into the proper position to form the bowl, and the piece of clay, with the needle remaining in it, is pressed into a mould to complete its form. The moulds are made of metal, in two halves. The bowl is partially hollowed by the finger, and completed by the insertion of an oiled stopper or mould. The wires are now withdrawn, and the pipes are taken out of the moulds, slightly smoothed over, and laid aside to dry. After drying for a day or two, any remaining roughness is removed by means of an instrument of bone or hard wood, and then the pipes are sometimes moulded a second time, and polished with a piece of flint bored with holes, through which the stem is passed repeatedly. The pipe-stems are thus far straight, but before going to the kiln they are slightly bent.

The tobacco-pipe kiln consists of a large but very light cylindrical crucible, with a dome-shaped top, and a circular opening in one side for the insertion of the pipes. This crucible is mounted in a brick furnace, lined with fire-brick, in such a manner as to leave a space of about four inches all round for the circulation of flame. The pipes are placed in the kiln, with their bowls against the circumference, and their ends supported at a considerable elevation upon circular pieces of clay set up in the centre. By this arrangement one furnace may contain fifty gross, or 7,200 pipes, which may all be baked within eight or nine hours.

A different kind of clay or earthen pipe is described under Meerschaum Pipes.

Mr. Skertchley patented a somewhat complicated machine for making tobacco-pipes, in 1848; and Messrs. Steel and Britten patented another machine for the same purpose in the same year.

TOMAHAWK. The tomahawks or hatchets of Indian manufacture are headed with stone, but the ordinary metal blades or heads are of European manufacture, and made expressly for Indian use. The handles are usually made by the Indians themselves, and are often highly ornamented. Some tomahawks are formed with a bowl for burning tobacco in the head, and a hole through the handle to serve for a pipe.

TOMATO. The tomato which is used as a condiment or sauce, is the fruit of one among many species of *Solanum*. It is a native of South America; but it is also well known and much cultivated in the United States, France, Germany, and Italy. The fruit is about the size of a golden pippin; it has an acid flavour, and is used as an addition to soups and sauces, as a preserve, and as a pickle. It is not much used in England; but in Italy whole fields are covered with it; and scarcely a dish is served up into which it does not enter as an ingredient.

TON or TUN. In modern English spelling the *ton* is a weight (twenty hundredweight, or 2240 lbs. avoirdupois), and the *tun* is a measure of wine (two pipes, or 252 gallons).

TOPAZ. The colour of this gem varies from white to a greenish-blue, and is translucent. Fragments exposed to heat emit a blue, green, or yellowish phosphoric light. Topazes occur generally in primitive rocks, and in many parts of the world, as Cornwall, Scotland, Saxony, Siberia, Brazil, &c. &c. They consist of alumina and silica, with a little fluoric acid.

TORMENTIL is a small perennial plant, growing in the whole of Europe and the north of Asia, in forests, bogs, and heaths. The root, or rather the rhizoma, is the most powerful of our indigenous astringents, and more easily assimilated than oak-bark or galls. Valuable as this substance is in medicine, it is of still greater utility in the arts and in agriculture. It may be most beneficially employed to tan leather, both where the oak grows and where it is absent, since one pound and a half of powdered tormentil is equal in strength to seven pounds of tan. It is used in Lapland and the Orkney Isles both to tan and to dye leather.

TORSION is that force with which a thread or wire returns to a state of rest when it has been twisted by being turned round on its axis. In the *torsion-balance* or *torsion-meter* (as it may be termed), the thread or wire, which is suspended vertically, is attached at the upper extremity to some object, and at the lower extremity is a weight with a horizontal index, or a stirrup, which is to carry a needle or bar in a horizontal position. So long as the force of torsion is moderate, its intensity is directly proportional to the angle or arc through which the extremity of the index is moved in twisting the wire, and that the time of a complete oscillation is constant, or that the vibrations are isochronous, like those of a pendulum which is acted upon by gravity. The experiments made with this instrument are chiefly in connection with science; but they have a bearing on civil engineering, insofar as they illustrate the strength and other properties of building materials.

TORTOISE-SHELL is procured from a marine tortoise called the hawk's-bill turtle, or *testudo imbricata*. Each animal furnishes thirteen principal plates, five along the centre of the back, and four on each side; and twenty-five smaller scales or plates, which constitute the margin of the shell. The horny plates which constitute true tortoise-shell are separated from the bony foundation which forms the shell or covering of the animal by the application of heat; the whole shell being commonly placed over a fire until the plates begin to start from the bone, and the separation being completed by the aid of a slender knife. The yellow-coloured shell bears a higher price than that which is mottled.

The processes of manufacturing articles of tortoise-shell are very similar to those described under Horn Manufacture, but on account of the high price of the material (often three guineas per lb.), it is economised as much as possible. In making the frames for eye-glasses, narrow strips of shell are used, in which slits are cut with a saw, the slits being subsequently, while the shell is warm, strained or pulled open, until they form circular or oval apertures, by the insertion of tapering triblets of the required shape. The same yielding or flexible property is made use of in the manufacture of boxes, a round flat disc of shell being gradually forced by means of moulds into the form of a circular box with upright sides. The union of two or more pieces of shell may be effected by carefully scraping the parts that are to overlap, so as to render them perfectly free from grease, even such as might arise from being touched by the finger, softening them in hot water, pressing them together with hot flat tongs, and then plunging the joint into cold water.

In veneering with tortoise-shell, by which very beautiful work may be produced, it is usual to apply fish-glue, mixed with lamp-black, vermilion, green, chrome, white, or other colouring matter, at the back of the shell, both to heighten its effect and to conceal the glue or cement by which it is secured to the wooden foundation.

TOULON. In this maritime French town there are two harbours, one for commerce, the other for the navy, which communicate with each other by a deep channel crossed by a swing bridge. The commercial port, the more eastern of the two, was constructed by Henri IV., and is surrounded by handsome quays. The naval port was formed by Louis XIV., and is surrounded by quays, and on the town side by a naval arsenal, stores, forges, cannon foundries, armories, covered slips for building ships, various naval schools, and all the establishments and machinery necessary for the construction, rigging, and fitting out of ships of war of all sizes. The rope-walk, built with cut stone, and covered with a vaulted roof, is 2000 feet in length. On the south-east and eastern moles of the naval port are the bagnio and hospital for convicts; in front of these are repairing docks. The artillery depôt is on the west side of the harbour, and contains an immense number of guns and projectiles. At the south-eastern angle of the town, new basins, wet docks, and yards for the construction of steam and sailing vessels, have been formed. The industrial products and commerce of Toulon, independent of its connection with the great naval establishment it contains, are not very important. Woollen cloth, hosiery, soap, candles, leather, and chocolate, are the chief manufactured articles; merchant ships are built. The commerce is composed of corn, flour, salt provision, wine, brandy, oil, capers, figs, raisins, and other fruits.

TOULOUSE. The industrial products of this important French city are of great variety, including coarse woollen cloth, blankets, silk goods, gauze, starch, straw-hats, vermicelli, wax candles, musical strings, card and room paper, pottery, scythes, steel, and hardware; it has a large porcelain manufactory, cotton yarn mills, dye-houses, several printing offices, brandy distilleries, copper and iron foundries, tan-yards, cannon foundry, powder-mill, and a tobacco factory. The city is the entrepôt for the iron of Ariège, and has considerable commerce with Spain, Bordeaux, and Marseille. The business done in wheat and flour is very important, causing a circulation of above half a million sterling annually; the commerce in wine and brandy too is very considerable; other articles of trade are colonial produce, oil, soap, salt geese, Spanish wool, broadcloth, hardware, and feathers.

TOY MANUFACTURE. The manufacture of childrens' toys is a remarkable one, which occupies a larger number of persons than would generally be supposed. In one of the excellent papers which have recently appeared in the *Morning Chronicle*, it is well observed:—"The sciences which are laid under contribution in the construction of toys are almost as multifarious as the arts which are employed in the manufacture of them. Optics gives its burning-glass, its microscope, its magic lantern, its stereoscope, its thaumatrope, its phantasmascope, and a variety of others; electricity, its Leyden jars, galvanic batteries, electrotypes, &c.; chemistry, its balloons, fireworks and crackers; mechanics, its clock-work mice—its steam and other carriages; pneumatics contributes its kites and windmills; acoustics, its Jew-harps, musical-glasses, accordions, and all the long train of musical instruments; astronomy lends its orreries; in fine, there is scarcely a branch of knowledge which is not made to pay tribute to the amusement of the young. Nor are the arts and artists that are called into play in the manufacture of toys less numerous. There is the turner, to turn the handles of the skipping-ropes, the ninepins, the peg, the humming, and the whipping tops, the hoop-sticks; the basket-worker, to make dolls' cradles, and babies' rattles, and wicker-work carts and carriages; the tinman, to manufacture tin swords and shields, pea-shooters, carts, money-boxes, and miniature candlesticks; and the pewterer to cast the metal soldiers, and dolls' cups and saucers, and fire-irons, and knives and forks, plates and dishes, chairs and tables, and all the leading furniture of the baby-house; the modeller, to make the skin and composition animals; the glass-blower, to make the dolls' eyes; the wig-maker, to manufacture the dolls' curls; the tallow-chandler, to mould miniature candles for the dolls' houses; the potter, to produce dolls' cups and saucers. Then there are image-men, conjurors, cutlers, card-makers, opticians, cabinet-makers, firework-makers, and, indeed, almost every description of artisan —for there is scarcely a species of manufacture or handicraft that does not contribute something to the amusement of the young."

Considerable imports of foreign toys are made yearly. These are chiefly from France, Germany, and Switzerland. The clock-work and mechanical toys are chiefly from France, where they are better made than in any other country. *Box-toys*, as they are called, that is, numerous little turned or carved toys sold in boxes, are chiefly from Germany—such as Noah's arks, troops of soldiers, tea-sets, farm yards, boxes of skittles, &c. Nürnberg, Frankfort, and the Black Forest, are the principal places in Germany where these toys are made. Women and children make them in the country districts, and take them for sale to the exporting merchants. Low as such labour may be considered to be remunerated in England, the earnings are very much lower in Germany; and it is on this account that such articles can pay the expence of transport from country to country. The Swiss toys are mostly in white wood, and comprise such articles as carved figures and Swiss cottages; they also include the jointed figures used by artists. The conjuring tricks, dissecting puzzles, skeleton maps, &c., are mostly English.

Among the English toy makers the variety is considerable. There are the toy turner, the green wood toy maker, the white wood toy maker, the fancy toy maker, the numerous ramifications of doll makers, the tin toy maker, the lead toy maker, the pewter toy maker, the basket toy maker, the firework maker, the kite maker, the drum and tambourine maker, and others which it would not be easy to range under any particular class. Far more women and children than men are employed in these trades.

A little has been said on one of these toy-departments in a former article. [DOLL MANUFACTURE.]

TRACERY, is a term used to denote that species of pattern-work which is formed or traced in the head of a gothic window by the mullions being made to diverge into arches, curves, and flowing lines, enriched with foliations. The term is also applied to ornamental design of the same character, whether for doors, panelling, or ceilings; the only difference being that in windows the pattern or tracery is perforated, and in other cases closed, that is, is a mere pattern carved on the surface of a solid part. In particular instances, where the tracery on parapets, battlements, turrets, spires, &c., is pierced, it is then named *Open-work*.

TRACTION, in Mechanics, is the act of drawing a body along a plane, usually by the power of men, animals, or steam; as when a vessel is towed on the surface of water or a carriage moved upon a road. The power exerted in order to produce the effect is called the force of traction.

Numerous experiments have been made for the purpose of ascertaining the value of a force so exerted. When men are employed to draw laden boats on canals, it is found that if the work be continued for several days successively, of eight hours each, the force of traction is equivalent to a weight of 31½ lbs., moved at the rate of two feet per second, or 1⅓ mile per hour (it being understood that such weight is imagined to be raised vertically by means of a rope passing over a pulley, and drawn in a horizontal direction). The force of traction exerted when, without moving from his place, a man pulls horizontally against a weight so suspended, is estimated at 70lbs. Mr. Tredgold considers that a horse exerts a force of traction expressed by 125 lbs. raised at the rate of 3⅔ feet per second, or 2½ miles per hour. A man or a horse can however double his power of traction for a few minutes without being injured by the exertion; and when the carriage is in motion, so that the friction on the ground is alone to be overcome, a horse can draw, during a short time, on a level road, a weight exceeding 1500 lbs.

Experiments have shown that when the *angle of traction*, as it is called, that is, the angle which the plane of the traces makes with the road on which a carriage is moving, is 15 or 16 degrees, a horse pulls with good effect; and the height of the points at which the traces are attached to a horse's collar being about 4 feet 6 inches from the ground, it follows that, in order to obtain this inclination, the lower extremities of the traces or shafts should be 2 feet 3 inches from the ground. In general however, in two-wheeled carriages, the height of these extremities is about 3 feet.

As an example of the force of traction exerted by steam, it may be stated that on a level line of railway, an engine with an 11-inch cylinder, and having an effective pressure of 50 lbs. per square inch in the boiler, drew 50 tons at the rate of 30 miles per hour, working 10 hours daily; and that the same engine, with an equal pressure in the boiler, drew 160 tons at the rate of 15½ miles per hour.

TRANSIT INSTRUMENT, is an astronomical telescope, made to move in the plane of the meridian, so that the moment of any star passing a vertical wire in the middle of the field of view (and which covers a part of the meridian) may be ascertained. Usually there are several auxiliary wires at equal distances on each side of the middle wire, and the mean of the times at which the several wires are passed, is more accurately the time of meridian passage than that derived from the middle wire itself. The instrument was invented about 1690, by Römer.

The main uses of the transit instrument are either, by means of a star of known right ascension, to determine the time of observation, or else, by means of the observed time at which a star passes the meridian, to determine the star's right ascension. The transit instruments in the principal observatories are specimens of the highest mechanical and optical skill.

TRANSYLVANIA. The products and industry of Transylvania are briefly illustrated under AUSTRIA.

TRAVERTIN, the Italian term for concretionary limestone produced from springs holding carbonate of lime in solution. A large proportion of the most splendid edifices of ancient and modern Rome are built of travertin derived from the quarries of Ponto Leucano.

TREACLE. [MOLASSES; SUGAR.]

TREBIZOND. This town, situated at the south-east corner of the Black Sea, and the north-east corner of Asia Minor, is a place of much commercial importance. The trade has greatly increased since the navigation of the Black Sea was opened to all nations, and especially since the establishment of steamers, by which this town has a direct and regular communication with Constantinople, Odessa, and the Danube. The number of sailing vessels engaged in the commerce of the port in 1849 was 87; and a large trade is carried on by steamers, of which 23 English, 30 Turkish, and 24 Austrian, entered the port in the course of the same year. The entire value of the imports was 53,409,215 francs; the exports amounted to 14,251,406 francs, being an increase on 1848, when the exports amounted to only 6,239,790 francs. The imports shew a decrease on those of 1848, caused by the cheaper and safer means of transit to Persia by the Russian ports of Redut Kalé and Tiflis. The increase in the exports is chiefly owing to the larger quantity of Turkish copper and other produce, and of Persian silks, gall nuts, &c., shipped to Europe from this port. The chief imports are cotton manufactures, sugar, coffee, and other colonial produce. The Austrian Steamboat Company plies regularly between Trieste and Trebizond, and has lately extended its line to Batoom and Redut Kalé, to which latter place Russia aims at diverting the Persian trade, from the old route through Trebizond, Erzeroum, and Bayazid.

TREENAILS. In ship-building the outer planks are fastened to the timbers by thick oak pegs called *treenails*, driven through holes bored in the wood. They are formed of the soundest oak, whose grain is straight and regular. They vary in size from a foot and a half to three feet in length, and from one to two inches in diameter. The pieces of oak which may be selected for this purpose are first sawed to the proper length; the treenail makers then rip each piece into a number of smaller pieces, and finally reduce them to a tolerably cylindrical shape by means of spoke shaves. The treenails are left many months to season before being used.

Treenails are occasionally cut by machinery. Mr. Wilkinson patented an apparatus in 1849 for compressing treenails before use, so as to give them as much solidity and hardness as possible.

TRIBUNALS OF COMMERCE are courts established in all the large towns of France for the quick and inexpensive decision of commercial disputes, and all matters relating to trade and debt. The presidents and judges are chosen from among the most intelligent and respectable merchants of their respective towns, and serve without emolument. A president and two judges form a court, which sits every day except Sunday. The clerks are the only officers who are paid. The expense of these courts for the whole of France does not much exceed 7000*l.* sterling; their decisions are admitted to be highly satisfactory and equitable.

There is a movement now being made towards the establishment of something which, whether called a *Chamber* or a *Tribunal* of Commerce, shall fill a place in London commerce somewhat analogous to those of the French Tribunals.

TRIESTE, at the north-eastern extremity of the Adriatic, has been long a free port, and is the most important and wealthy commercial city in the Austrian dominions. Consuls of almost every nation in Europe reside there. The commerce of Trieste was much increased by the commercial treaty concluded with Greece in 1835, and by the new institution of the Austrian Lloyd's, which is supported by the government. The number of ships engaged in the commerce of Trieste is about 2400, of which, in 1849, 403 were employed on long voyages, and 27 were steamers. The steamers ply to Venice, Greece, Constantinople, Trebizond, and Egypt. A terminus for the Vienna-Trieste Railway, which is now opened nearly throughout, has been lately finished. Among the manufactures, oil-soap, leather, rosoglio, and wax, are the principal. Among the exports are the productions of the mines of Idria, those of Hungary, linens, tobacco, and woollens from different parts of the Austrian dominions, and printed calicoes from

Switzerland. The imports are cotton from Egypt; hides, raisins, silks, rice, and oil from the Levant; wheat from Odessa; and all kinds of tropical and colonial produce from the West and East Indies and Brazil. Ship-building, including the construction of frigates and men-of-war, is carried on to a great extent.

TRIFO'RIUM is a term applied to the upper galleries formed by small open arches above those dividing the nave from the side-aisles of a church, and beneath the clere-story windows: this intermediate tier being within the sloping roof over the aisles. In general the triforium is very shallow or narrow, and the arches in front of it small and low; but there are great differences in these respects even in buildings of the same period and style.

TRIGONOMETRICAL SURVEY. The merit of first applying trigonometry to geodetic operations belongs to Willebrord Snell, who in 1617 undertook a survey of Holland, for the double purpose of establishing the geographical positions of the principal cities in that country, and measuring a degree of the terrestrial meridian. The method which he followed was the same in principle as that which would be adopted at the present time. Having formed a series of triangles extending over the country, he observed their angles with a quadrant, and computed their sides from a base which was carefully measured with wooden perches on the ground. He also determined the direction of the meridian at Leyden, and observed its inclination to a side of one of his triangles, and thereby obtained the bearings of the different angular points. Lastly, by observing the altitude of the pole-star with a five-feet quadrant at Alkmaar, Leyden, and Bergen-op-zoom, he determined the amplitudes of two celestial arcs; and thence deduced the quantities of which he was in quest.

Since that time, trigonometrical or geodetic surveys have been made in various countries. A general survey of the British Islands, under the direction of the master-general of the Ordnance, was begun in 1791, and has been continued to the present time. The first conductors of this national undertaking were Colonel Williams and Captain (afterwards General) Mudge, of the Royal Engineers, and Mr. Dalby, who had previously assisted General Roy. Were it not for the admirable maps which are from time to time issued from the Ordnance map-office, it might be inferred that the survey had been discontinued during the last thirty years. The operation has however never been lost sight of. For some years after the last published account, the triangulation was carried on in Scotland, both along the eastern and western coasts. All the Ordnance maps of Great Britain south of a line from Preston to Hull have been published on a scale of one inch to a mile; but operations have commenced for publishing the northern section on the magnificent scale of 6 inches to a mile.

In respect to Ireland, the survey of that country was begun about 1818. A base was measured on the banks of Lough Foyle, near Londonderry, with an apparatus differing from any which had previously been used, and with precautions to ensure accuracy which probably have never been surpassed. Depending on this base, a net-work of triangles was established over the whole of Ireland. The topography of Ireland has been completed; and the angles of the different chains of primary triangles extending over the whole of Scotland and the adjacent islands have now also been observed. The entire map of Ireland has been published on the six-inch scale.

As one of the results of the various trigonometrical surveys, we give the following table of the lengths of degrees of latitude and longitude in English feet:—

Latitude.	Degree of Meridian.	Degree of Parallel Circle
0°	362748.5	365185.8
10	362858.0	359674.0
20	363173.7	343296.4
30	363658.1	316524.3
40	364254.0	280135.0
45	364575.6	258657.3
50	364889.9	235197.9
60	365489.1	183051.6
70	365978.9	125270.5
80	366299.2	63620.1
90	366410.5	0.0

TRINIDAD. The most remarkable physical feature of Trinidad is the Pitch Lake. It is about a mile and a half in circumference. The pitch at the side of the lake is perfectly hard and cold, but as one walks towards the middle with the shoes off in order to wade through the water, the heat gradually increases, the pitch becomes softer and softer, until at last it is seen boiling up in a liquid state. The air is then strongly impregnated with bitumen and sulphur, and the impression of the feet is left upon the surface of the pitch. During the rainy season it is possible to walk over the whole lake nearly; but in the hot season a great part is not to be approached.

Trinidad possesses some excellent harbours; Chaguaramas, Guaya-guayara, and Puerta d'España. On the last named stands the town called the Port of Spain, the capital of the island. Before 1783 the commerce of

Trinidad was very trifling. In 1787 the first sugar-plantation was established. All the usual productions of tropical countries grow luxuriantly. The nutmeg, cinnamon, and clove, have been introduced, and succeed remarkably well. In 1848 the exports amounted to 282,131*l.*, the imports to 309,257*l.*, and the revenue to 75,874*l.* Sugar, molasses, coffee, and cocoa, are chief articles of export.

The value of the British produce and manufactures exported to Trinidad in 1849 was 247,779*l.*

TRINITY HOUSE. This remarkable corporation has the management of some of the most important interests of the seamen and shipping of England. James II. granted the Trinity House the charter which is now in force, in the first year of his reign. It directs the masters and wardens to examine such boys of Christ's Hospital as shall be willing to become seamen, and to apprentice them to commanders of ships. It also enables them to appoint and license all pilots into and out of the Thames, and prohibits, under penalties, all other persons from exercising that office; it also authorises the corporation to settle rates of pilotage, &c.; to hold courts, &c.; to punish seamen deserting, &c.; and make laws as to other subject-matters not inconsistent with the laws of the kingdom. It also contains many provisions directed to the object of keeping the navigation of the channels secret from foreigners, and renders the officers of the corporation liable to attend when required at the king's bidding. Since that time several acts of parliament have been passed for the purpose of authorising the Trinity House to regulate matters connected with the pilotage, &c., of vessels.

The various provisions in matters of pilotage under the management of the corporation were repealed in 1826, and new arrangements made. At present, besides those under the jurisdiction of the Trinity House and of the lord warden of the Cinque Ports, many independent pilotage establishments exist in various parts of the kingdom; but the expediency of subjecting all these to the uniform management of the Trinity House has been felt for some time past. The inconvenience resulting from the exercise of similar authorities vested in the hands of different parties had been felt with regard to the *lighthouses* on the coast, several of which had been vested in private hands by the crown; while some had been in times past leased out by the corporation itself, the lights in both instances being found to be conducted probably rather with a view to private interest than public utility. By an Act, therefore, of 1827, provision was made for vesting all the lighthouses and lights on the coast of England in the corporation of Trinity House, and placing those of Scotland and Ireland under their supervision. Under this act purchases have been made by the corporation of the whole of the lighthouses not before possessed by that body, the amount expended for which purpose is near 1,000,000*l.*

The annual revenue of the corporation is very considerable, and is derived from tolls paid in respect of shipping, which receives benefit from the lights, beacons, and buoys, and from the ballast supplied. The ballast is raised from such parts of the bed of the river as it is expedient to deepen, by machinery attached to vessels, and worked partly by the power of steam and partly by manual labour. [DREDGING MACHINES.] The revenue is employed upon the necessary expenses of the corporation in constructing and maintaining their lighthouses and lights, beacons and buoys, and the buildings and vessels belonging to the corporation; in paying the necessary officers of their several establishments, and in providing relief for decayed seamen and ballastmen, their widows, &c. The deputy master and elder brethren are employed on voyages of inspection of their lighthouses and lights, beacons and buoys, not unfrequently in most trying weather and seasons; and they are also often engaged in making surveys, &c., on the coast, and reports on such matters of maritime character as are referred to them by the government.

TRIPOD is any article of furniture resting upon three feet, whence the name is given to tables, chairs, moveable altars, and other articles of the same kind. A chair or an altar of this kind must be understood when we read that the Pythia of Delphi gave her oracles from a tripod. We find also mention of tripods containing a certain measure of fluid, and in this case we have to understand a bowl resting upon a pedestal with three feet. The crater, or the vessel in which the wine was mixed with water at the banquets of the ancients, was very frequently a tripod of this description. The tripod was generally of metal and often of exquisite workmanship. Tripods were the most common presents to the temples of Apollo; tripods were given to the victors in the games which were celebrated in honour of Apollo; and tripods appear on innumerable coins which have any relation to the worship of that god. Some ancient tripods are preserved in the British Museum.

TRIPOLI. In this region of Northern Africa, those parts of the country which are moderately fertile produce a variety of grain, fruit, and trees. The wild trees and bushes are only used to make charcoal. Where charcoal is not to be had, camel's dung is used as fuel. Metals do not appear to be found; but salt is collected at a few places.

In *Tripoli*, the chief town and port, the trade is carried on in small vessels, seldom larger than brigs, none of which are now owned in the country. It has no direct trade with England, but an indirect one through Malta. Marseille, Leghorn, and the commercial towns of the Adriatic and the Levant, likewise trade with Tripoli. The trade of Tripoli must greatly depend upon the communication with the interior; and it profits once or twice a year from the passage of the pilgrims from Western Barbary on their way to Mecca. Formerly these caravans, composed partly of penitents and partly of traders, started from Fez, and passing through Tlemsen, Algiers, and Tunis, increasing as they went, on arriving under the walls of Tripoli, amounted sometimes to 3000 persons, and half as many camels and horses, with their goods and merchandise, returning by the same route. But the pilgrims now take a different route; and the caravans which stop at Tripoli in the present day seldom amount to more than a few hundred persons and animals. The cafilas or small caravans from Fezzan and Ghadamis are now the principal medium of inland trade. These people exchange their merchandise for that of Europe, and pay the balance in gold-dust.

TROMBO'NE, the same instrument as the *Sacbut*, is a deep-toned trumpet, composed of sliding tubes, by means of which every sound in the diatonic and chromatic scales, being within its compass, is obtained in perfect tune. The trombone is of three kinds—the *alto*, the *tenor*, and the *base*, and these, in orchestral music, are generally used together, forming a complete harmony in themselves.

The scale of the *Alto-Trombone* is from C, the second space in the base, to G, an octave above the treble clef; that of the *Tenor-Trombone* is from B, the second line in the base, to A, the second space in the treble; and that of the *Base-Trombone* is from C, an octave below the second space in the base, to G, the second line in the treble.

TROY WEIGHT. The troy pound is the legal standard, though only actually used in weighing precious metals and stones, and apothecaries' drugs. There is no doubt that it was originally the pound of silver, the pound sterling, and there is evidence that this pound was sometimes described as divided into twenty parts called sterling shillings. The pound troy is now divided, for gold and silver, into twelve ounces, each ounce into twenty pennyweights, and each pennyweight into twenty-four grains. But for medicines, it is divided into twelve ounces, each ounce into eight drams or drachms, each drachm into three scruples, and each scruple into twenty grains. A cubic foot of water weighs 75.7374 pounds troy. [Apothecaries Weight; Avoirdupois Weight.]

TRUCK SYSTEM. This system has much influence on the relation between employers and workmen, in the manufacturing districts. The term truck, which means exchange or barter, is now used to signify the payment of wages of labour in goods, and not in money. By the truck-system is meant this mode of paying wages, together with all its tendencies and results. The Truck Act is an act passed in 1831, which, repealing all the previous acts passed for the same purpose, made stricter provisions for the prevention of payment of wages in truck in the departments of industry therein enumerated. The wages of agricultural labourers and domestic servants are exempted from the operation of the act. The evidence published in the Report of the Select Committee of the House of Commons on this subject, in 1842, shows that, notwithstanding the Truck Act, the truck-system is still in extensive operation in mills, factories, iron-works, collieries, and stone-quarries in the kingdom, and abundantly illustrates the evil tendencies of the system.

The chief part of the evil of what is called the truck-system is incidental, and not essential to the payment of wages in truck, and arises out of the power of the master over the workman, which enables the master to use this mode of paying wages to defraud and oppress the workman. A master may pay the wages of his workmen wholly or in part in truck, in articles of food, clothing, &c., either by agreement or with only the understood consent of his workmen; and if he supply these articles at prices no higher than those at which they are to be procured elsewhere, and study to meet the various wants of the workmen and their families, the utmost harm that can result is the loss to the workmen of the moral and economical lessons which the disbursement by themselves of weekly money-wages is fitted to supply, and the interference with the business and profits of neighbouring retail shopkeepers; and there will always in such cases be some advantage to set against these, so far as they go, evil results. Where the truck-system acts beneficially, it is owing entirely to the justice and benevolence of the individual truck-masters. On the character of the master everything depends. In the hands of masters of opposite character, and under circumstances, whether of scarcity of employment, of isolated situation, or of combination among masters in the same business, or through an extensive district, which place the workman more or less at the mercy of his employer, the payment of wages in truck may be, and continually has been, and is still extensively, used for the defrauding and oppressing of workmen.

TRUMPET. This musical instrument is of the highest antiquity. It is a single tube eight feet long, less in diameter than the horn, doubled up in a parabolic form, sounded by means of a mouthpiece, and subject to the same acoustical laws which govern all instruments of this class. [HORN.] The natural scale of the trumpet extends to about twenty notes; but by the assistance of a small brass tube, called the tuning-pipe, or shank, by which the tube of the trumpet is lengthened, the number of notes may be increased. Music for the trumpet, as in the instance of the horn, is always written in the natural key of C, and the key to which the instrument is to be adapted is pointed out by the composer.

TRUSSING. The rods or bars which are added to a girder for the purpose of trussing or supporting it may be applied in two sets, one on each side of the girder, and connected together by short cross-pieces at the necessary points; or the beam or girder itself may be divided longitudinally into two halves, or flitches, separated just so far as to admit a single truss between them, and held in the right position by the insertion of small blocks. One of the simplest methods of trussing girders is that in which the beam rests upon walls at its extremities, and has two inclined struts, resting on notches in the timber at the lower end, and supported at the centre or junction by a vertical kingpost, screwed by a nut beneath the beam. This form is improved by connecting the lower ends of the inclined bars by an iron rod stretching in a perfectly straight line, and capable of being brought to any required degree of tension by means of screws or keys.

Cast-iron beams are frequently trussed with wrought-iron rods, in a similar manner to those of wood, and are applied to purposes for which great strength is required.

TUBES. Under the heading of PIPES is given a short notice of the different modes of making tubes, pipes, cylinders, and barrels, according to the nature of the material employed and the purposes to which the articles are to be applied. Mr. Hick has recently invented a contrivance for making *taper* tubes; that is, tubes which taper or diminish in diameter from one end to the other. The tubes are first made parallel or cylindrical, and are tapered afterwards. The machine employed effects this by excentric grooved rollers: a greater or less degree of taper being obtained by varying the proportion between the rate at which the tube is drawn through the machine and that at which the rollers revolve.

TUBULAR BRIDGE. [MENAI BRIDGES.]

TUMBREL, or TUMBRIL, was the name of a machine formerly used for the punishment of scolding women, consisting of a stool or chair attached to the end of a long pole, mounted in such a manner that the chair, with the offender placed in it, might be swung over a pond, and immersed as often as might be necessary. The tumbrel was also used as a punishment for brewers and bakers who transgressed the laws relating to them. The name is also applied to the covered carts used to carry tools, &c., in a train of artillery.

TUN. [TON.]

TUNGSTEN. This metal was first obtained in a perfect state by M. d'Elhuyart, in 1781. The name is formed of the Swedish words *tung sten*, 'heavy stone.' It has a grayish-white colour and considerable lustre. It is brittle, and nearly as hard as steel. Its specific gravity is 17.4, and with the exception of platina, gold, and iridium, is the heaviest known metal. It requires a very high temperature for fusion. It is not altered by exposure to the air. When heated to redness in the open air it takes fire, combines with oxygen, and is converted into tungstic acid. Nitric acid produces the same effect.

The chief minerals which contain tungsten are *Tungstic Acid*, or *Scheelic Acid; Tungstate of Lime; Wolfram*, or *Tungstate of Iron and Magnesia;* and *Tungstate of Lead.*

Tungsten combines with several of the simple substances; but the compounds have not yet been applied to many useful purposes.

TUNING FORK. In tuning the notes of a musical instrument, such as the pianoforte, the first point is to fix upon some one note, by the pitch of which all others may be determined. The only way of retaining a permanent pitch for use is by having an instrument which time will not alter. A standard pitch is usually obtained, or professed to be obtained, by the *tuning fork*, an instrument consisting of two steel prongs extending from a steel handle. When these prongs are sharply struck they vibrate, and if the instrument be then held to the ear, or placed upon the flap of a table, or any other sound board, a low and very pure sound is heard, if the prongs be perfectly equal. These tuning-forks are usually made to sound either C or A, and they would answer their purpose exceedingly well if there really were in existence any rigorous standard from which they were made. But there is not; and the consequence is, that not only do the tuning-forks of different makers frequently vary a little from each other, but the new forks are sensibly higher than the old ones.

In the tuning-forks employed by Mr. Hullah's Singing Classes, the tone is made to correspond to a certain definite number of vibrations in a second, as determined (nearly) by a remarkably delicate little acoustic instrument called the *siren.*

TUNIS. The foreign commerce of Tunis is the most considerable of all the Barbary states. It is not confined to the capital, but is also carried on briskly from the ports of the eastern coast. Among the manufactured articles of export are—soap, marocco leather, shawls, and red skull-caps. Wheat and barley, as well as the inferior grains, olive oil, wool, hides, bees'-wax, dates, and almonds, are the principal articles of produce exported. Those received from the interior of Africa, and afterwards exported, are—ivory, gold dust, ostrich-feathers, senna, and madder-roots. The imports are woollen cloths, cotton-prints, calicoes, muslins, coarse linens, damasks, raw and wrought silks, fine wool, gold and silver tissues, coffee, sugar, spices, iron, tin, lead, hardware, cutlery, arms of all sorts, earthenware, paper, wine, spirits, and tobacco. As ports of loading, those of Sfax and Susa are preferred to Tunis, in consequence of the distance and delay of transporting merchandise in lighters across the lake to the Goletta, where ships generally lie; the commerce of the country is consequently best carried on in vessels under 150 tons burden. The trade with central Africa passes through Gadamis. The caravans arrive at Tozer, Cabes, and Sfax about twice in the year, and barter their merchandise, which is thence introduced in various directions into Tunis.

It is exceedingly interesting to find that this distant, and (comparatively) little known country, has contributed liberally to the display of the world's industry at the Great Exhibition.

TUNNEL, in civil engineering, is an arched passage formed underground to conduct a canal or road on a lower level than the natural surface. Long tunnels are usually made through hills in order to avoid the inconvenience and loss of power occasioned by conducting a canal, road, or railway over elevated ground, and also the enormous expense of such an open excavation as would be necessary in order to preserve the requisite level. Those of less extent are frequently constructed to avoid the opposition of landowners, or to afford uninterrupted passage under a road, canal, or river.

Rocky strata, if the stone be of a nature to work freely, are usually the cheapest for tunnelling, owing to the absence of lining, and the power of saving labour by the use of gunpowder. Tunnelling in clay is frequently attended with formidable difficulties which render it very expensive. It is, when tough, a difficult material to remove, blasting being of no use, and spades and pick-axes being almost inapplicable. In such cases hatchets may be used to advantage, but cross-cut saws answer best. Tunnels formed through chalk are often impeded by faults or cavities filled with wet gravel or sand, which pour a flood of semifluid matter into the excavation as soon as they are cut into. The irruption of such loose materials, as well as of water alone, has in many cases occasioned difficulties almost insurmountable. Loose sand is perhaps the most difficult stratum that can be met with in tunnelling, but it has been in several instances successfully passed through.

Short tunnels are occasionally excavated from the ends only, but those of considerable length are usually formed by sinking vertical shafts, about nine feet in diameter, down to the level of the tunnel, and excavating in each direction from the bottom of each shaft, until the several parties of workmen meet in the intermediate portions. By this means the work can proceed at any required number of points or faces, so as to bring the execution of the tunnel, whatever may be its length, within a moderate period of time. The number of working shafts in a given length of tunnel is determined by the nature of the ground and the time allowed for excavation. Besides the working-shafts there are usually small air-shafts of three or four feet diameter to prevent the accumulation of foul air in the workings of the tunnel. In very long tunnels one or more large shafts are desirable for the purpose of ventilation, and also to admit some degree of light. When a complete brick lining is required, the bottom is the part first built, and it is completed by a course of stone laid along each side, at the point where the side walls spring from it.

The Thames Tunnel.—Many projects have been started for making a tunnel under the Thames; but the only one put into successful operation is that for which an act was obtained in 1824, with Mr. (afterwards Sir M. I.) Brunel as the engineer. Operations were commenced early in 1825 by the construction of a shaft 50 feet in diameter, at a distance of 150 feet from the south side of the river, at a point about two miles below London Bridge. A similar shaft was sunk on the north side of the river. The excavation for the tunnel was an oblong square, 38 feet wide and 22 feet 6 inches high, presenting a sectional area of 855 square feet. The shield by which the excavation was effected consisted of twelve massive frames of iron, placed side by side, and capable of being slid forward for a short distance independently of each other. The whole apparatus may be compared to a massive cofferdam laid on its side, and capable of being moved forward by the action of screws abutting against the end of the completed brick-work, which followed it up closely. Each frame of the shield consisted of three stories, each of which formed a cell large enough for one man to work in conveniently. The arrangements for supporting the wet clay of the Thames bed while the brickwork was being prepared, were of a very ingenious description.

The excavation of the tunnel was commenced in January, 1826, in a stratum of clay; but several irruptions of the river took place; one, in 1828, was so serious in its consequences that the Company did not resume operations till 1835. The tunnel is 1200 feet in length between the two shafts on the opposite banks of the river. It was not until 1843 that the Thames Tunnel was opened for foot passengers.

This grand undertaking has altogether failed to realise the commercial anticipations of its projectors. It has been, and still is, little more than a penny 'lion' of London; nor is it easy to see any probability that it will acquire trading importance.

TURF. A few details respecting turf will be found under FUEL and PEAT.

TURIN is the name not only of the capital of the Sardinian dominions, but also that of a division of the continental territory of the kingdom of Sardinia. This division has many provinces, which vary in produce and industry. In *Pignerol*, corn, excellent fruits, good wine, chestnuts, and silk, are the chief products. The forests are extensive, and there are many factories of silk, woollen, and leather. In the province of *Torino*, extensive forests and pastures, abundant wheat-crops, wine, and silk, form the elements of the wealth of this country; iron, vitriol, marble, and lime, are the chief minerals. The industrial and commercial activity is considerable. The province of *Susa* produces corn, wine, flax, hemp, and mulberries; and there are manufactures of leather, gloves, and thread. In the province of *Ivrea* the soil produces abundantly corn, excellent wine, and hemp. The pastures are good and cattle very numerous; silk is an important product. Iron, copper, marble, slate, and building stone, are the chief minerals. In the capital, *Turin* or *Torino*, the manufactures comprise woollen cloths, silks, hosiery, hats, gloves, optical instruments, chocolate, liqueurs, tobacco, leather, paper, earthen, and china-ware, carriages, arms, and tapestry

TURKEY. The large but ill-organised Turkish Empire is composed of many distinct portions, the produce, industry, and commerce of which have been briefly noticed under various headings relating to those districts and provinces. We may however state that the value of the British produce and manufactures exported in 1849, to European Turkey, exclusive of Wallachia and Moldavia, was 2,371,669.

Of Turkish industry, we have had a few opportunities of judging at the Great Exhibition.

TURKEY-HONE is a slaty, grayish, opaque, soft kind of stone, found in various parts of Europe and Asia. It is composed of silica, lime, alumina, and carbonic acid. When cut and polished, it is used for sharpening small cutting instruments. [GRINDSTONES.]

TURMERIC comprises many species of the *Curcuma* genus of plants. Of the *broad-leaved Turmeric*, the tubers are aromatic, and are used by the Hindoos, not only as a stimulating condiment and a medicine, but as a perfume. Its sensible properties are much like those of ginger, but not so powerful. It is employed in the East in cases of disease, as colic, cramp, torpor, &c., where stimulants are required. It is a native of Bengal, China, and various other parts of Asia, and of the Asiatic Islands. Some of the other species yield a kind of ginger, and some a kind of arrow root. The *common Turmeric* is occasionally wild, and it is also extensively cultivated in China, Java, Malacca, and in Bengal, prospering in a moist but not swampy soil. The Chinese sort is most esteemed, rather on account of its superior richness in colouring matter than from any other cause. Two varieties are found in commerce, the Round Turmeric and Long Turmeric. Turmeric possesses an acrid volatile oil and a colouring matter. It is used on account of the latter principle as a dye. The volatile oil gives it aromatic qualities, which render it useful in languid habits, where digestion is difficult and the circulation slow. It is of some importance as a dye; but it is as a condiment, both in the East and in this country, that it merits notice, as it is an ingredient in all *curry powders* and *curry pastes*.

TURNING is the process of giving a circular form to wood and other materials, by means of a lathe and cutting tools, as in wood and metal turning; or by the thrower's wheel (which is also a species of lathe) and shaping instruments, as in the manufacture of earthenware. The lathe may be described as a machine for moving the material to be wrought in such a manner that, being fixed opposite to the tool, any point in the circumference will act upon the whole circle in precisely the same way

Of all the publications which have appeared relating to the mechanical arts, there are few that we can rank with the late Mr. Holtzapfel's work on turning; for elaborate details, profuse illustrations, and instructive collateral information, it may almost be said to exhaust the subject to which it relates.

TURNTABLE. The *turntables*, or circular iron plates seen at most of the principal railway stations, are platforms on which a locomotive or carriage can be placed in order to be turned round in direction; the platform rotates on a central axis, and the road accompanies it. Where only a locomotive or an ordinary railway carriage are placed on the turntable, the latter need not be of great diameter; but in the instances where both a locomotive and its tender, or such long carriages as are now used on the North Kent and the North Woolwich Railways, are to be reversed, the turntable must be of very large diameter. A description has been lately given at a meeting of the *Institution of Civil Engineers*, of a turntable 42 feet in diameter, used on the Bristol and Exeter Railway. This turntable worked on a ball-pivot, and consisted of two central cast iron arms, or brackets, which carried at their extremities hollow wrought iron transverse girders for supporting the longitudinal timber beams, forming a framing on which were placed the rails—the outer ends being supported by other girders attached to the traversing wheels, which were 3 feet in diameter. It afforded a perfect and equal bearing throughout its entire length, not being depressed more than half an inch when the leading wheels of the engine struck the table; and an engine and tender, together weighing forty tons, were turned by the driver and stoker in three minutes. Tables on this principle have been erected both at Bristol and Exeter, and the cost, with the foundation, has been about 400*l*. each.

TURPENTINE. The common turpentine of commerce is imported from America in barrels and casks. It is a stiff, adhesive, honey-like paste, midway between the solid and the liquid state. It consists of two very different component parts: a clear transparent liquid, which constitutes *oil* or *essence of turpentine;* and a yellowish or brownish solid which forms common *resin*. The separation of these two substances is effected at the turpentine works, of which there are several in this country. The thick turpentine is put into a still and exposed to heat; it first melts into a liquid, and then the essential or oily portion rises in vapour, leaving the resinous portion still liquid. The vapour leaves the still, and passes through a refrigerator or cooling vessel, whereby it is brought to a liquid form. When the residue is removed from the still, it forms *black resin* or *yellow resin*, according to the kind of turpentine which had been employed.

The turpentine imported in the last three years amounted to the following quantities:—

1848	401,787 cwts.
1849	412,042 ,,
1850	434,621 ,,

TURQUOISE. This beautiful mineral occurs in masses; it has a greenish blue colour, and is usually opaque. It is found in alluvial clay, near Nishapoor in Persia. It consists chiefly of phosphate of alumina.

TURRET or toweret is used as the diminutive of *tower*, and denotes that what is so described is small in comparison with the main structure, of which it forms a part. Turrets are frequently attached to one or more of the angles of a tower, and contain a winding stair leading to the roof of the tower. Sometimes they are formed on the upper part only of a building.

TUSCANY. About one-sixth part of this Italian State is planted with vines and olive-trees; another sixth is cultivated as arable land; nearly two-sixths are either forests or plantations of chestnut-trees, which afford food to the population of the mountains; and nearly as much again is pasture land. The most common way of letting land is on the 'metayer' system, by which the farmer finds half the seed and implements, and gives the owner half the produce in kind; the landlord stocks the farm, and a valuation is given to the farmer, who is to make all good on leaving.

Tuscany, besides the usual agricultural crops, produces wine, oil, and silk. The other articles of native produce exported are—fruit of various sorts, lamb and kid skins, potash, timber, cork, juniper-berries, marble and alabaster, iron from Elba, borax, sulphur, alum, and anchovies, which are fished off the coast. Nearly the whole trade of Tuscany with other countries is carried on through the port of Leghorn. The mineral products are—iron, from the island of Elba, the ore of which is smelted and cast on the mainland, at Cecina, Valpiana, and Follonica; copper, lead, marble, sulphur, rock-salt, alabaster, and alum. Sea-salt is made chiefly in Elba.

The manufactures of Tuscany consist of woollen, hempen, and linen cloths; woollen caps for the Levant; silk stuffs, paper, glass, leather, wax; coral, which is gathered on the coast of Barbary and worked at Leghorn; iron-ware, alabaster vases, and other ornaments, wrought at Volterra; china and delft ware. The straw-plat manufacture has declined greatly of late years.

The exports of British produce and manufactures to Tuscany in 1849, amounted in value to 777,273*l*.

TUTENAG, is an alloy used in China in the manufacture of the *Gong*. It is white, resembling silver in appearance, and is very sonorous when struck. It consists of copper 40, zinc 25, nickel 32, iron 3. It is susceptible of a fine polish, and does not readily tarnish. At common temperatures, and even at a red heat, it is malleable, but when heated to whiteness it is rendered brittle. The composition is nearly the same as that of German Silver.

TYPE-FOUNDING. In the article PRINTING a general view is given of the various steps in the invention of typography, or the art of printing from moveable types, and a brief notice of the individuals whose ingenuity contributed, more or less, to the perfection of the process of type-founding. Most of the early printers, in England as well as on the Continent, were accustomed to cut and cast their own types. It has since become a separate business

The first and most important operation of a type-foundry is the formation of the *punches*, which are well-tempered pieces of steel, each of which bears on its surface a single letter, formed with the greatest possible accuracy by filing, cutting, and punching the hollows with smaller punches. The face of the punch exactly resembles that of the finished type, the letter being reversed, and in high relief. The punch-cutter has to exercise great care and judgment for making the letter of precisely the right size, form, and thickness, so that it may range well with other letters of the same *Fount*, or set. When the punch is completed and hardened, it is struck into a piece of copper, which, when it has received the impression from the end of the punch, is called a *Matrix*, and forms a mould for the face of the type.

The *Mould* for casting the type consists of two halves, each of which is made of steel, and attached, for convenience of holding, to a piece of wood. The two halves of the mould are so formed that they may be instantaneously fitted together, leaving a square funnel-shaped opening at the top, by which the type-metal is poured into the mould to form the body of the type, with the matrix at the bottom to form the letter or face. The two halves of the mould are capable of adjustment to the varying widths of the letters. The type-metal is usually melted in a small cast-iron pot, set in brickwork with an enclosed fire under it, and is poured into the mould by a very small ladle. The caster then jerks the mould quickly upwards by a peculiar motion of his arm, and thereby expels the air, and forces the fluid metal to enter the cavities of the matrix. Some founders use a small force-pump to aid this operation. When the metal is set, the caster removes the pressure of a long curved spring which is attached to the bottom of the mould, and thereby separates the matrix from the face of the type. The mould is then opened, and the type is removed by the application of a hook attached to the upper part of the mould.

When the types leave the caster, each of them has a small block of metal attached to the shank, or body of the type, being that which filled the throat or funnel of the mould. These are removed by a boy. The next operation is that of rubbing the flat sides of the types upon a piece of gritstone. The types are then set up by boys in long rows or lines, and these are firmly secured in long frames, which hold them together while the dresser scrapes or polishes the flat surface which form the top and bottom of the body, and cuts a groove or channel along their lower ends by means of a small iron plane. While they are in the frame the types are also *bearded*, an operation which consists in planing away to a bevel the upper angle of the body at the feet of the letters. After dressing, the types are tied up in such lines as may be convenient, and the proportionate numbers of every type of which a fount consists are selected. All the types belonging to one fount are distinguished by one or more grooves or *nicks* across the lower edge or bottom face of the body, by which simple contrivance the compositor is enabled to pick up the types and place them all upright without looking at the letter. These nicks are formed by the insertion of one or more wires in the mould. Four casters and two boys can cast, break, and rub 2,000 types in an hour.

The composition of type-metal greatly varies; the chief component however is lead, alloyed by one or more of the following metals —iron, antimony, copper, brass, tin, and bismuth.

As the several letters of the alphabet are, in common printing, required in very different proportions, the number cast of each letter in a fount needs to be carefully regulated. The proportions vary in different languages, and in different kinds of work; but for ordinary English book-work they are about as follows:—

a	8,500	n	8,000	ff	400
b	1,600	o	8,000	fi	500
c	3,000	p	1,700	fl	200
d	4,400	q	500	ffi	150
e	12,000	r	6,200	ffl	100
f	2,500	s	8,000	æ	100
g	1,700	t	9,000	œ	60
h	6,400	u	3,400	,	4,500
i	8,000	v	1,200	;	800
j	400	w	2,000	:	600
k	800	x	400	.	2,000
l	4,000	y	2,000	'	700
m	3,000	z	200		

The names of the various founts, beginning with the smallest and ending with one of the largest used in ordinary book-printing, are— *Diamond, Pearl, Ruby, Nonpareil, Minion, Brevier, Bourgeois, Long Primer, Small Pica, Pica, English, Great Primer.* Larger founts than any of these are occasionally used.

At the Great Exhibition, Messrs. Miller and Richards have displayed type still smaller than *Diamond*, and said by them to be the smallest ever made in this country. The name of *Brilliant* is given to it. Gray's Elegy (32 verses), printed in this type, occupies a space rather less than 4 inches by 3.

The following details have recently been given concerning the types for printing the Great Exhibition Catalogues:—"The first step towards the accomplishment of this vast undertaking was the creation of the type necessary to print four editions—and Messrs. Clowes and Son, being type-founders as well as printers, came to the resolution of having the whole of the type cast specially for the purpose. Their first effort was directed to produce the type for the small English, French, and German catalogues; the quantity cast for the purpose was 16,000 lbs. For the large and illustrated edition they have, in addition to their own foundries, employed those of Messrs. Figgins, Messrs. Bezley and Co., and Mr. Caslon, of London, and Messrs. Miller and Richards, of Edinburgh. The joint exertions of these firms have added 25,000 lbs. more to the general stock set apart for this vast undertaking; making a total of 41,000 lbs. The casting of this large quantity of type gave employment to 250 persons for ten weeks. The number of separate pieces in 20 tons of type amounts to upwards of 26 millions, and each type or piece of metal passes through the hands of five persons in the process of manufacture."

TYROL. In this very interesting country the most fertile lands are in the valleys of the Inn and of the Adige. Wheat, rye, barley, and oats are cultivated; in some parts buckwheat is grown; and millet is also grown, but not extensively. Indian corn is the principal object of agriculture in the southern valleys, and potatoes are nearly as much cultivated as in the northern. Hops grow wild, and tobacco is cultivated to some extent in the southern valleys. Flax and hemp are grown. Fruit-trees abound in the southern valleys, and large quantities of fruit are exported to Bavaria. Near Trent are plantations of fig-trees, and at Roveredo chestnuts are very common. In these parts are also plantations of olive-trees and mulberry-trees. A considerable quantity of silk is annually collected. On the banks of the Lago di Guarda are plantations of oranges. Wine is made in large quantities, and some sorts are very good, but they do not keep. Gold, silver, and copper are found; lead, iron, calamine, and coal mines are worked. There are productive mines of rock-salt near Hall, below Innsbruck. In the southern districts there is a valuable kind of white marble which is much worked.

Though the inhabitants are extremely industrious, Tyrol is not a manufacturing country. The women spin flax, weave linen, knit caps and stockings, make baskets and straw hats; the only manufactures of any importance are carried on in the chief towns. The transit trade of Tyrol is considerable, and much facilitated by the admirable roads. Many of the inhabitants annually migrate as pedlars or hawkers.

U

ULMIC ACID, or ULMINE. Some trees, and more especially the elm, when it is old, secrete a liquid which dries as it exudes; the residue consists principally of mucilaginous matter, with some carbonate or acetate of potash, and eventually the mucilaginous matter undergoes a change, and, combining with the potash, forms a substance which was first examined by Vauquelin and Klaproth, and Dr. Thomson gave it the name of *Ulmin.* It is of a deep brown colour, very brittle, and breaks in angular fragments, and is almost insoluble in water. It may be procured from soils, rotten leaves, bog-earth, wood-soot, or turf. It is an important element in manures and soils; and what is called *moss-water* owes its peculiar properties to its presence. It is a powerful manure, especially when combined with lime or with ammonia.

ULTRAMARINE, is a well-known blue pigment of extraordinary beauty and great permanence.

Ultramarine was originally prepared from the *lapis lazuli* or *lazulite.* This mineral presents itself in small masses of granular structure, in a rock of heterogeneous structure; this rock, which in commerce is called *lapis*, sells for a higher or lower price for pigments according to the proportion of lazulite which it is found to contain. The most perfect specimens of lazulite are used as gems; while the less perfect are used in the preparation of ultramarine. The lazulite is made red hot, quenched, pounded to powder, washed, dried, made into a paste with pure linseed oil and certain resinous substances, kneaded, diffused in hot water, and allowed to settle until the ultramarine (leaving all the other ingredients) falls to the bottom. The whole of these processes require great care.

This colour is now prepared at a very moderate price, and equal in beauty to that obtained from the lazulite. M. Gmelin of Tübingen considers that sulphuret of sodium is the colouring principle both of the natural mineral and the artificial products. The artificial ultramarine is stated to be prepared by adding freshly-precipitated silica and alumina, mixed with sulphur, to a solution of caustic soda, and the mixture is to be evaporated to dryness: the residue is put into a covered crucible and exposed to a white heat, by which, when the air has partial access to it, a dark pure blue mass is obtained. The product is then reduced to impalpable powder. The proportions of materials to be used are, about 36 silica, 36 alumina, 24 soda, and 3 sulphur.

UMBER, is an ore of iron and manganese, employed as a brown pigment. The structure is earthy, and the colour varied from red to brown. It occurs in beds with brown jasper in the Isle of Cyprus.

UNGUENTS. [OINTMENTS.]

UNITED STATES. The following details will illustrate a few among the many aspects under which the produce, industry, and commerce of the United States of America present themselves to our notice.

In the year ending June 1850, the United States imported 247,951 tons of bar iron, 14,706 tons of hammered iron, 10,104 tons of scrap iron, and 74,874 tons of pig iron. New York exported 4,844,574 dollars' worth of produce and commodities in that year, more than two-fifths of which went to Liverpool alone. The cotton exported in the same year was 635,381,604 lbs., being far below the average of recent years.

The exports from the United States in the year ending June 1849 amounted in value to 145,755,820 dollars of which two thirds were in United States' vessels. The imports (paying duty) in the same period were 147,857,439 dollars; of which five-sixths were in United States' vessels. The domestic exports were thus made up:—

	Dollar
Produce of Fisheries (fish, fish-oil, spermaceti, whalebone, &c.	2,547,654
Produce of Forests (timber, bark, dyes, potash, turpentine, tar, &c.) . .	5,917,994
Produce of Agriculture (cattle, meat, butter, cheese, corn, cotton, &c.) . . .	111,059,378
Manufactures and Miscellaneous,	13,141,929
	132,666,955

The remainder of the exports (about 13,000,000 dollars) were re-exported foreign commodities.

More than half of the entire exports of domestic produce were sent to Great Britain.

In the next following year, that is, the year ending June 1850, the exports of domestic produce from the United States was 136,946,912 dollars, of which Great Britain and its dependencies took the enormous value of 81,687,051 dollars; considerably more than half of which was comprised in the single article of cotton.

The following table shows the progress of the population and wealth of New York:—

Year.	Population.	Value of Real and Personal Estate.
1800	60,489	24,486,370 dollars.
1810	93,373	69,530,753 „
1820	123,706	69,530,573 „
1825	166,086	101,160,046 „
1830	202,589	125,283,518 „
1835	270,089	218,723,703 „
1840	312,852	252,843,163 „
1845	371,223	239,938,317 „
1850	517,849	256,217,093 „

To show how the various states of the American Union stand related in respect to ship-building, we give the numbers for the year ending June 1850:—

States.	Steamers.	Total—Ships and Steamers.	Total Tonnage.
Maine	6	326	94,211 73
New Hampshire	—	10	6,914 32
Vermont	1	1	77 41
Massachusetts	2	121	35,836 14
Rhode Island	1	14	3,537 15
Connecticut	1	43	4,819 79
New York	32	224	53,342 73
New Jersey	3	57	6,201 68
Pennsylvania	31	185	21,409 93
Delaware	1	16	1,813 82
Maryland	4	150	15,964 80
District of Columbia	—	8	288 17
Virginia	5	34	3,534 04
N. Carolina	5	33	2,691 55
Georgia	3	5	683 82
Florida	—	2	79 75
Alabama	—	3	118 66
Louisiana	4	24	1,582 38
Kentucky	34	34	6,460 69
Missouri	5	5	1,353 82
Illinois	1	13	1,691 21
Ohio	16	31	5,214 62
Michigan	3	14	2,061 63
Texas	1	1	105 54
Oregon	—	2	122 42
Total	159	1,356	270,117 80

In the year ending June 1850, the merchant ships which left ports of the United States amounted to 18,195, of which 8379 were American and 9816 foreign. The tonnage of these vessels was 4,361,002 tons. The total of the crews entered as belonging to those vessels was 195,871. From New York alone the number of ships cleared was no less than 2818, of 1,106,070 tons. In the first nine months of 1850, there were 19 steam ships and 18 sailing vessels launched at New York; and at the end of that period there were 19 other steamers and 12 other sailing vessels building. The numbers of passengers which have arrived at New York during the last ten years are as follow:—

Year.	Passengers.	Vessels.
1841	57,337	2,118
1842	74,949	1,960
1843	46,302	1,832
1844	61,002	2,208
1845	82,960	2,044
1846	115,230	2,289
1847	166,110	3,147
1848	191,909	3,060
1849	221,799	3,237
1850	126,287	3,489
	1,143,885	25,384

In June 1850 the length of the inland mail routes in the United States (not including Oregon and California) was 178,672 miles; and the annual transport on those roads amounted to 46,541,423 miles. The number of post offices in the United States in that month was 18,417.

On January 1, 1851, the length of Railways in the United States amounted to nearly 9000 miles, and the cost to upwards of 60,000,000*l.* sterling. They were distributed among the states in the following ratios:—

	Miles.	Cost.
New York	1402	56,202,060 dollars.
NewHampshire,	452	15,046,080 „
Rhode Island	50	2,614,484 „
Maine	220	5,765,518 „
Vermont	348	10,038,897 „
Massachusetts	1056	48,235,997 „
Connecticut	513	15,245,508 „
New Jersey	259	8,225,000 „
Pennsylvania	917	35,008,033 „
Delaware	17	600,000 „
Maryland	322	13,044,172 „
Virginia	384	7,378,349 „
NorthCarolina,	249	4,000,000 „
SouthCarolina,	271	6,243,678 „
Georgia	716	11,572,280 „
Alabama	114	950,000 „
Florida	54	280,000 „
Mississippi	90	795,600 „
Louisiana	89	603,000 „
Tennessee	33	600,000 „

	Miles.		Cost.	
Kentucky....	77	..	1,480,000	dollars.
Indiana.....	219	..	4,600,000	„
Ohio........	450	..	7,268,793	„
Illinois......	117	..	2,100,000	„
Michigan....	352	..	7,704,633	„
Wisconsin...	20	..	400,000	„

URA'NIUM, is the name given to a metal discovered by Klaproth, in 1789, who named it after the planet Uranus, the discovery of which had previously occurred in the same year. The mineral from which it was first obtained is called *Pechblende*, or *Pitchblende*. It is a white lustrous metal. At a moderate degree of heat, in contact with the air, it burns with a white and shining light. The combustion occurs at so low a temperature, that it may take place on paper without causing it to burn. If small particles be shaken from the filter on which the metal in powder has been collected, portions so minute as to be scarcely visible burn with brilliant sparks on coming near the flame of a candle. When heated in a capsule, uranium burns brilliantly and is converted into a deep green-coloured oxide, the bulk of which is considerably greater than that of the metal employed. It does not appear to suffer any alteration by exposure to the air, nor does it decompose water at common temperatures.

The minerals which contain uranium, and from many of which it may be obtained, are numerous. They comprise *Pitchblende* (oxide), *Uranite* (calcareo-phosphate), *Chalcolite* (cupreo-phosphate), *Uran Bloom* (carbonate), *Johannite* (sulphate). The various compounds of the metal with other substances are of but limited use in the arts; the *protoxide*, however, is employed in colouring glass, to which it imparts a fine lemon yellow.

URUGUAY, or *Banda Oriental*, an independent Republic in South America, is of moderate natural richness. A valuable copper mine is worked near San Carlos. The valleys on the west and south are well adapted to a great diversity of production. Wheat, rye, barley, Indian corn, rice, peas, beans, water-melons, and other kinds of melons, with onions, are cultivated; also some cotton, mandioca, and the sugar-cane. Hemp and different qualities of flax grow in great abundance Timber is by no means abundant. More than four-fifths of the country being only fit for pasture, cattle of course constitute the chief wealth. Some cattle are consumed in the country, and others sent to the slaughter-houses of Monte Video, whence hides are exported in large numbers. By far the greatest proportion of the flesh is converted into jerked beef, which is salted without the bones, dried in the sun, and exported to different parts of America, especially Brazil. Every great pro prietor breeds also a certain number of horses and mules, and some of them a great number of sheep, which have a fine wool.

UTRECHT, one of the Dutch provinces, is a productive and busy district. The natural productions are—the common domestic animals, poultry, fish, bees, wheat, tobacco, buckwheat, pulse, garden-fruit, culinary vegetables, flax, and hemp. The manufactures are chiefly in the towns, and consist of woollen, cotton, silken, and linen fabrics: there are also breweries and distilleries. The exports are—corn, cattle, swine, butter, cheese, some manufactured goods, bricks, and tiles. The roads in this province, which are remarkably smooth, are paved with clinker bricks. All the heavy traffic is carried on by the canals or railroads to Amsterdam and Arnhem. Another line of railway now unites the town of Utrecht to Rotterdam. In Utrecht, the capital of the province, the inhabitants manufacture woollen cloths, silk, lace, and needles; they have also sugar refineries and bleaching grounds.

V

VACUUM, or VOID. In scientific enquiries the name *vacuum* is given to space wholly free of matter, or perfectly empty. In the common phrase, space is called empty when, so far as air can fill space, it is full of air; and even in a more scientific form of speech, there is said to be a vacuum when there is only such an approach to a vacuum as the operations of philosophy can procure. Thus in the vacuum of the air-pump, however long the attempt at exhaustion may be continued, there is always air left, though in a highly attenuated state; and even in the mercurial vacuum, or in the space which is left over the mercury of the barometer, there is not unfrequently a slight portion of air, and always an atmosphere of the vapour of mercury. Physically speaking, it is perhaps impossible to procure a vacuum: it is most likely that, even if a real vacuum could be procured for an instant, air or other vapour would at once begin to be disseminated from the sides of the vessel in which the vacuum was made, and that the vacuum would thus instantly cease to exist.

In steam machinery, the whole efficacy of the apparatus is dependent on the recurrence, at regular intervals, of a vacuum, or an approximation towards a vacuum, in certain cylinders into which steam passes. [AIR-PUMP; HYDRAULICS; STEAM ENGINE.]

VALENCIA. A large proportion of this beautiful Spanish province is among the most fertile and best cultivated districts in Europe. The plain or vega of Valencia is about 30 miles long and 20 wide; the whole of this district is planted with olive, mulberry, ilex, algaroba, orange, and palm-trees, and has the appearance of an immense garden. Such is the fertility of the soil that two and three crops in the year are generally obtained. The rice crops are the most valuable, and are chiefly produced in the tract which is irrigated by the Albufera, a large lake in the neighbourhood of Valencia. The other chief product is the white mulberry, for the feeding of silkworms: the produce of silk from the vega of Valencia amounts to above one million of pounds yearly, a great part of which is exported in its raw state to France. The export of fruit from Valencia is also considerable; of raisins, the quantity exported has in some years been close upon 150,000 cwts. to England alone. The exports of barilla, almonds, figs, oil, saffron, wool, brandy, and wine, from different ports of Valencia is also very great, particularly the wine called Beni Carlo, which comes from a town of that name.

Mercury, copper, sulphur, arsenic, gold, silver, lead, iron, coal, and antimony, are among the mineral products. Woollen, linen, and silken goods are made in several towns of the province, but chiefly for home consumption. Cordage made from the fibre of the esparto, mats, tiles, soap, glass, paper, pottery, and earthenware, are exported to all parts of Spain. Salt is largely exported to Sweden.

In the city of Valencia, the imports are codfish, bricks, iron, coals, tobacco, colonial produce, hides, manufactured goods, linen, hardware, trinkets, Norway deals, and Dutch cheese. The exports are composed of barilla, wine, raisins, almonds, lead, brandy, oranges, raw silk, saffron, oil, wool, bass mats and ropes, salt, liquorice, and aniseed. The inhabitants are chiefly devoted to agriculture, although many branches of trade flourish in the city. Velvets, taffetas, flowered damask, and other silk stuffs are manufactured for the home market. Woollens, camlets, hats, table-linen, gauzes, artificial flowers, pottery, and earthenware, glass, and paper, are also made in small quantities.

VALERIAN is a herb or undershrub possessing many valuable qualities. It is a native of Europe, and by the sides of rivers and in ditches and moist woods is abundant in Great Britain. The root has a very strong smell, which is dependent on a volatile oil. It is very attractive to cats, and also to rats, and is employed by rat-catchers to decoy rats. It is employed also in medicine at the present day. The root, or more properly the rhizoma, with its root-fibres, is used in medicine. The medicinal action is chiefly due to the volatile oil and extractive.

VALPARAISO, a large town and important seaport of Chile, is yearly rising into rank as one of the leading commercial depôts on the Pacific shore of America. In 1809 only 9 vessels entered the harbour, in 1836 the number averaged 40 per month; in 1849 the total number of foreign vessels that entered was 968. The customs revenue for 1849 was 2,022,577 dollars. There are large ship-building yards, and extensive bonding ware-houses. Many vessels engaged in the Pacific trade come to Valparaiso for provisions, which may be put on board without their dropping an anchor. Valparaiso is the central depôt for the produce of Chile. Large quantities of corn, and other articles of provisions, are shipped here for Callao, Panama, and San Francisco. Besides wheat, the chief exports are—copper (of which 76,515½ quintals were shipped in 1849), gold, and silver; tallow and hides; timber, indigo, wool, sarsaparilla, fruits, &c. The imports are—foreign manufactured goods, chocolate, tea, coffee, sugar, tobacco, hardware, &c., &c. The British exports to Valparaiso exceed a million sterling annually. The French and American commerce with this port is also very important. The trade of Valparaiso has greatly increased since the discovery of gold in California. Steamers ply regularly to Callao and other Pacific ports.

VALVE is the name given to any apparatus by which, in an hydraulic or pneumatic machine, the bore of a pipe or any orifice may be alternately covered and uncovered, in order in the one case to prevent, and in the other to permit, the passage of the fluid.

The ordinary pump-valve, frequently called a *Clack*, consists of a piece of leather rather larger than the bore or orifice. Circular plates of lead or brass are fastened to the upper and lower surfaces of the leather; and the valve thus formed is capable, from the flexibility of the leather, of turning, as on a hinge, at the place of its connection with the rim. After a certain quantity of water has forced its way through the orifice, the valve, by its weight, falls, and closely covers the orifice, so that the water above is in great part prevented from returning.

Frequently a narrow bar of metal is made fast across a circular orifice in the direction of a diameter, and two semicircular valves of leather, each of which is covered above and below with a brass plate of the same form, turn upon the sides of the bar as upon hinges. This is called the *Double-Clack*, or the *Butterfly*-Valve.

The conical or *Spindle* Valve is a metal body in the form of a frustum of a cone, the side of which makes an angle of 45 degrees with a diameter of the base, and its convex surface is ground so as to fit exactly the corresponding side of the orifice. It is usually employed as the safety-valve to the boiler of a steam-engine. The frustum is lifted up vertically by the pressure of the steam, and when the steam has passed, it falls back by its weight.

The valve employed for the usual air-pumps consists merely of a slip of thin bladder thoroughly soaked in oil, its breadth being little more than is necessary to cover the orifice. When the pressure of the atmosphere is in part removed from the barrel, some of the air which is in the receiver forces its way, by its elasticity, through the orifice, and escapes at the sides of the valve. The valves of machines for condensing air are like those of a rarefying pump, but they are placed in contrary positions.

VANA'DIUM, a metal discovered in 1830, has somewhat of a silvery lustre, is extremely brittle, is a conductor of electricity, and at common temperatures is not acted upon by air or water; when heated to low redness in the air, it burns and is converted into black oxide. The compounds which this metal forms with other substances have not yet been applied to much practical use.

VAN DIEMEN'S LAND. The mineral wealth of this British colony is not yet much known. So far as it has been investigated, it includes copper, iron, lead, zinc, manganese, coal, slate, salt, and sandstone. Little has yet been done in mining operations. All grains cultivated in England succeed well. Wheat is of excellent quality, weighing generally from 62 to 64 pounds the bushel: considerable quantities are exported. Barley and oats will only thrive in a good soil. The vegetables and fruits of Europe are cultivated by the colonists in great abundance. The spermaceti whale is very abundant in Bass's Strait, and many of them are annually taken, but more by the inhabitants of Australia than by those of Van Diemen's Land. Black whales abound in all the seas round the island, and a very lucrative fishery is carried on along the southern coast. Whale-bone and train oil are important articles of export. The most useful tree in the colony is the Stringy Bark Tree, which is used for building and fencing; and the Blue Gum Tree, of which most of the boats in the colony are built. The smaller trees are used for masts for small vessels.

The efforts of the local government are rapidly extending improvements over the island. No fewer than 24 bridges were built by the government between 1842 and 1847. In 1847, 5538 emigrants arrived in the colony from Great Britain, and 4787 departed from it (chiefly to Port Philip and South Australia). Among the greatest works now constructing is a bridge over the Derwent, on the high road from Hobart Town to Launceston; it is of wood, and will have twenty bays or arches of 32 feet span each. The manufacturing establishments of Van Diemen's Land in 1847 included 46 breweries, 15 candle factories, 4 dye-works, 17 engineering and foundry works, 80 mills, 3 potteries, 10 printing-offices, 16 ship-yards, and 44 tan-works. The vessels which entered the colony in 1847 were 617 (burthen, 86,940 tons). The vessels built in the colony in that year were 12 (burthen, 1361 tons). The vessels belonging to Hobart Town were 140 (burthen, 11,521 tons); and those to Launceston 44 (burthen, 3373 tons). The value of the fisheries in that year was estimated at 70,000*l.* The live stock comprised 16,212 horses, 82,194 cattle, 1,833,866 sheep, and 2964 pigs. The staple article of produce is wool. A considerable trade is carried on with South Australia and Port Philip, in sheep. Van Diemen's Land produces not only a sufficient supply of grain for domestic consumption, but has contributed for several years to supply the deficiency in New South Wales.

The total exports for 1847 were valued at 600,867*l.*; the four chief items were—wool, 247,240*l.*; wheat, 85,683*l.*; flour, 40,595*l.*; and oil, 63,165*l.* The imports in the same year were valued at 724,593*l.*; the five chief items were—woollens, 108,175*l.*; cottons, 35,679*l.*; apparel and haberdashery, 48,388*l.*; hardware, 41,030*l.*; and sugar, 51,615*l.* The British produce and manufactures imported in 1849, were valued at 315,021*l.*

VANILLA. As the greater portion and the finest kinds of the Vanilla of commerce are imported from Vera Cruz, the most important species must be natives of Mexico. The fruit is the only part of the plant that is used. It has a balsamic odour, and a warm agreeable flavour. For these properties it is indebted to a peculiar volatile oil, and to a considerable quantity of benzoic acid. The fruit is gathered when it gets yellow, and it is first allowed to ferment for two or three days: it is then laid in the sun to dry, and when about half dried it is rubbed over with the oil of cocoa: it is again exposed to the sun to dry, and oiled again a second time. The fruit is then collected in small bundles, and wrapped up in the leaves of the Indian reed. Neither in Guiana nor in Mexico is the vanilla plant cultivated, but the fruit is collected by the natives, who sell it to the Europeans.

VAPOUR consists of ponderable matter combined with sufficient heat to enable it to retain its aëriform state. The difference between *vapour* and *gas* is one of degree only: for when atmospheric air containing, as it always does, the vapour of water, is suddenly cooled by exposure to a colder substance, the water which it contained in the state of invisible vapour it deposited in the state of palpable water on the colder body; and many gaseous bodies which were once considered as permanently elastic have been shown by the important investigations of Dr. Faraday to be reducible to liquids. [EVAPORATION.]

VARNISH is a fluid applied to the surfaces of various articles, as wood, &c., and which, by the evaporation or chemical change of a portion, leaves upon them a shining coating impervious to air and to moisture. Varnishes may be divided into three classes, alcoholic or *spirit* varnishes, *volatile oil* varnishes, and *fixed oil* varnishes.

Spirit varnishes are in general prepared very readily, are easily applied, soon become dry, and emit no disagreeable smell: they are, however, liable to crack or scale off, and are incapable of resisting friction or blows. The following are among the most approved spirit varnishes:—Take of mastich 6 ounces, sandarach 3 ounces, reduced to fine powder, and add 4 ounces of coarsely-powdered glass, which prevents the resins from agglomerating into a mass, or sticking to the bottom of the vessel; digest in a quart of spirit of wine, contained in a loosely-corked vessel for three days in a warm room, shaking the mixture frequently; then add 3 ounces of melted Venice turpentine to the warm solution, stirring thoroughly till mixed; let the mixture remain in a warm room for about a week, and then strain it. This is a strong varnish applied to chairs and other articles of furniture. Another varnish is formed of copal which has been liquified and afterwards very finely powdered, 3 ounces, mastich 2 ounces, and elemi 1 ounce; digest in a warm room in a quart of spirit, and when the solution is complete, add 2 ounces of Venice turpentine. This is a good varnish for violins and other musical instruments. For different purposes the ingredients of spirit varnishes are considerably varied: seed-lac, benzoin, anime, or frankincense, entering into the composition, according to the use to be made of them.

The only essential or volatile oil largely used in varnishes is oil of turpentine, or, as it is commonly called, spirit of turpentine; and one of the best varnishes into the composition of which it enters is copal varnish. This is chiefly used for pictures. Another powerful varnish is prepared by adding to highly rectified oil of turpentine about an eighth of its weight of caoutchouc.

In these varnishes the volatile solvents evaporate, but in the case of fixed oil varnishes, the solvent undergoes a chemical change, and dries with the substance dissolved—these are sometimes termed fat varnishes. One kind of fixed oil varnish consists of a mixture of 4 ounces of copal, which has been liquefied and finely powdered, oil of turpentine, and drying linseed oil, each 10 ounces; digest in a gentle heat till the whole is dissolved; strain it after standing a few days. This forms a solid and nearly colourless glazing, and dries easily at common temperatures.

The *varnish tree* of Birma and Japan abounds in every part with a viscid ferruginous juice, which quickly becomes black by the contact of the atmosphere. The varnish is collected by inserting pointed joints of bamboo, which are closed at the other end, into wounds made in the trunk and principal boughs. The joints of bamboo are removed after from twenty-four to forty-eight hours, and their contents, which rarely exceed a quarter of an ounce, emptied into a basket made of bamboo and rattan, previously varnished over. In Birma almost every article of household furniture intended to contain either solid or liquid food is lacquered by means of this varnish. It is also much employed in the process of gilding: the surface, being first besmeared with this varnish, has then the gold leaf immediately applied to it. The beautiful Pali writing of the Birmese, on ivory, palm-leaves, or metal, is entirely done with this varnish in its native and pure state.

VASES. The most numerous class of ancient vases are those painted vases of dried or baked clay which have of late years been discovered by thousands in Etruria, southern Italy, Sicily, Greece, and some of the Grecian islands. Such vases are frequently found in tombs, catacombs, and other depositories of the dead. The period during which the art of vase painting completed its development from the rudest elements to the highest perfection, is comprised in the three centuries before the Christian æra, from B. C. 500 to about 200.

The most convenient criterion for classifying the ancient vases is their style of painting, which alone affords a very obvious distinction, and also marks the different stages of the art. They may be thus classed as follows :—

1. Vases with paintings in the *Egyptian style*. The vases are of a pale yellow colour, on which the figures, generally of animals or flowers, are painted in a black or brown colour, sometimes with the addition of purple or white tints. Grace is entirely wanting. These vases occur most frequently in the tombs of Volci in Etruria, and in those of Nola; and they are supposed to have been made about B. C. 500.

2. Vases with paintings in the *archaic* or *ancient style*. The vases of this class have black figures on a red ground, and the figures are no longer mere animals and ornaments of the vessels, but contain scenes taken from the stories about the gods and heroes of Greece, and from the occurrences of ordinary life. The form of these vases, which is usually that of the amphora, has a freedom and elegance of proportions which are wanting in those of the first class; and they vary greatly in size. The peculiarities of the designs are strong outlines of the main parts of the human body, and the expression of the highest degree of physical strength. In the representation of animals, especially horses, there is sometimes a considerable degree of boldness and beauty. The majority of vases of this class are generally believed to have been made previous to the year B. C. 430.

3. Vases with painting in *the severe style*. In the vases of this class the figures are red, the natural colour of the clay, on a beautiful black ground. The most striking features in the design are a certain moderation and harmony. The drapery forms varied and rich folds, though they show a conventional regularity. The heads are worked with great care, and sometimes are truly graceful; the hands and feet are better drawn than on the vases of the former classes. The subjects represented are the same as those on the vases of the second class, but repose is more frequent than action. The forms of the vases are elegant, and they present great variations both in shape and size. They occur most frequently in Etruria and at Nola. Vases of this class are commonly assigned to the period from B. C. 460 to 420.

4. Vases with paintings in *the beautiful style*. In all the vases which are regarded as the true representatives of this period, all harshness and severity of style have disappeared: liveliness in the composition, perfect freedom in action and movement, as well as in the drapery, are the essential characteristics of this style. The colour of the figures, as in the third class, is the natural red of the clay, and white is used to represent a variety of things, such as ribbons, garlands, the flames of torches, and the like. The inscriptions too are usually painted in white. Vases of this class are not often found in Etruria: they are most frequent in Nola, Sicily, and Attica. The vases of this class, which show the highest perfection of the art, appear to belong to the period beginning with the year B. C. 400.

5. Vases with paintings in *the rich style*.

These differ but little from the preceding class, and are often difficult to assign with certainty. The designs are frequently executed with considerable carelessness, and show the sinking condition of the art. The best specimens of this class of vases are of extraordinary beauty, but the worst of them are so bad that they can scarcely be regarded as the works of Greeks.

There is a large collection of these vases, including all the classes, in the British Museum.

VEGETABLE SUBSTANCES. To treat of botanical classification, or of the phenomena of vegetable growth, would be beyond the limits of the present work. In respect to the vegetable substances employed in food, medicine, and the arts, many are described under their proper headings.

When the Commissioners were forming the skeleton for the arrangements of the Great Exhibition, they devoted one of the four sections of the entire collection to *Raw Materials and Produce;* and this section they divided into *animal*, *vegetable*, and *mineral.* It may be useful to give here, in an abridged form, the system on which vegetable substances were divided.

The whole series of vegetable substances, so far as usefully employed, were placed in four groups: 1st. *Substances used chiefly in food;* 2nd. *Materials used chiefly in the chemical or medical arts;* 3rd. *Materials for building, clothing, &c.;* 4th. *Miscellaneous substances.* The first group comprised agricultural produce, such as corn, pulse, oil seeds, &c.; dried fruits and seeds; substances used in the preparation of drinks; spices and condiments; different varieties of starch; different varieties of sugar; fermented liquors and distilled spirits from unusual sources. The second group comprised different varieties of gum; resins, such as balsams, gum resins, and elastic gums; oils, such as volatile oils, fat oils, drying oils, solid oils, and wax; acids and alkalies; dyes and colours; tanning substances; intoxicating drugs; medicinal substances. The third group comprised fibrous substances, such as cordage and clothing materials; cellular substances; timber and fancy woods. The last group, as its name pretty nearly implies, comprised all the substances which could not very well be included under any of the other three, and which were necessarily of a diverse character.

So far as was practicable, this system of classification has been attended to in the arrangement of the Exhibition; but it has unavoidably happened that some of the varieties are less fully represented than others.

VEGETABLE WAX. Various plants yield a substance like wax, which is obtained, like the vegetable butter, by bruising and boiling them in water, when the wax melting floats to the surface, and there concretes on cooling. Of these the most remarkable instance is the *ceroxylon andicola*, the wax palm, palma de cera of the American Spaniards. Myrica gale, candleberry myrtle, or sweet gale, a native of this country, yields a substance resembling bees'-wax when its catkins or cones are boiled in water: so *myrica cerifera*, a native of North America, yields a similar substance when its berries are thus boiled: candles are made of it also, whence the plant is commonly called tallow-shrub or candleberry tree. *Myrica quercifolia*, a native of the Cape of Good Hope, is another species which yields a vegetable wax. It grows along the coast, on dry sandy plains exposed to the sea-air, where hardly any other plants will vegetate. The wax invests the berries in the form of a rough crust, which is separated by means of boiling water. It is of a greenish colour, but may be bleached. When made into candles it gives a very fine light. A vegetable wax is also obtained in China from *ligustrum lucidum*, which is frequently mentioned as the wax tree in Dr. Abel's and other travels.

VELOCIMETER. Various machines have been invented and introduced under this name for measuring velocities. Dixon's Velocimeter is intended to measure the speed of railway trains; it is somewhat complicated in arrangement; but when placed in connexion with one of the wheels of the engine or carriage, there is a kind of clock-work mechanism which shows how often the wheels have revolved, and consequently how much space has been passed over in a given time. In one form it simply indicates to the engine driver the speed of the train; but by an additional apparatus it may be made to *register* its results on paper. Mr. Alliot patented a peculiar method, in 1849, of determining the velocity of a railway train by the pressure of water in a chamber or vessel. Mr. Berthon's apparatus for measuring the velocity of a ship's motion through the water is noticed under Log and Logline.

VELVET MANUFACTURE. This beautiful substance is mostly a silk fabric, remarkable for the softness of its surface. This softness is owing to a loose *pile* or surface of threads, occasioned by the insertion of short pieces of silk thread doubled under the shoot, weft, or cross threads. These stand upright so thickly as entirely to conceal the interlacing of the warp and shoot. The richness of the velvet depends upon the closeness of the pile-threads. The insertion of these short threads is effected in the following manner:—Instead of having only one row of warp-threads, which will be crossed alternately over and under by the shoot, there are two sets, one of which is to form the regular warp, while the other is to constitute the pile; and these two sets are so arranged in the loom as to be kept separate. The quantity of the pile-thread necessary is very much more than that of the warp-thread; and therefore must be supplied to the loom by a different agency.

If the pile-threads were worked in among the shoot, in the same way as the warp-threads, the fabric would be simply a kind of double silk, but without any kind of pile; the pile-threads are therefore formed into a series of loops, standing up from the surface of the silk; and by subsequently cutting these loops with a sharp instrument, the pile is produced. Thin brass wires are temporarily woven in among the weft-threads, to assist in forming the loops; and by a delicate cut or scission made with a sharp instrument, the loops are cut and the wires liberated. Striped velvets are produced by some of the pile-threads being uncut.

Cotton is now employed, as well as silk, in the manufacture of velvet. The different varieties of *fustian* are a kind of cotton-velvet.

VENEERING is the art of laying thin leaves, called *Veneers*, of a valuable kind of wood upon a ground or foundation of inferior material, so as to produce articles of elegant appearance at smaller cost than if they were composed entirely of the ornamental wood. Small veneers are cut by hand with a thin saw, the block being held firmly in a vice; but large ones are usually cut by machinery. They are carefully brought to the right thickness by fine planes; cut precisely to the required shape; and then glued down to the ground, which should be of dry wood, with strong glue. Precautions are taken to prevent the veneer from springing or loosening before the glue is dry. The work is afterwards finished with very fine planes and scrapers, and polished with fish-skin, wax, and a brush or polisher of shavegrass.

Mr. Meadows patented a veneering machine in 1849, by which, by means of clamps and screws of peculiar kind, he can veneer surfaces much more curved and tortuous than can usually be so treated.

VENEZUELA. This republic of South America is rich in vegetable produce. The articles of cultivation which are grown for exportation are cotton, indigo, cacao, coffee, sugar, tobacco, and cocoa-nuts. Indigo, which was once the most important object of cultivation, is much neglected, and cotton, coffee, and sugar have taken its place; but indigo is still grown in some places within the coast-range. The cocoa-palm is met with to the height of 700 feet, and yields valuable articles of export. The tobacco is of the best quality, and includes the well-known Varinas. Maize is extensively cultivated all over the country, but wheat only in the more elevated tracts. Rice is grown in a few places in the lower tracts, and barley only on the declivity of the Andes. Millet is also an object of cultivation.

Venezuela is not rich in minerals. Gold is found in several places, and a valuable mine has recently been discovered in the mountains south of the Orinoco. Silver, tin, copper, iron, and lead occur; but only the copper ore is worked profitably. Coal, natron, salt, and petroleum are found in different places.

The few manufactures of this country are in the Sierra Nirgua and on the declivities of the Andes, at Tocuyo, Barquicimeto, Trujillo, and Merida, where straw hats, hammocks, coarse cotton cloth, some worsted stuffs, and earthenware, are made. The commerce of Venezuela diminished greatly during the war of independence, but it has since recovered. Custom duties are laid on the importation of hardware, cottons, woollens, silks, linens, and about forty miscellaneous articles. The income and the expenditure of the republic for 1846 were each about 2,000,000 dollars.

The British produce and manufactures exported to Venezuela in 1849 amounted in value to 56,066*l*.

VENICE. This far-famed city has fallen greatly from its once high importance; but it will ever remain a most remarkable place. The islands on which the city stands are about 80 in number, divided from each other by narrow canals, which form the highways of communication, as streets in other towns, and are spanned by 450 bridges. Carriages and horses are useless, and therefore not seen in Venice, and their place is supplied by boats called 'gondole,' which are continually plying in all parts of the town. The city is two miles distant at the nearest point from the main land, and has a circumference of about 8 miles. There is a tide from the Adriatic, which rises a few feet over the lagunes, part of which are left nearly dry at ebb, excepting the 7 large canals, which intersect the lagunes, and keep up the communication between the city and the ports of Malamocco and Chioggia on the Adriatic, and the landing-places of Mestre, Fusina, and others on the main land. The arsenal or dock-yard is surrounded by a high wall, and occupies an area of about three miles in circumference. When the Abbé

Richard saw it (1761-2), there were about forty ships of war, of which twelve were three-deckers, in the docks ready for sea; arms for 150,000 men, 2500 pieces of brass ordnance, besides 1500 iron cannon, and vast stores of provisions; cables, sails, timber for ship-building, brought from the forests of Istria and Dalmatia, and all other appurtenances of such an establishment. The arsenal is now the dockyard for the insignificant Austrian navy. A railroad has been formed between Venice and Verona. The mercantile shipping of the port has assumed a new activity, and trades all over the Mediterranean. The number of vessels which enter the port of Venice yearly is between 1200 and 1300, including small craft; and Venice has seemed within the last ten or twelve years to show symptoms of commercial revival; but the disasters of 1849 gave it a severe check.

VERDIGRIS. [COPPER.]

VERDITER. [COPPER.]

VERMICELLI is a dried paste, manufactured chiefly in Italy, in the form of smooth round strings. The name has been given to it on account of its worm-like appearance, *vermicelli* in Italian signifying 'little worms.' *Maccaroni* is manufactured of the same kind of paste as vermicelli, and in a similar manner; but is rather larger in diameter, and is hollow like the tube of a tobacco-pipe. *Fedelini* is a kind still smaller than vermicelli.

The paste is made of wheat stripped of the husk, and ground roughly into a sort of grit. The kind of wheat preferred by the Italians is a small hard-grained species which they now cultivate on purpose, but which they formerly imported from the coasts of the Black Sea—'Grano di Mar Nero.' The ground wheat is mixed with clear soft water, and made into a paste by kneading it on a large block. The toughness and elasticity of the paste result from a long and powerful process of kneading. The paste is next forced by strong pressure through round holes in the bottom of a cylinder; but, to form maccaroni, a wire extends from a bridge in the upper part of the cylinder through the centre of each of the largest holes, and the paste, being forced through each hole around the wire, is consequently hollow. The strings, several feet in length, whether of maccaroni, vermicelli, or fedelini, having been thoroughly dried, are ready for use.

Tho Italians manufacture the paste into many other forms; into thin flat strips like ribbons, into thin sheets like paper, into round balls, and into beans and peas. The Neapolitans, who use great quantities of maccaroni as their favourite food, use nothing but the pure paste of wheat and water, but the Genoese mix saffron with it, which gives it a yellow tinge. The French, who also manufacture a good deal of it, frequently season the paste with various condiments.

VERMILLION. [MERCURY.]

VERMONT. A few statistical and industrial notices of Vermont will be found under UNITED STATES.

VIENNA. This large and important city, besides being the centre of the Austrian dominions, is likewise the principal seat of commerce and manufactures. Its commerce is with Hungary, Turkey, Italy, and other countries. Since the establishment of the Danube Steam Navigation Company, whose vessels go to Constantinople, Trebizond, and Smyrna, the trade with the Levant has greatly increased. Manufactures of every kind are carried on in Vienna, and employ above 80,000 workmen. The principal are, silk, velvet, shawls, gold and silver lace, cottons, woollens, ribbons, carpets, leather, porcelain, jewellery, mathematical and musical instruments, fire-arms, gold and silver plate, watches, fine cutlery, carriages, gloves, lace, straw hats, paper, &c.

The beautiful specimens of household furniture which adorn the Austrian division of the Great Exhibition are mostly from Vienna.

VINEGAR MANUFACTURE. The relation which vinegar bears to the acetic and pyroligneous acids is noticed under ACETIC ACID. In countries which produce wine vinegar is obtained from the acetous fermentation of wine; but in this country it is usually procured from malt, and the process employed resembles the first stages of the brewer's operations. [BREWING.] The malt is ground and mashed with hot water. The wort, after being cooled, is transferred to the fermenting tun, where by the addition of yeast it undergoes the acetous fermentation; and when this is over the liquor is transferred to small vessels, which are kept warm by means of a stove: in these it remains for a shorter or longer period, according to the temperature of the stove and the strength of the liquor. The process of acetification is assisted by introducing into the casks with the wort what is called *rape*, which is a quantity of the residuary fruit which has served for making domestic wines, or has been preserved by the vinegar-maker from one process to another in his own factory. The use of the rape is to act as an acetous ferment, and thus induce sourness in the wash, it being well impregnated with vinegar and continually kept sour. Acetification is sometimes carried on by transferring the wort, after it has undergone the vinous fermentation, into casks, the bungholes of which are left open and loosely covered with tiles; the casks are then exposed for a long time to the air; but the use of stoves has greatly superseded this mode, has abridged the time of the operation, and rendered it less liable to failure. The vinegar, after it has reached its greatest degree of sourness, is rendered clear and fit for use either by subsidence or by the employment of isinglass.

Vinegar may be prepared in small quantities from the fermentation of a solution of sugar mixed with yeast; or it may be obtained by the fermentation of various fruits; thus the juice of good apples contains a sufficiency of sugar to afford tolerably good vinegar without any addition.

In France vinegar is made from poor wine; and there are two kinds—the white, prepared from white wine; and the red, by the acetification of the red wine: these are finer flavoured and somewhat stronger than the malt vinegar of this country.

Vinegar acts as an effectual preservative from the putrefactive fermentation of dead organic tissues, and is hence employed as the means of forming pickles, or meat in a dried state, by simply immersing the substance in it for a few minutes. Wood vinegar, or pyroligneous acid, is most efficacious for this purpose, owing to the creasote present in it. Crude pyroligneous acid is one of the most effectual applications to timber, both to prevent the dry rot and the ravages of insects. Concentrated acetic acid acts on the living tissues as a caustic poison; applied to the skin it causes heat, redness, and rapid inflammation.

VINES; VINEYARDS. The cultivation of the vine extends from near 55° N. lat. to the equator; but in south latitudes it only extends as far south as 40°. In Middle Germany the vine-culture ceases at 1000 to 1500 feet above the level of the sea; on the south slope of the Alps it reaches 2000 feet; in the Apennines and Sicily 5000; and on the Himalaya as much as 10,000 feet.

The spots where the vine flourishes and where vineyards are kept up are said to depend more on the climates of spring and autumn than on those of summer and winter; and this explains many seeming anomalies in the location of vineyards. The vine grows best in a soil where few other shrubs or plants would thrive, such as a deep loose rocky soil. On the steep slopes of hills towards the south, and sheltered from the north-east, the grapes attain the greatest maturity, and the vintage is most certain. The culture of the vine is perhaps one of the most anxious and fatiguing which field labour presents, so numerous are the demands on the time and attention of the grower. The vine will bear any degree of heat, but not heat combined with moisture; hence a wet European season is usually a bad wine season.

Grapes, as is well known, are a favourite fresh fruit. They are also made into *British* or *home-made* wine in this country. In hotter countries they are dried and prepared into *raisins* and *currants*. But the most abundant employment of grapes is in making wine. We may refer for further details to BORDEAUX: CHAMPAGNE; CLARET; CURRANTS; GRAPES; RAISINS; WINE MANUFACTURE; WINE TRADE.

VIOL, was an ancient musical instrument, which may be considered as the parent of all modern instruments of the violin family. It was a fretted instrument, of three sorts—treble, tenor, and base, each furnished with six strings, and played on by a bow. The Treble Viol was rather larger than our violin, and the music for it was written in the treble clef. The Tenor Viol was in length and breadth about the size of the modern viola, but thicker in the body, and its notation was in the soprano or C clef. The Base Viol scarcely differed in dimensions from our violoncello: the music for it was written in the base clef. Other instruments of the viol kind are numerous. The *Viol da Gamba* was the last survivor of the family of viols. It derived its name from being held between the legs. It has been superseded by the violoncello. The *Viola*, or *Tenor Violin*, is a larger kind of violin, to which the part between the second violin and base is assigned. It has four gut strings, the two lowest covered with silver wire, which are tuned A, D, G, and C, an octave above the violoncello. The *Violin* has been known, in some shape, in most countries, and from very early times. The modern violin has four gut strings, the last, or lowest, covered with silver wire. These are tuned in 5ths, E, A, D, G. The wood of which the instrument is made is generally of three sorts: the back, neck, sides, and circles are of sycamore; the belly, bass-bar, sound-post, and six blocks, of deal; the finger-board and tail-piece of ebony. The finest violins are those which were made at Cremona, by the family of the Amati, and by Straduarius and Guarnerius. The *Violoncello* is an instrument of four gut strings, the two lowest covered with silver wire, and tuned in 5ths, A, D, G, and C.

VIRGINAL. This musical instrument is now entirely disused. It was a keyed instrument of one string, jack, and quill, to each note, like a spinet, but in shape resembling the present small pianoforte. The compass was from the 2nd added line below the base to the 2nd added line above the treble, or four octaves.

VIRGINIA. [UNITED STATES.]

VITRIOL. [COPPER; IRON; ZINC.]

VITRIFICATION. Illustrations of the process of vitrification will be met with under ENAMEL; GLASS-MANUFACTURE; GLASS-PAINTING; POTTERY AND PORCELAIN.

VOLTAISM; VOLTAIC ELECTRICITY. In so far as this interesting science has a bearing on practical results, the reader will find various details under ELECTRIC LIGHT, ELECTRO METALLURGY, ELECTRO MOTIVE FORCE, ELECTROTYPE, and TELEGRAPH.

VOTING MACHINE. A singular contrivance has been lately invented in France for registering the votes of deliberative assemblies. It is primarily intended for taking the votes at the National Assembly; and the Assembly granted 30,000 francs for its construction; but if the principle and the action are found to be correct, many useful applications of the machine will present themselves. The mechanism and arrangement are as follow.

Before the commencement of a sitting of the Assembly, the ushers deposit on the desk of each representative a small case, very closely resembling a domino-box, containing ten small oblong plates of polished steel. Six of these, upon which, with the name of the particular member, the word *pour*, or aye, is engraved, are white in colour: four, which also bear a member's name, are inscribed with *contre*, or no, and are blue. When a division has been demanded and accorded, twelve ushers remove twelve balloting-boxes or urns from the secretaries' desk, and convey them to the different parts of the Chamber. On the upper surface of each urn are two separate apertures, designed to receive the ballots, signifying aye and no respectively.

The edges of the steel balloting plates are milled or grooved, so as to correspond exactly with the apertures; and accordingly, neither an affirmative nor a negative ballot can find its way into the receptacle intended for votes in the contrary sense. As soon as the ushers have made the round of the whole Assembly, the urns are taken to the president. Up to this time they have not exhibited anything which distinguishes them materially from common balloting boxes; but the moment a small door is opened in front of them, the full ingenuity of the invention is disclosed. By a delicate mechanical contrivance, each piece of steel, as it slipped into the compartment proper to it, has been made to fall evenly and horizontally on the top of the ballot inserted immediately before it, so that the whole of the ballots are found to have arranged themselves in two completely regular piles, consisting of white and blue plates respectively. By each pile is a scale of degrees graduated with nearly as many divisions as there are members in the Assembly, and from this scale the president proceeds to read off the height of the piles precisely as we read off the height of the mercurial column from the register of a thermometer. Since the thickness of all the steel ballots is exactly the same, the height of each pile, as determined by the scale, denotes accurately the number of votes which have been given for or against a proposition; and when the results from the several urns have been combined, the general result of a division is known of course immediately.

Another voting machine, having many distinctive features, has been patented in England, and a specimen deposited in the Great Exhibition.

W

WAFER is a small round piece of dried paste, which is used to fasten letters. The piece of consecrated cake which is given by the Roman Catholic priest in extreme unction is also called a wafer; and thin cake formed into a roll, and called wafers, is still sold by pastrycooks. In fact the word was used in England to signify a thin cake long before wafers for sealing letters were invented. *Waffel* is the name given by the Germans to a thin cake made with flour, eggs, sugar, &c.; the Dutch call such a cake *wafel*, and the Danes *vaffel*. The Anglo-Saxons also had the name *waffel*.

In making common wafers for securing letters, wheat flour is mixed with isinglass and white of egg into a paste; the paste is spread evenly over tin plates, several of which are piled one on another and put into an oven. The layer becomes thus both baked and polished. When baked, the layers are taken from the tins, piled into a heap an inch or more in depth, and cut into wafers by means of hollow punches. They are coloured with the usual mineral colouring materials. *Medallion* wafers are made of very pure glue, coloured to any desired tint. A seal or medallion is moistened with a weak solution of either white or coloured gum, which gum is wiped off all except the sunken parts. The glue is then poured over the medallion in a very thin layer; and the result produced is a medallion wafer, either white or coloured, but standing out in relief from a ground of another colour. *Isinglass* or *gelatine* wafers are made of a coloured solution of isinglass, which is poured in a very thin layer on a glass plate, and afterwards cut into any desired form.

WALES. The principal manufacture in Wales is that of iron, and this is chiefly confined to Glamorganshire. Large quantities of ore are raised in that county, where the most extensive smelting furnaces in the empire are to be met with. In 1840 South Wales had 132 furnaces in operation, which consumed during the year about 1,436,000 tons of coal, and produced 505,000 tons of iron. North Wales had 12 furnaces, which consumed about 110,000 tons of coal, and produced 26,500 tons of iron. In 1847 the total quantity produced in Wales was 884,000 tons. The principal iron-works are at and around Merthyr-Tydvil, Tredegar, Aberdare, and Ruabon.

Copper-ore, brought from Cornwall and other parts of England, from Ireland, and foreign countries, is smelted in large quantities at Swansea. The average quantity of ore smelted there in 16 years (1833 to 1848), was 194,142 tons; the average quantity of copper produced was 18,567 tons.

The great coal-field of South Wales affords employment to a number of hands. The quantity of coal exported at the different ports of South Wales and Monmouthshire in 1848 was nearly two million tons. North Wales also yields some coal and iron, from the vicinities of Wrexham and Ruabon in Denbighshire. Lead (with some silver ore) and copper are raised in Anglesey, Cardiganshire, and other parts of Wales, as well as large quantities of slate, limestone, and marble. Various manufactures in lead, iron, copper, and brass are carried on at Holywell in Flintshire. Flannel in considerable quantities, coarse cloth, and stockings are manufactured in Montgomeryshire and other parts of North Wales.

Further illustrations of the industry of Wales will be found under COPPER; GLAMORGAN; IRON; MERTHYR TYDVIL; SWANSEA.

WALES, NEW SOUTH. The produce of this colony is briefly adverted to under AUSTRALIA. The following details relate to its commerce and produce in recent years.

In 1848 the shipping inwards amounted to 199,304 tons; outwards, to 187,322 tons. The wool exported was 22,969,711 lbs., valued at 1,240,144*l*. On Jan. 1, 1849, the total number of sheep in the colony was 11,660,819; of cattle, 1,752,852; of horses, 113,895; of pigs, 70,875. The produce of wheat in 1848 was 1,528,874 bushels; of maize, 262,340 bushels; of barley, 145,219 bushels; of oats, 116,634 bushels; of potatoes, 14,954 tons; of tobacco, 3059 cwts.; of hay, 37,795 tons; of wine, 103,106 gallons; of brandy, 1263 gallons.

The value of the imports and exports in recent years is shown as follows:—

	Imports.	Exports.
1844	931,300*l*.	1,128,100*l*.
1845	1,233,900	1,556,000
1846	1,600,500	1,481,500
1847	1,982,000	1,870,000
1848	1,556,500	1,830,400
1849	1,793,400	1,891,300

In the years 1846 and 1847, the imports exceeded the exports; in the other four the exports exceeded the imports.

The relative value of imports and exports per head of population was as under:—

		Imports per head.	Exports per head.
1844-46	per annum	6*l*. 18*s*.	7*l*. 11*s*.
1847-49	per annum	7*l*. 19*s*.	8*l*. 6*s*.

The following results relate to the countries of which the imports and exports are respectively the produce or manufacture:—

IMPORTS.

Articles the produce or manufacture of the United Kingdom	1,207,800*l*.	
Less re-exported	108,900	
Retained for home consumption		1,098,900*l*.
Articles the produce or manufacture of other British dominions	149,100	
Less re-exported	18,600	
Retained for home consumption		130,500
Articles the produce or manufacture of Foreign States	436,500	
Less re-exported	62,700	
Retained for home consumption		373,800
Total imports retained for home consumption		1,603,200*l*.

EXPORTS.

Articles the produce or manufacture of New South Wales	1,701,100
Net excess of exports over imports.	97,900*l*.

The trade to and from Great Britain was as follows:—

	Imports from.	Exports to.
1844	643,400*l*.	854,900*l*.
1845	777,100	1,254,900
1846	1,119,300	1,130,200
1847	1,347,200	1,503,100
1848	1,084,100	1,483,200
1849	1,371,200	1,572,600

The annual averages of the trade with this country per head of the population were about as follows:—

		Imports per head.	Exports per head.
1844-46	per annum	4*l.* 12*s.* ..	5*l.* 17*s.*
1847-49		5*l.* 13*s.* ..	6*l.* 16*s.*

The value of articles the produce or manufacture of New South Wales exported in the three years 1844-46, was 3,335,200*l.*; the value of those articles exported in the last three years was 4,971,600*l.*, being an increase of 1,636,400*l.*, or more than 39 per cent.

WALNUT-TREE. The uses of the walnut-tree are various. Before the introduction of mohogany and other foreign woods, the wood of the walnut-tree was held in higher estimation than that of any other European tree; and many specimens of furniture and carving still exist, to testify the beauty (somewhat sombre) of the wood. In almost every stage of its growth the fruit of the walnut-tree is used. When young, green, and tender, walnuts are pickled and preserved with the husks on. About the end of June they may be preserved with or without the husks. When the nuts are fully ripe, which is generally at the end of September or the beginning of October, the kernel, deprived of its investing skin, is eaten in great quantities. As long as the skin can be easily removed, they are a nutritious and healthy article of diet; but when they get dry, so that their skins stick to them, they become indigestible. A great number of the walnuts consumed in England are of foreign growth.

The albumen which constitutes the bulk of the seed of the walnut contains an oil, which is used in large quantities, especially on the Continent. It is obtained by reducing the seeds to a pulp by means of a stone wheel and basin, and then expressing the oil, first without heat, and then by the application of heat. The oil obtained by heat is used by artists, and also for lamps.

All parts of the walnut-tree, excepting the albumen of the seed, possess a bitter principle, which acts as a tonic and anthelmintic, and was formerly much esteemed as a medicine.

WARMING AND VENTILATION. Under the headings Arnott's Stove, Cooking Apparatus, and Stove, descriptions are given of various *grates*, *stoves*, and *fire-places*; other modes of warming buildings call for a little notice here.

The employment of steam-boilers in large establishments where steam-engines are worked, is one of the circumstances which have led to the very extensive adoption of the method of warming by steam. A marked difference is observable in the principle of this method, as compared with that of hot-air warming. The steam is not permitted to mingle with the air of the room which is to be warmed, but acts through the medium of the metallic tube which confines it, and which it raises to a temperature sufficient to warm the room. The efficacy of this mode of heating depends on the great capacity for heat which steam possesses, a capacity equal to 1000°; that is, a pound of water at 212° will absorb a thousand degrees of heat in becoming a pound of steam. Mr. Scott Russell calculates that a room containing 500 cubic feet of air, and exposing 400 feet of surface, may be maintained at a temperature of 20° above that of the air without—that is to say, at 60° in the inside of the room when the atmosphere is at 40° without—for a space of twelve hours, by the evaporation of two gallons of water, and at the expense of about three pounds of coal. This mode of heating buildings is adopted to a very large extent in the steam-power factories.

The method of heating by hot water, though not so much adopted in factories as the steam method, is perhaps of more extensive application in other buildings. Where all the apartments to be warmed are on one level, an open boiler may be used; but where it is necessary to carry the pipes to different floors of a building, some of them much above the level of the boiler, the boiler must in that case be closed. When an open boiler is employed, a pipe branches out from the upper part of the side, extends horizontally through the rooms to be warmed (without in any case rising above the level of the water in the boiler), and returns again to the boiler, which it enters at a lower level than the other. Under this arrangement a current of heated water will flow from the boiler at the upper orifice, and, after traversing the tube, return to the lower orifice. The closed boiler is however more extensively useful, since it enables all the stories of a building to be warmed by one apparatus. The whole system, including both tubes and boiler, is filled with water at a valve at the highest point; and when heat is applied to the boiler, a circulation ensues which speedily causes the whole length of tubing to become hot. Various modifications of this hot-water system are adopted in the new Houses of Parliament, in the British Museum, and other public buildings.

Ventilation.—There is an important but often neglected circumstance attending the artificial warming of buildings, viz. that the amount of fresh air, requisite under any condition for animal respiration, must be more and more increased in proportion to the fuel burned in the room; or, more correctly, there must be one portion of air to feed combustion, and another portion to aid respiration. Tredgold, Arnott, Reid, and others, have calculated the quantity of air required for these purposes. Tredgold states that when a room containing several persons is heated to the average and customary degree, it will be necessary to supply four times as many cubic feet of fresh air per minute, as there are persons in the room; that is, four feet for each person. But there must be an outlet for the vitiated air equal to the inlet for pure air; and as it is found that respired air ascends to the upper part of the room, it follows that the ceiling or some neighbouring part is the proper place for an outlet.

In ordinary English houses no steps whatever are taken to regulate either the supply of pure air or the exit of vitiated air; but it is probable that our large fire-places regulate this matter tolerably well. In crowded rooms however, where the amount of vitiated breath bears a much larger ratio to the cubical contents, and where the doors are generally small compared with the height of the room, the impure air cannot escape by these means, and some arrangements must be made near the ceiling for the removal of the air. These methods are chiefly of two different kinds; the one by the use of a revolving wheel or fan-ventilator, and the other by the action of a chimney or tube. At the Reform Club-House, London, a steam-engine works a revolving fan, capable of throwing eleven thousand cubic feet of air per minute into a subterranean tunnel under the basement story; and the steam from the small steam-engine which works the fan supplies three cast-iron chests with the requisite heat for warming the whole building.

The second mode of effecting ventilation, viz. by the use of a tube or chimney opening into the air from the upper part of an apartment, depends for its action on the ascensive power possessed by a lofty aërial column. As the heated air of a furnace-chimney carries up the smoke, &c., more rapidly if the chimney be very lofty, so does a lofty chimney exceed a low one in carrying off vitiated air; and for the same reason, even if no chimney, properly so called, be provided, a lofty room, furnished with appropriate openings in its ceiling, will furnish a draught to carry off impure air more rapidly than a low room; and in many of our public buildings this arrangement is deemed sufficient.

Dr. Arnott has made use of the ascending force of the column of heated air in an ordinary chimney as a means of ventilating ordinary sitting rooms, by placing a balanced valve in an opening from the room into the chimney. He has also introduced very recently a mode of ventilating large buildings by applying the pressure of a column of water to work a forcing air-pump. These admirable contrivances, so worthy of the accomplished physician to whom they are due, are noticed under ARNOTT'S VENTILATOR. Many forms of ship-ventilation depend on the use of an air-pump.

WARWICKSHIRE. The minerals of this county consist chiefly of one small coal field, and some quarries of gritstone. There are no less than 170 miles of canal in this county; and it is also well supplied with railways. Warwickshire stands on the verge of a manufacturing district and contains within itself many busy towns. The two most notable of these, in an industrial point of view, are noticed elsewhere. [BIRMINGHAM; COVENTRY.]

WATCH. [CLOCK AND WATCH MAKING.]

WATER, in its liquid, aëriform, or solid state, is universally diffused through nature. It was once considered as one of the four elements, and is in common language still frequently so termed. Water however is now known to be a compound substance consisting of hydrogen and oxygen. It is colourless, transparent, inodorous, and insipid; it is an imperfect conductor of heat and electricity; it is very slightly compressible, yielding only about 46·65 millionths of its bulk to the pressure of the atmosphere. Its specific gravity is 1, being the unit to which the density of all liquids and solids is referred, as a convenient standard, on account of the facility with which it is obtained in a pure state. Like all other fluids and substances it expands by exposure to an increase of temperature; and with a curious exception, the dilatation within certain limits is proportionate to the degree of heat to which it is subjected. When water is heated to a certain point, which is arbitrarily fixed on the scale of Fahrenheit's thermometer at 212°, it acquires the greatest volume it is capable of assuming; it then boils, and is converted into vapour. Steam at 212° occupies about 1700 times as much space as the water does from which it is generated. It is upon the elastic force of steam communicated by heat, and the instantaneous annihilation of it by cold, that the working of the steam-engine depends.

Water is seldom found in a state of perfect purity, but, from its great solvent and absorbent power, it is impregnated with a variety of saline substances, gases, and animal and vegetable substances, either living or undergoing a process of decomposition. The effect of these is to communicate different properties, and generally give it a peculiar taste, and not unfrequently an odour, which, if not cognisable by the blunted senses of man, is so by animals, especially the camel, which can scent water at a great distance in the desert. The specific gravity is often much increased, especially that of sea-water and of mineral waters, from the saline ingredients, and of some of the great rivers, from the quantity of mud and other matters which they contain.

Rain-Water is commonly reckoned the purest: but it is by no means so free from accidental impregnations as is generally supposed. Whatever foreign ingredients exist in the atmosphere of any place are brought to the ground by the first rain that falls. Rain-water, from its great purity, has high solvent powers, which fit it well for the part it has to perform in the economy of nature, and also for many operations in the laboratory. In this respect it is nearly equal to distilled water. The surface water of sandy districts is the purest that can be obtained naturally.

Dew differs little from rain, save in containing more atmospheric air. *Ice-water* differs when first obtained, from rain, in being destitute of atmospheric air, and hence it cannot sustain respiration in fishes; it is for the same reason mawkish and insipid; but by exposure to the air it speedily absorbs a due proportion. *Snow-water* is nearly similar.

Spring-water is of various degrees of purity, according to its source and the strata through which it passes. Its most common source is rain, which percolates through some of the superficial strata, and, meeting with some obstacle, is forced up to the surface. *River-water* mostly originates in springs, augmented by rain-water. If it flows over sand or granite, it is found very pure, depositing in its course many earthy salts, especially the calcareous ones, from the escape of carbonic acid. This circumstance renders the water vapid, and less pleasant to drink than spring-water. It possesses however the property of absorbing much oxygen; hence the surface-water both of rivers and the ocean holds more oxygen than the atmospheric air, to the amount even of 29·1 per cent. This contributes both to the maintenance of the respiration of fishes, and these, in their turn, to the growth of aquatic plants. *Well-water* is generally obtained from a greater depth than spring-water. It is also generally hard, or is apt to become so if kept in a reservoir lined with bricks, unless they be coated with an insoluble cement. The water from old wells is more pure than from recent ones, the soluble particles being all gradually washed away. The pump and well waters in and about London, and chalky districts in general, are mostly hard.

Lake-water varies much in its composition. The main difference depends on the lake possessing an outlet or being destitute of one. The water of the former generally corresponds with that of the rivers which flow into it; but the flow becoming slower, there is more scope for the development of animal and vegetable matters, and for the decomposition of organic remains.

Marsh-water is stagnant, and abounds in animal and vegetable remains, either in a state of decomposition or passing into new combinations, generally of a low grade, as the lowest members of the vegetable kingdom and those of each section of the animal are mostly aquatic. These waters are for the most part unwholesome, both from the gases they emit, and also when used as drink. Impure or putrid water may be rendered pure by adding alum or recently prepared charcoal, or by simply pouring it from one vessel into another in the sun.

Sea-water abounds in saline matters so much, that it is unfit for use internally, except in small quantity as a medicine. Sea-water may be rendered fit for drinking by pressure, filtration, and freezing, or simply by boiling it, and condensing the steam as it arises. For many chemical, pharmaceutical, and even dietetical purposes, water must be of greater purity than it is generally found. For this end it is directed to be distilled, in which process never more than two-thirds of the water put into the still should be allowed to pass over.

Mineral Waters are generally characterised by possessing some principle different from what is found in common water, or some of the ordinary principles in unusual proportion; yet among these are reckoned certain springs which have no claim to repute beyond what is due to their extreme purity, such as Malvern and Holywell, or to having a higher temperature throughout the year than the mean of the latitude where they are situated. These last are classed among the *thermal* springs, which are properly divided into two sections, the *mineralised hot* springs and the *unmineralised*, among which are some only tepid, such as Matlock, where some springs, are 66° the lowest of the class in Britain, and others cold, presenting this peculiarity, that the tepid springs arise from fifteen to thirty yards above the level of the river Derwent, whilst those which arise either above or below this range are cold.

For practical purposes mineral-waters may be classed under four heads, each susceptible of secondary heads, according as they are hot or cold, or have other peculiarities, viz.: *saline*, *alkaline*, *chalybeate*, and *sulphureous*.

It has never ceased to be an object of interest to determine whether sea-water can be so distilled on board a ship as to yield drinkable fresh-water. Many processes have been devised for this purpose; but all have been wanting in some one or more desired qualities. Some of the government ships have lately been provided with Grant's Distilling and Cooking Galley; during the period it is required to keep the fires alight in these galleys for purposes of cooking, the distillation of salt water is going on so as to yield one gallon of distilled water per man per day. Like all distilled water, it is vapid at first from the loss of oxygen during the process; but the motion of the ship is said to aerate the distilled water in the tanks, by agitation. Experiments have been made in one of the government ships, to see whether the oxygen might be restored to distilled water by an electrical current passed through it; but this seems too complicated an arrangement for the rough usages of a ship.

WATER SUPPLY; WATER WORKS. Before the building of New London Bridge, a considerable part of the metropolis was supplied with water by machinery, placed close to the old bridge; but that machinery being removed, other arrangements for supply have had to be made.

The following are the modes in which London is now supplied with water. The *New River Company* obtains its supply from the rivers Lea and Armwell; the *East London Company* from the river Lea; the *Hampstead Company* from springs near Hampstead; the *Grand Junction Company* from the Thames near Kew; the *West Middlesex Company* from the Thames near Barnes; the *Chelsea Company* from the Thames near Chelsea; the *Southwark and Vauxhall Company* from the Thames near Battersea and the *Lambeth Company* from the Thames near Thames Ditton. When certain new arrangements of the various companies are complete, no supply will be obtained from the Thames at a lower point than Chelsea. Most of the companies have filtering or settling reservoirs, for purifying the water a little before it reaches the service mains.

The agitation for improved and increased water supply is well known to all newspaper readers; some projectors suggest that water should be obtained from a yet higher point in the Thames; some select the Verulam; some the Wandle; some the Colne. Many think that Artesian Wells might supply the whole of London; while a recently proposed plan, which has been received with much favour, is for catching the rain-water over a large sandy surface. The subject is now before the legislature.

See other details under AQUEDUCTS; ARTESIAN WELLS.

WATERFORD. The Waterford mountains contain two varieties of slate: the old transition slate, coloured gray, which is extensively used for roofing, and the newer slate, which rests on the older; the lower portions of its strata consist of alternating beds of brownish-red quartzose conglomerate and coarse red slate. The valleys are occupied by limestone, and there is a clay-slate district, which contains several copper and lead mines, some of which are worked. Iron-ore is also found. Of the entire area of the county (461,553 acres) 325,345 acres are arable, 105,496 uncultivated, 23,408 in plantations, and the rest covered by water or occupied by towns. The common course of tillage is potatoes, wheat, oats, and again potatoes; but some of the better farmers grow only one corn crop in the course. The common Irish cow is the general dairy stock.

In Waterford town the exports are chiefly to England, and almost wholly agricultural—bacon, pork, butter, grain, flour and meal, cattle, sheep, and pigs. The gross produce of the customs' duties in 1848 was 134,897*l*. The sailing vessels registered as belonging to the port in 1848 were 78 under 50 tons, and 123 of 50 tons and upwards; the aggregate burden was 23,244 tons; steamers, 14 (3187 tons).

WATERPROOF COMPOSITIONS. Many patents have been taken out for methods of rendering cloth and leather waterproof. In 1835 Mr. Hellewell, of Salford, took out a patient for a solution, which, by immersion, should render cotton and other fabrics waterproof; it is a composition of rock alum and whiting in water, and its action is aided by a subsequent application of soap and water. Mr. Hall, of Doncaster, patented in 1839 a method of waterproofing cloth by immersion; one solution described consists of alum, white lead, and water; and another of alum, white lead, acetic acid, and water; and the cloth, after steeping in one of these solutions, is passed through a solution of quick lime, and a third time through a solution of boiled Irish moss, which acts as a mucilage. There are other patents of a somewhat similar character to the above, and there have also been numerous methods published but not patented.

The surface-application of a species of varnish has been the subject of many patents. A composition was introduced for this purpose some years ago, formed of linseed oil, pipe-clay, burnt umber, white lead, pounded pumice-stone, and one or two other substances. This was not intended as a waterproof composition for ordinary clothing, but rather for tarpauling, awnings, coach-top covers, boat-cloaks, and other coarse materials. Mr. Newberry's patent, taken out in 1140, is for a mode of applying waterproof composition in such a way as to leave one side of the woven fabric free from its influence, thereby presenting to the eye a texture nearly resembling that of ordinary cloth. The application of a layer of cement, gum, or varnish between two other substances, with a view to render the inner one impervious to water, has been practised under many different modifications, including that which is known by the name of the inventor, *Mackintosh.* In the year 1824 Mr. Weise, of Bermondsey, devised a peculiar kind of fabric, which consists of fibrous materials spun into yarn; the yarn is dipped in caoutchouc solution before weaving; and in order to render the meshes impervious to water, the cloth is drawn over a heated cylinder, whereby the composition is so far melted as to flow into them. The waterproof or Macintosh cloth is made by applying a layer of dissolved caoutchouc to cotton or other cloth. The cloth is stretched upon frames and brushed over with it; and the surfaces of two such pieces, while in a partially damp state, are laid one upon another, and pressed between rollers till they firmly and inseparably unite. The double fabric thus produced is wholly impervious to water, and is at the same time free from any adhesive substance on the surface.

The useful application of air for beds, cushions, seats, and similar articles, is dependent on the formation of air-tight cases; and this air-proof quality is brought about by nearly the same means as waterproofing. When a bag has been made of caoutchouc or similar cloth, and rendered also air-tight by somewhat similar means at the seams, air may be passed into it as a substitute for more solid materials. In practice there are some very neat arrangements adopted in effecting this. Temporary air-seats or cushions are made by forming a bag of air-tight cloth, perfectly enclosed at every part except one corner, where is inserted a small tube and stop-cock, capable of admitting or preventing communication from the interior to the exterior. The cock being opened, and the tube applied to the mouth, air is blown into the cushion, until it expands to the desired degree of fulness; the cock is then closed, and the air remains imprisoned. In this state the cushion is of a more equable kind than any one stuffed with solid materials; and if the envelope be well made, it will retain its efficacy for a long time. When not in use, such a cushion can have the air expressed from it, and may then be folded up into a small space.

It is obvious that seats, cushions, pillows, and beds of various kinds, having a similar object in view in respect to softness, fulness, and elasticity, may be made by similar means. When the quantity of air included in an envelope is greatly increased, it may be made the means of producing actual pressure in a more equable way than by any solid bodies. Thus, an air-tight bandage, so formed, is often used in surgical operations.

The patents for caoutchouc waterproof materials taken out by Mr. Hancock, Mr. Sievier, and other inventors, within the last few years, are so exceedingly numerous that we can only speak of them generally. One patent is for cutting cotton and other fibres into very small fragments, mixing them with dissolved caoutchouc, and forming sheets of material from this mixture. Another patent relates to a method, in which very thin sheets of caoutchouc are cemented by a solution of caoutchouc to gauze, bobbin net, or other open material; and on this, as a ground, and with a similar cement of quick-drying caoutchouc, is laid a stratum of fibres. The fibres are pressed and dressed; and the open and extensible meshes of the gauze or bobbin-net give to the whole an elasticity which closely-woven textures cannot impart.

The attempts to render leather waterproof depend in general on the filling up of the small pores which have previously admitted the tannin, the substance imbibed being such as will repel or resist water. Many such compositions have been proposed at different times, of which the mention of a few will here suffice. Melt over a slow fire a quart of boiled linseed oil, a pound of mutton suet, three-quarters of a pound of yellow bees'-wax, and a half a pound of common resin, or smaller quantities in the like relative proportions; and with this mixture saturate the leather of new boots or shoes, while the latter is slightly warm. Another method is to melt two ounces of yellow bees'-wax, two ounces of

Burgundy pitch, and two ounces of turpentine, in a pint of linseed oil, and with this mixture to saturate the warm leather. Another mixture for this purpose consists of six ounces of caoutchouc boiled for two hours in two quarts of linseed or neat's-foot oil. Lastly, a mode has been much recommended of applying a hot mixture of two parts tallow and one part resin, with which the leather may be completely saturated, the resin imparting an antiseptic quality to the tallow.

WATT, JAMES. Of all the great men whose names are indissolubly connected with the history of the steam-engine, James Watt undoubtedly takes the lead. Watt was born at Greenock in 1736; and in his 16th year he was apprenticed to an instrument maker in Glasgow. At the end of three years he removed to London, in 1755, and placed himself with a mathematical instrument maker; but in little more than twelve months the state of his health compelled him to return to Scotland.

Shortly after his return from London, Watt established himself as an instrument maker within the precincts of Glasgow University. In 1763 Professor John Anderson, who then occupied the chair of natural philosophy in the university, having requested him to examine and repair a small model of Newcomen's steam-engine, which could never be made to work satisfactorily, his sagacity led him to discover and remove the defects of this model; and he also discovered the imperfections of the machine itself, and was led to investigate those properties of steam upon which its action depended. The character of Watt's improvements is briefly noticed in the article STEAM-ENGINE. He next opened a shop in the Salt Market, Glasgow, where he continued to make improvements in the steam-engine; and where, in addition to his employment as a mathematical instrument maker, he devoted much time to the practice of land-surveying. He afterwards adopted the profession of a civil engineer. In 1768 he found in Dr. John Roebuck an individual capable of appreciating the value of his improvements in the steam-engine, and sufficiently enterprising to support him in further experiments. The assistance of this gentleman enabled him to set up an engine, for which he obtained a patent, Jan. 5, 1769. Matthew Boulton, of Soho near Birmingham, purchased Roebuck's share; and in 1774 Boulton and Watt entered into partnership.

At the latter end of 1774 Watt completed at Soho his fourth model engine, which was exhibited to a deputation from the Cornish miners, and to other persons competent to judge of its performances, which were deemed highly satisfactory. Perfect however as was the action of the improved machine, the patentees knew that much remained to be done to bring it into extensive operation; and they succeeded in obtaining an extension of the patent till the year 1800. Of the spirited manner in which Boulton conducted the mercantile department of the great adventure some idea may be formed from the fact, that upwards of 47,000*l.* was spent before the patentees began to receive any return; but at length their remuneration began to pour in, and in no scanty stream. They were, however, put to great expense by legal proceedings against infringements of their patent, and in defence of the patent itself.

At a social meeting of scientific men, a suggestion was thrown out which led Watt to the invention of the useful little machine known as the *Copying Press*, for which he obtained a patent. Towards the latter end of 1786, on a visit to Paris, undertaken at the instance of the French government for the purpose of suggesting improvements on the Machine de Marly, Watt became acquainted with Berthollet, whose method of bleaching with chlorine he brought to this country, and introduced, with certain improvements of his own, in the bleach-works of Mr. Macgrigor, near Glasgow, whose daughter he had married in 1775.

Concerning Watt's share in the discovery of the composition of water, an investigation in which he, Cavendish, and Lavoisier, were engaged about the same time, we must refer those who are curious to Arago's Life or 'Eloge' of Watt, and to the 'Historical Account of the Discovery of the Composition of Water,' by Lord Brougham.

One of the last of the projects to which Watt devoted his attention after his retirement from business was a machine for copying sculpture, with which he proceeded so far as to execute several specimens.

In acknowledgment of his invaluable services it was intimated to Watt a few years before his death, that 'the highest honour usually conferred in England on men of literature and science (knighthood) was open to him, if he expressed a wish to that effect;' but while he felt flattered by the intimation, he determined to decline it. He became a member of the Royal Society of Edinburgh in 1784, of that of London in the following year, of the Batavian Society in 1787, and in 1808 a correspondent of the French Institute; and in 1814 the 'Académie des Sciences' of the Institute elected him one of its eight foreign associates. In 1806, by a spontaneous vote, the university of Glasgow conferred upon him the honorary degree of LL.D. In 1824 a subscription was entered into for a statue, which was sculptured by Chantrey, and is now in Westminster Abbey. Another statue by Chantrey adorns an elegant chapel erected by Watt's only surviving son, at the parish church of Handsworth, near Birmingham, in the chancel of which he was interred. Other statues have been erected in St. George's Square, Glasgow, and in the university of Glasgow.

Every Exhibition of manufactures owes a debt to James Watt, of which it would be in vain to attempt to determine the value.

WAX. There are several varieties of this substance. *Bees' Wax* is a secretion from the ventral scales of the bee. With this substance the comb is constructed. From the comb the wax is extracted chiefly by pressure and by melting it in hot water, in which the impurities subside, after which the wax is poured into moulds. The wax has a yellowish or orange colour, and a peculiar odour. Even in winter it is soft enough to be indented by the nail, and in summer it is much softer. It melts at about 143° to 150° Fahr.

White Wax is obtained by melting yellow wax by means of steam, running it off into a perforated trough called a Cradle, from which it falls into water. By this means the wax is solidified and converted into a kind of ribbon; it is afterwards bleached, re-melted, re-bleached, and refined. Pure wax thus obtained is nearly devoid of smell, and is white with a yellowish tint; it is brittle and insipid; its melting point is 158° Fahr., and it solidifies at 149°.

Sealing Wax is not properly a wax. It is composed of shel-lac (4 parts), Venice Turpentine (1 part), and cinnabar (3 parts). The round sticks of sealing-wax are made by hand on a smooth slab of marble, which is kept at a moderate temperature by a brazier or chafing-dish placed beneath it. A quantity sufficient to make about six sticks is rolled out on the slab into one long stick, which, when of proper diameter, is cut into lengths. The sticks are then rolled on a cold slab beneath a smooth piece of wood or metal, and are afterwards polished by gently fusing the surface, and devices are stamped upon them. Sticks of a more complicated shape are cast in moulds. For the best black sealing-wax, the finest ivory-black is substituted for the cinnabar. Inferior materials are used for cheap wax. Soft sealing-wax contains bees'-wax in the place of the shell-lac.

A peculiar kind of wax is yielded by the *Ceroxylon Andicola*, or *Wax-Palm* of South America. Near the Andes this tree grows in all its grandeur, elevating its majestic trunk, coated with a thick incrustation of wax, to the height of 180 feet among the most rugged precipices of the wild region which it inhabits. It does not extend over more than 15 or 20 leagues of country altogether. The trunk is distinctly marked by rings caused by the fall of the leaves, which are from 18 to 20 feet long. The spaces between the rings are pale yellow, and smooth like the stems of a reed, and covered with a thick coating of wax and resin. This substance, melted with a third of fat, makes excellent candles. Vauquelin ascertained that this vegetable matter consists of two-thirds resin, and one-third-wax, which is only a little more brittle than bees'-wax.

WEATHER GLASS. [Barometer.]

WEAVING. We shall glance rapidly over this subject in the following order:—*Plain Weaving; Pattern Weaving; Double Weaving; Cross Weaving; Chain Weaving; Pile Weaving; Power Weaving.*

Plain Weaving.—Calico, Irish linen, and plain silk, are good representatives of this kind of weaving. In the language of weavers, the long threads are called, according to circumstances, *warp*, *twist*, *caine*, or *organzine;* while the cross threads are called *weft*, *woof*, *shoot*, or *tram.* We shall here use the simple terms *warp* and *weft.* The warp is always affixed to the loom or weaving machine; while the weft is contained in the shuttle, a small boat-like instrument.

The first operation consists in laying the requisite number of threads together to form the width of the cloth: this is called *warping.* Supposing there to be 1000 threads in the width of a piece of cloth; then the yarn, wound on the bobbins as it leaves the hand of the spinner, must be so unwound and laid out as to form 1000 lengths, constituting, when laid parallel, the warp of the intended cloth. The ancient method was to draw out the warp from the bobbins at full length in an open field; and this is still practised in India and China; but the *warping-frame* is now employed, in which the threads are arranged by means of a frame revolving on a vertical axis. When the warp is arranged around this machine, the warper takes it off and winds it on a stick into a ball, preparatory to the process of *beaming*, or winding it on the beam of the loom. The threads, in this latter process, are wound as evenly as possible on the beam; a separator, ravel, or comb being used to lay them parallel, and to spread them out to about the intended width of the cloth. Arrangements are then made for *drawing*, or attaching the warp-threads individually to certain mechanism of the loom. In this process all the threads are attached to stays fixed to two frames called *heddles*, in such a manner that all the alternate threads (1st, 3rd, 5th, &c.) can be drawn up or down by one heddle, and all the rest (2nd, 4th, 6th, &c.) by the other.

There are three movements attending every thread of weft which the weaver throws across the warp. In the first place he presses down one of the two *treadles*, by which one of the two heddles is depressed, thereby forming a kind of opening called the *shed*. Into this shed, at the second movement, he throws the shuttle containing the weft-thread, with sufficient force to drive it across the whole web. Then, at the third movement, he grasps the *batten*, which is a kind of frame carrying at its lower edge a comb-like piece having as many teeth as there are threads in the warp, and with this he drives up the thread of weft close to those previously thrown. One thread of weft is thus completed, and the weaver proceeds to throw another in a similar way, but in a reverse order, that is, by depressing the left treadle instead of the right, and by throwing the shuttle from left to right, instead of from right to left. In the commonest mode of weaving the shuttle is thrown by both hands alternately; but about a century ago John Kay invented the *fly-shuttle*, in which a string and handle are so placed that the weaver can work the shuttle both ways with one hand.

In weaving plain silks, calicoes, and other webs of moderate width, there are two leaves of heddles and two treadles, for dividing the warp into two parcels. In weaving broader webs, such as floor-cloth canvas, the heddles and treadles are more powerful. In weaving ribbons, galloons, &c., the *engine-loom* is employed, noticed under RIBAND.

Pattern Weaving. — Pattern-weaving has many varieties, in which different colours are combined by weaving. If all the threads of the warp are of one colour, and all those of the weft another colour, it produces the peculiar effect called *shot* patterns. A *stripe* is a pattern in which parallel lines run either along or across the warp; while a *check* is an alternation of rectangles like a chess-board, or more properly like the varieties of Scotch plaid. The production of a stripe depends either upon the warper or the weaver; the production of a check depends upon both. [CHECK.] In the *twill*, which includes satin, bombazeen, kerzeymere, &c., the weft-threads pass over one warp-thread and under two, over one and under three, or over one and under eight or ten, according to the kind of twill; the effect of this is, to produce a kind of diagonal ribbed appearance, either on the 'right' or the 'wrong' side of the cloth, and a smooth and glossy appearance on the other, according as the one thread is crossed above or below by the weft. [BOMBAZEEN; CHECK.] To produce such results, more than two leaves of heddles are required, and more than two treadles to work them; and the weaver's loom is a much more complicated machine than that for plain weaving.

When, instead of, or in addition to a twill, the weaver has to produce sprigs, flowers, spots, or any kind of figure, a great increase of complexity occurs. The weft may pass over four and under one at one part of the width of the cloth; over two and under two at another; over one and under four at another; according to the part of the figure which may happen to occur at any particular part of the width of the cloth. The complex movements thus rendered necessary gave rise to the invention of the *draw-loom*, in which strings are so arranged that a boy can draw down the requisite warp-threads preparatory to the movement of the shuttle. Early in the present century two inventions were made with the view of rendering the draw-loom more automatic. One of these, called the *draw-boy*, not only superseded the necessity of employing a boy to pull the handles, but removed, by the unerring certainty of its operation, all possible chance of mistake in pulling the wrong handle. The other was the *automatic carpet-loom* of Mr. Duncan, in which the threads were moved by pins inserted in a rotating barrel, somewhat on the principle of the musical box.

But the draw-loom, the draw-boy, and the barrel-loom, have been alike eclipsed by the exquisite apparatus of M. Jacquard. [JACQUARD.]

Double Weaving.—In all the fabrics hitherto noticed, there is but one layer of threads, formed by the intersection of the weft among the warp, both weft and warp being individually single. But there has long been practised the weaving of a kind of double cloth, composed of two webs, each consisting of separate warp and weft, but both sets interwoven at intervals. The junction of the two webs is formed by passing each of them occasionally through the other, so that each particular part of both is sometimes above and sometimes below. [CARPET MANUFACTURE.]

Cross Weaving.—*Gauze* and *Bobbin-Net* may be taken as the chief representatives of this kind of fabric. *Net* is the generic name for these goods; and according as slight deviations were made in the mode of crossing the threads, so were distinctive names given to the material produced; such as *whip-net*, *mail-net*, *patent-net*, *drop-net*, *spider-net*, *Paris-net*, *balloon-net*,

&c. All these varieties are produced at the loom, with warp-threads stretched horizontally, and weft-threads thrown across by means of a shuttle; and the difference between them depends on the manner in which the warp-threads were made to cross one another, and in which the weft-thread was thrown. [GAUZE; LACE MANUFACTURE.]

Chain-Weaving.—We may apply this term to a mode of using threads in which a series of loops is formed by a continuous thread, each loop or link being so connected with others as to form a kind of chain; and this chain-work may either be worked upon a ground woven at the loom, or may constitute the woven material itself. *Sampler work, lace running, tambouring, pillow lace, rug work, Berlin work, tapestry,*—all may be regarded as varieties of chain-work. The manufacture of *stockings*, whether by the humble process of knitting, or by the use of the stocking-frame, is in strictness to be called *chain-weaving;* for the fabric itself is produced by a series of links or loops in a thread of worsted, cotton, or silk. In the process of knitting, still carried on to a small extent in secluded country districts, polished steel needles or wires are used to link threads together into a series of loops, closely resembling in their character the loops produced in tambouring. But this method has been almost entirely superseded by the ingenious *stocking-frame.* Various kinds of chain-weaving are noticed under BERLIN WORK; EMBROIDERY; HOSIERY MANUFACTURE; LACE MANUFACTURE; TAPESTRY.

Pile-Weaving.—If we examine *velvet, fustian, velveteen, moleskin, doeskin,* or a *Turkey* or *Wilton carpet*, we shall find that in all of these fabrics the warp and weft threads are almost concealed by a kind of down, nap, or pile, which imparts a peculiarly soft and smooth texture to them. Fustians are in fact a kind of cotton velvet, as Turkey carpeting is a woollen velvet. A few details respecting this kind of weaving will be found under CARPET; FUSTIAN; VELVET.

Power-weaving.—In 1678 M. de Gennes invented a rude kind of weaving machine, intended to increase the power of the common loom; and other looms were invented which were to be worked by a winch, by water-power, or by some contrivance more expeditious than the common hand-weaving; but a greater step in advance was made by the invention of Dr. Cartwright's power-loom in 1785. [CARTWRIGHT.] One cause which delayed the adoption of power-looms was the necessity for stopping the machine frequently, in order to dress the warp with paste or size, as it unrolled from the beam, which operation required a man to be employed for each loom, so that there was no saving of expense. But the successive inventions ot Radcliffe, Horrocks, Marsland, Roberts, and others, have since brought the dressing-machine and the power-loom to a high state of efficiency.

Taking a piece of calico as the representative of plain fabrics generally, the mode of proceeding in power-loom factories may be shortly sketched as follows;—The *warping-frame* is so arranged as to be worked by steam-power, and to bring the yarns into a parallel layer, which is transferred to the *dressing-machine*. This latter is a large piece of mechanism, in which the threads dip into paste on their way to the warp-beam; undergoing a process of brushing after the dipping. After this dressing the *drawing* and mounting for the loom are attended to. When the warp is properly arranged in the loom, steam-power does all the rest: it forms the shed or division of the warp into two parts; it throws the shuttle; it drives up the weft with the batten; it unwinds the warp from the warp-roller; and winds the woven material on the cloth-roller.

WEDGE-PRESS. [OIL-MILL.]

WEDGWOOD, JOSIAH will ever be associated with the history of the porcelain and pottery manufacture in this country. He was born in 1730 at Burslem, in Staffordshire, where his father, Thomas Wedgwood, and some other members of his family, were engaged in the manufacture of pottery, a branch of industry then in a very imperfect state. His education was very limited; and at the age of eleven years Josiah worked in his elder brother's pottery. The small-pox, which left an incurable lameness in his right leg, so as afterwards to require amputation, compelled him to relinquish the potter's wheel. After a time he left Burslem, and entered into partnership with a person named Harrison, at Stoke; and during this partnership his talent for the production of ornamental pottery is said to have first developed itself. He returned to Burslem in 1759, and set up for himself. His business being prosperous, he took a second manufactory, where he made white stone-ware, and a third, at which was produced the improved cream-coloured ware by which he gained so much celebrity. Wedgwood presented some articles to Queen Charlotte, who ordered a complete table service, and appointed him her potter. He soon afterwards opened a warehouse in the metropolis for the sale of his productions. One of his principal works was his imitation of the Portland Vase, of which he made fifty copies. But though these were sold for fifty guineas each, that sum did not, it is said, repay him for his expenditure. He succeeded in producing the most delicate cameos, medallions, and miniature pieces of sculpture, in a substance so extremely hard, that they appear likely to exceed even the bronzes of antiquity in durability. Another important discovery made by him was that of painting on vases and similar articles, without the glossy appearance of ordinary painting on porcelain or earthenware; an art which appears to have been lost since the time of Pliny. The fame of his operations was such that his works at Burslem, and subsequently at Etruria, a village erected by him near Newcastle-under-Lyne, and to which he entirely removed in 1771, became a point of attraction to numerous visitors from all parts of Europe. The result of Wedgwood's talent and energy not only obtained for him extensive patronage and an ample fortune, but were of the highest importance to the commercial interests of his country.

In addition to the attention bestowed by Wedgwood upon this manufacture, he deserves remembrance for the public spirit displayed by him in the encouragement of various useful schemes. Among these the Trent and Mersey Canal is conspicuous. Wedgwood's pyrometer is noticed elsewhere. [PYROMETER.] He died at Etruria in 1795.

WEIGHING-MACHINE, is any contrivance by which the weight of an object may be ascertained. Under the words BALANCE, GOLD WEIGHING-MACHINE, SPRING-BALANCE, and STEELYARD, the machines by which materials of comparatively small magnitude are weighed are explained. The Weighing-Machine, which is usually employed at the toll-gates on roads for the purpose of determining the weights of laden carriages, may be described as a platform sunk on a level with the road, and made to rest at four points on a double lever of the second kind. [LEVER.] The extremities of the arms of these levers rest upon a third lever, which may be of the first or second kind; and this last lever may either serve as a steelyard, or may be connected with one arm of an ordinary balance, or with the extremity of a steelyard.

Mr. Elliott has sent to the Great Exhibition a new form of weighing-machine, somewhat on the principle of a steelyard, but with certain new features of construction. With one ball or weight of 4 lbs., the instrument will determine all weights from a quarter of a pound to 56 lbs. It is also graduated with *kilogrammes*, to measure French weights.

WEIGHTS AND MEASURES. Under APOTHECARIES' WEIGHT, AVERDUPOIS WEIGHT, STANDARD, and TROY WEIGHT, many details are given on this subject. We will here give a few brief notices concerning *Foreign* weights and measures, as they are often useful while reading industrial statistics of foreign countries.

France.—The new French system is called *metrical*, as derived from the measurement of the earth. Its first measure, the *metre*, is presumed to be the ten-millionth part of a line drawn from the pole to the equator, and is 39.37079 English inches. All the multiples and subdivisions of every measure are decimal, and are formed by the same prefixes. For 10, 100, 1000, and 10,000, the syllables *Deca*, *Hecto*, *Kilo*, and *Myria* are prefixed; and for tenths, hundredths, thousandths, the syllables *Deci*, *Centi*, *Milli*. Latin prefixes indicate division, Greek prefixes multiplication. Thus the hectometre is 100 metres, and the centimetre the hundredth part of a metre. The metre being thus settled, the other fundamental measures are formed as follows:—For surface or area, the *Are*, which is a decametre square, or 100 square metres, or .02471143 of an English acre, or 3.9538 English perches. For solidity, the *stere*, or cubic metre, 35.32 cubic feet English, or 220.09687 imperial gallons English. For liquid measures the *litre*, or cubic decimetre, .22009687 of an imperial gallon, or a very little more than a pint and three quarters English. For weight, the *gramme*, a cubic centimetre of distilled water at the freezing point, .00220606 of an English pound averdupois, or 15.442 grains English. The *kilogramme* is therefore 2.2 pounds averdupois, or, roughly, 50 kilogrammes make a hundredweight. The *franc*, the unit of money, is divided into 10 decimes, and each decime into 10 centimes. The *sous* is 5 centimes.

Austria. The metrical system is introduced in the Italian dominions. In Austria proper gold and silver are weighed by the *Vienna marc* of 4333 grains. The *pfund* is 1.235 lb. averdupois. The *metzen* is 1.691 of the English bushel. The *eimer* is 12.444 gallons. The *foot* is 12.45 inches; the *ell*, 30.66 inches. The *joch* is 1 acre, 1 rood, 28 perches.

Bavaria. The *Augsburg marc* is 3643 grains; 24 lb. *commercial* weight is 25 lb. averdupois, and 24 lb. *carriers'* weight is 26 lb. averdupois, nearly. The *metzen* is 1.515 of the English bushel; the *fuder* is 31.24 bushels. The *foot* (half the short ell) is 11.667 inches. The *long ell* is 24 inches. The German *geographical mile* is 4.6 miles English.

Belgium. The French metrical system.

Constantinople. The *chequee* is 4957 grains. The *oke* is 2.832 pounds averdupois. The *killow* (dry) is 7.296 gallons. The *almud* is 1.150 of the English gallon. The *pike* is 27 inches.

Denmark. The *pound* for gold and silver is 7266 grains. The *commercial pound* is 1.1028 lb. averdupois. The *barrel* is 3.8264 bushels. The *viertel* is 1.701 of the English gallon. The *foot*, or *half-ell*, is the Rhineland foot of 12.356 English inches. The *toende* of corn is 5½ acres.

Florence and Leghorn. The *cantaro* is 150 pounds of .74864 lb. averdupois each. The *stajo* is .6702 of the English bushel. The *barile* is 10.033 gallons. The *braccio* is 22.98 English inches. The *saccata* is 1 acre 36 perches.

Frankfort. For gold and silver the *Cologne marc.* The common *pound* is 1.03 lb. averdupois. The *centner* is 112.25 lb. averdupois. The *malter* is 2.9705 bushels. The *ohm* is 32.454 gallons. The *foot* is 11.27 inches, the *ell* 21.24 inches.

Genoa. The *pound sottile* for gold and silver is 4891.5 grains. The *pound grosso* is .76875 lb. averdupois. The *mina* is 3.321 bushels. The *mezzarola* is 32.57gallons. The *palma* is 9.725 inches.

Hamburg. The *Cologne marc* is 3608 grains; the *pound troy* is two marcs. The *commercial pound* is 1.068 lb. averdupois. The *last* of wheat (30 scheffels) is 10.9 quarters; the *ahm* is 31.85 gallons. The *foot* is 11.289 inches. The *scheffel* of land is 1 acre 6 perches.

Holland. The *marc* is 3798 grains; the *pound* is 2 marcs; but the *commercial pound* is 1.0893 lb. averdupois. The *last* is 10.231 quarters. The *aum* is 34.16 gallons. The *Rhineland foot* is 12.36 inches. The *Rhineland perch* is 12 Rhineland feet; and the *Rhineland morgen* or *acre* is 2 acres 16 perches.

Lübeck. For gold and silver, as at Hamburg. The *commercial pound* is 1.0685 lb. averdupois. The *scheffel* is .92 of the English bushel. The *ahm* is 31.85 gallons. The *foot* or *half-ell* is 11.346 inches.

Malta. The *pound* for gold and silver is 4886 grains. The *commercial pound* is 1.745 lb. averdupois. The *salma* is 7.968 bushels. The *foot* is 11.167 inches. The *canna* (8 palmi) is 81.9 inches.

Milan. The *mark* is 3627 grains. The *pound sottile* is .7206 lb. averdupois; the *pound grosso* is 1.682 lb. averdupois. The *moggio* (32 quartari) is 4.0234 bushels. The *brenta* (12 quartari) is 15.71 gallons. The *braccio* is 23.42 inches. The metrical system is also introduced.

Naples. The *pound* for gold and silver is 4950 grains. The *cantaro grosso* is 196.5 pounds averdupois, the *cantaro piccolo* 106 pounds averdupois. The *tomolo* is 1.407 of the English bushel. The *barile* is 9.172 gallons. The *palmo* is 10.38 inches. The *moggia* is 3 roods 12 perches.

Netherlands. The French metrical system.

Portugal. The *marc* is 3541.5 grains. The *commercial pound* is 1.0119 lb. averdupois. The *moyo* is 22.39 bushels. The *almude* is 3.6407 gallons. The *foot* is 12.944 inches.

Prussia. The *Cologne marc* is 3609 grains 2 marcs are a *commercial pound*, or 1.0311 lb. averdupois. The *scheffel* is 1.5116 of the English bushel. The *eimer* is 15.11 gallons. The *foot* is 12.356 inches; the *ell* two-thirds of a metre. The *morgen* or *acre* is 2 roods 21 perches.

Rome. The *pound* is 5234 grains, or .7477 lb. averdupois. The *rubbio* (4 quarte) is 8.1012 bushels. The *barile* (32 boccali) is 12.841 gallons. The *foot* is 11.72 inches; The *builders' canna*, of 10 palms, is 87.96 inches.

Russia. There is but one *pound*, .9026 lb. averdupois. The *pood* is 36 lb. averdupois. The *chertwert* is 5.7698 bushels. The *vedro* is 2.7048 gallons. The *inch* is the English one; the *arshine* is 28 inches; the *foot* is 13¾ inches; but the English foot is in common use. The Russian *verst*, or *werst*, is 0.664 (or about two-thirds) of an English mile. The *dessetina* is 2 acres, 2 roods, 32 perches.

Sardinia has lately adopted the French metrical system.

Saxony. For gold and silver the *Cologne marc.* The *commercial pound* is 1.0294 lb. averdupois. The *Dresden wispel* (24 scheffels) is 69.85 bushels; the *Leipzic wispel*, 91.747 bushels. The *Dresden eimer* is 14.89 gallons; the *Leipzic eimer* 16.75 gallons. The *Dresden foot* is 11.14 inches; the *Leipzig foot* is 11.13 inches. The *acre* is 1 acre, 1 rood, 18 perches.

Sicily. The *pound* is 7 pounds averdupois. The *cantaro grosso* is 192.5 pounds averdupois; the *cantaro sottile* is 175 lb. averdupois. The *salma grossa* is 9.46 bushels; the *salma generale* 7.59 bushels. The salma of wine is 19.23 litres. The *palmo* is 9.5 inches.

Smyrna. The *chequee* is 4958 grains. The *rottolo* is 1.2748 lb. averdupois. The *killow* is 11.3 gallons. The *pike* is 27 inches.

Spain. The *Castilian marc* for gold and silver is 4800 grains. The *commercial pound* is 1.0144 lb. averdupois. The *fanega* is 1.55 of the English bushel. The *arroba* of wine is 3.538 gallons. The *foot* is 11.128 inches; the *vara* is 33.384 inches. The *fanegada* (for corn-land) is 1 acre, 21 perches.

Sweden. The *Mint marc* is 3252 grains. The *commercial pound* is .9376 lb. averdupois. The dry *tunna* is 4.028 bushels; the *liquid tunna* is 48 *kanns* of .5756 of the English gallon each. The *foot*, or *half-ell*, is 11.684

inches. The *tunneland* is 1 acre 35 perches.

Switzerland adopted the French metrical system by a law passed in 1849.

United States. The weights and measures are those of England before the introduction of the imperial standard.

WEIR, or WEAR, is a dam erected across a river, either for the purpose of taking fish, of conveying a stream to a mill, or of maintaining the water at the level required for the navigation of it. By the laws of England, no weirs can be maintained on any rivers to the prejudice of the public, or even of individuals, except such as have existed time out of mind, or such as have been erected under local acts of parliament for the navigation of particular rivers.

WELLS. [Artesian Wells; Boring.]

WEST INDIES. With the exception of Hispaniola or Hayti, which is an independent republic, the islands composing the West Indies are subject to six different European nations — the Spaniards, English, French, Danes, Dutch, and Swedes.

The Spanish possessions are the largest, and comprehend more than half the area of the archipelago; they consist of Cuba, Puerto Rico, Culebra, and Bique. The English possessions are next in extent. They consist of Jamaica, the Bahamas, the Virgin Islands, (Tortola, &c.), Anguilla, Barbuda, Antigua, St. Christopher, Nevis, Montserrat, Dominica, Santa Lucia, Barbadoes, St. Vincent, Grenadines, Grenada, Tobago, and Trinidad. The French possess only a few of the Lesser Antilles, namely Guadaloupe, with several smaller islands in its vicinity, and Martinique. The Danes possess three of the Virgin Islands, viz. St. John, St. Thomas, and Santa Cruz. The Dutch possessions consist of three Lesser Antilles, viz. St. Eustatius, Saba, and St. Martin.

Since the abolition of negro slavery in the British West Indies in 1834, immigrants and liberated Africans have arrived there to assist in cultivating the sugar estates. Their number from 1834 to 1849, was, in—

Jamaica	14,519
Trinidad	13,356
Grenada	1,476
St. Vincent	1,197
Antigua	1,075
Dominica	732
Nevis	427
St. Kitt's	95
	32,877

The British produce and manufactures exported to the British West Indies in 1849 were valued at 1,521,954*l.*

The imports from the British West Indies and Honduras in 1849 included—

Cocoa	3,159,086 lbs.
Coffee	3,596,839 lbs.
Molasses . . .	605,628 cwts.
Rum	4,329,640 galls.
Sugar	2,897,837 cwts.

The imports from the foreign West Indies and Hayti in 1848 included—

Coffee	3,639,108 lbs.
Molasses . . .	95,893 cwts.
Rum	156,185 galls.
Sugar	957,015 cwts.
Tobacco	573,316 lbs.

A few further industrial and commercial statistics will be found under the names of the principal islands.

WESTERN AUSTRALIA dates its history as a British colony from the year 1829. Its progress has hitherto been comparatively slow. The imports in 1848 were valued at 45,411*l.*; the exports at 29,598*l.* The shipping inwards was estimated at 15,494 tons; outwards at 13,957 tons. The wool exported amounted to 301,965 lbs., valued at 9666*l.* The gross revenue was 18,188*l.*, but this included a sum of 7695*l.* voted by the British parliament for the service of the colony. Western Australia is, as yet, one of the poorest of the British Colonies; and little can be said concerning its produce, industry, or commerce.

WESTMORELAND. Geologically, this county may be regarded as consisting of three parts. The slate rocks of the Cumbrian mountain group form the first part or division; the formations of the great carboniferous and mountain limestone series of the north of England, of which formations the Pennine Chain forms the western outcrop, constitute the second division; and the new red sandstone of the valley of the Eden forms the third division. Westmoreland contains some very fertile valleys, in which there are many well-cultivated farms. The soil in the valley is mostly a dry gravelly mould, composed different earths washed down from the hil and forming a soil well fitted for the culti tion of turnips, of which great crops are rais on some well-managed farms. Near Kend a great breadth of potatoes is planted for the supply not only of the immediate neighbourhood, but also of the adjacent counties, many thousand loads being annually sent into Lancashire and Yorkshire. Grass land being abundant and the climate favourable to pasthres, a great portion of the soil is devoted to the maintenance of cattle; good meadows let at a high rent, and are carefully manured with composts; and great crops of hay are made in favourable years.

Westmoreland is not a manufacturing county; but considerable manufactures are carried on at Kendal of cotton checks, kerseys and other woollens, linsey, blanketing, fancy waistcoating, carpets, girths, hosiery, sacking, and worsted.

WESTPHALIA, is one of the richest and busiest of the Prussian provinces. The vegetable products are—corn of all kinds, peas, beans, garden vegetables, fruit, hemp and flax (which are staple articles), hops, and timber. The minerals are—iron, copper, lead, calamine, marble, slate, freestone, salt, and coal: there are extensive turf-moors. The manufactures include linen, cotton, woollen cloth, silk, leather, hosiery, and paper. There are numerous iron, copper, and steel-works, and manufactories of all kinds of cutlery and copper, brass and iron goods. There are also many sugar refineries, brandy distilleries, and tanneries in the province. The commerce in the products indicated and in hams is important. The Cologne-Minden railway, with branches to Münster and Paderborn, traverses the province, and connects it with Berlin, Hanover, Hamburg, and Bremen.

WEXFORD. The agriculture of Wexford is generally in a creditable state, considering the natural disadvantages of the soil. The crops consist of the various kinds of grain, of which barley is the principal, beans, tares, rape, turnips, and potatoes, the last being the staple crop, and that upon which most manuring is bestowed. Dairies are numerous, and much butter is exported. The great extent of sea-coast and the numerous banks in the vicinity render the fisheries of Wexford very important to its population, many of whom are engaged in them; the coast presents very numerous creeks capable of accommodating open boats, and at most of these some fishermen are resident, but there are no harbours suitable for large vessels. The manufactures of the county are of little importance; woollen cloths, checks, and coarse linens are made, but on a small scale.

WHALE FISHERY. Whales are sought after for many useful purposes which they render to man. The flesh of the *Manatee* whale is excellent eating. The *Narwhal*, a kind of whale, is valued for its blubber and its ivory tusk. The *Sperm Whale* yields eight or ten barrels of spermaceti, besides oil and whalebone. To the Esquimaux and the Greenlander the *Greenland Whale* is all in all. They eat the flesh and fat with indescribable relish. The membranes of the abdomen serve them for clothing, and the thin transparent peritoneum admits light through the windows of their huts, whilst it keeps out the weather. The bones are made into props for their tents, or aid in the formation of their boats, and supply them with harpoons and spears for the capture of the narwhal, the seal, and greater sea birds. The sinews divided into filaments are used as thread for sewing their dress, &c. To civilised nations, the oil made from its fat or blubber, and the whalebone, have long made it a great commercial object.

The Arctic regions, between the northern parts of America and Europe, have for some centuries been the chief seat of the Whale Fishery. The whales were so abundant that the fishing was easy and the profits great; but in later years the whales have evidently lessened in number, and the fishery has become gradually more precarious. At first there were settlements on the shores of Greenland and other lands in the north, where the whale blubber was boiled down into oil, and in that state sent to England; but in later years it has been the practice to bring the blubber itself to England, and there boil it down. Between 1815 and 1834 the number of English ships engaged in the northern whale fishery varied from 76 to 159; the annual capture of whales varied from 161 to 2018 (so very uncertain is the success of this employment); the annual yield of oil, 2199 to 18,745 tuns; and of whalebone, 119 to 946 tons. So hazardous are these enterprises, that there were not less than 99 whale ships lost in the above-named twenty years, of which 19 were lost in the disastrous year 1830. Hull and Peterhead are the chief British ports to which the whalers belong; but the northern whale fishery has materially declined in the seventeen years since 1834.

The Whale Fishery of the Southern Ocean has sprung into importance as that of the Northern has declined. The relation which the newly-settled Auckland Isles bear to the Southern Whale Fishery is noticed in an earlier article [AUCKLAND ISLANDS]. The southern fishery is prosecuted energetically by the United States, as well as by Britain and other countries.

The following are the numbers of vessels engaged in the American whale fisheries, and the quantities of sperm oil and whale oil procured, in the last 10 years:—

	Ships.	Barrels—Sperm.	Barrels—Whale.
1850	177	86,157	191,752
1849	188	99,433	256,183
1848	196	108,531	243,876

1847	253	121,410	320,545
1846	199	92,877	219,763
1845	242	158,484	274,843
1844	(?)	138,585	267,082
1843	145	167,134	205,861
1842	207	163,697	163,816
1841	222	157,643	205,164
1840	213	156,445	203,441

Whalebone also forms an important item in the products of the fisheries. The quantities imported into the United States during the last ten years have been as follow:—

1850	2,242,012 lbs.
1849	1,990,640 „
1848	1,755,892 „
1847	3,450,124 „
1846	2,723,939 „
1845	3,116,100 „
1844	3,015,145 „
1843	1,933,321 „
1842	1,329,234 „
1841	1,942,885 „

The year 1850 was a very profitable one in the southern fishery, and more than usually unprofitable in the northern.

WHARF, is a place constructed or set apart for the loading and unloading of goods. In this sense the word includes the quays of all sea-ports at which goods are required to be shipped or landed. The sea-beach or natural ground on the banks of a river or canal, is not a wharf. Wharfs in docks and similar situations are made legal by special acts of parliament, as the London Docks, &c., and there are some places which are deemed wharfs from immemorial usage. For the use of a wharf certain rates are usually charged, which are called *wharfage*. The wharfs of the port of London were established in 1558, in the first year of the reign of Queen Elizabeth. Several *sufferance wharfs* have been since added to these, under the authority of the commissioners of customs, and other sufferance wharfs are occasionally authorised for the landing and keeping of goods by the custom-house till the duties are paid or the goods bonded.

No goods except diamonds and bullion, fresh fish of British taking, and turbots and lobsters fresh, however taken or imported, are allowed to be unshipped from any ship arriving from foreign parts beyond seas, or landed or put on shore, except at legal quays appointed by her majesty for landing of goods, or at some wharf appointed by the commissioners of customs. Goods entitled to drawback or bounty are only to be shipped in Great Britain by wharfingers appointed by the commissioners of customs.

WHEAT. The species and varieties of wheat are numerous; but there are three principal kinds, so different in appearance that they claim peculiar attention. These are the *hard* wheats, the *soft* wheats, and the *Polish* wheats. The hard wheats are the produce of warm climates, such as Italy, Sicily, and Barbary. The soft wheats grow in the northern parts of Europe as in Belgium, England, Denmark, and Sweden. The Polish wheats grow in the country from which they derive their name, and are also hard wheats. It is from their external form that they are distinguished from other wheats. The hard wheats have a compact seed nearly transparent, which, when bitten through, breaks short, and shows a very white flour within. The soft wheats are those usually cultivated in Britain; they have an opaque coat or skin; which, when first reaped, gives way readily to the pressure of the thumb and finger. These wheats require to be well dried and hardened before they can be conveniently ground into flour. The Polish wheat has a long chaff which is much longer than the seed, a large oblong seed, and an ear cylindrical in appearance. It is a delicate spring wheat, and not very productive in the climate of England.

The hard wheats contain much more gluten than the soft wheats. It is this quantity of gluten which causes the Italian wheats to be used exclusively for the pastes which form so large a portion of the food of that nation. [VERMICELLI.] The soft wheats contain the greatest quantity of starch, which fits them for the vinous fermentation, by its conversion into sugar and alcohol: for brewing or distilling, therefore, the soft wheats are the best.

The distinction between the *winter* and *summer* wheats is one which arises entirely from the season in which they have been usually sown; for they can readily be converted into each other, by sowing earlier or later, and gradually accelerating or retarding their growths. The difference in colour between *red* and *white* wheats is owing chiefly to the soil; white wheats gradually become darker and ultimately red in some stiff wet soils, and the red wheats lose their colour and become first yellow and then white on rich, light, and mellow soils.

The quantity of wheat imported in 1849 was 3,872,134 quarters; the quantity entered for home consumption was 4,509,626 quarters. The gross amount of duty received was 226,785*l.*

WHEEL AND AXLE is a machine consisting usually of a cylinder to which a wheel is firmly united, so that the axes of both are coincident. The *capstan*, the *windlass*, and the *helm-wheel* of a ship are only so many different forms of the same class of machines. Frequently also the axle is made to carry a wheel with teeth on its circumference, in order that, by revolving, motion may be communicated to machinery: such are the *wind-mills* and *water-mills* which are employed for grinding corn.

Considered as a mechanical aid in locomotion, lifting, transference of power, &c., the wheel and axle act like a lever of the first kind.

WHEELS. In machinery, wheels are generally used for transmitting motion, regulating velocity, converting one species of motion into another, reducing friction, or equalizing the effect of forces applied in an intermittent or irregular manner.

The simplest mode of transmitting motion from one wheel to another is by causing their peripheries to revolve in contact and pressing them together, in order to prevent slipping. Another mode of transmitting rotatory motion more effectually than by simple contact is by the use of endless bands or straps passing over the peripheries of the wheels which are intended to revolve together. Straps or belts are much used in cotton-factories, and other works in which moving-power has to be communicated to a great number of machines in different parts of a building, and they are preferred to cog-wheels in cases where sudden strains are liable to occur, because of the yielding character of the connection effected by them. Such straps were formerly made of leather; but caoutchouc and gutta percha are now largely used. Sometimes a chain of links is used instead of a band.

To convert rotatory motion into rectilinear, or rectilinear into rotatory, various forms of the rack and pinion are used. In its simplest form this contrivance is applied in raising sluice-gates, in lifting-jacks, and various other machines in which a fixed pinion or small toothed wheel is made to give motion to a straight toothed bar capable of moving in the direction of its length. A crank is also applied in various ways for converting rotatory motion into rectilinear, or rectilinear motion into rotatory. Of the *Excentric* and other wheels for producing rectilinear or irregular motion from a revolving axis, or for producing uniform rotation from an intermittent force, the varieties are numerous.

The escapement-wheels of clocks and wheels furnish types of another important class of wheels for modifying motion; and snail-wheels, pin-wheels, ratchet-wheels, and fusee wheels, are among the ingenious contrivances by which the rotatory motion of a wheel and axle may be made to set in motion a train of complicated machinery, or to regulate and vary motion at pleasure. Another class of wheels, called *Friction-Wheels* are intended to lessen the evils of friction in machinery.

Wheels introduced into machinery for the purpose of overcoming inertia, or of rendering uniform and steady a motion derived from an intermittent or variable source, are called *Fly-Wheels.* Since they owe their effect to their weight, fly-wheels are usually heavy, and as much as possible of their weight is disposed in the rim, where, owing to the effect of centrifugal force, it is of far more value than when near the centre. The steam-engine, the stamping-press, the common lathe, the coffee-mill, and a variety of other machines exhibit the useful application of a fly-wheel. In roasting-jacks, musical-boxes, the striking-apparatus of clocks, and various other contrivances in which a retarding force is required to prevent the moving power of a spring or weight from running down too rapidly, wheels with projecting vanes, which encounter sufficient resistance from the air to moderate their velocity, are used under the name of *Flys* or *Flyers.*

A small wheel having cylindrical staves or spindles fixed between two circular boards or plates of metal, in positions parallel to the axis of rotation, is called a *lantern wheel:* and when a wheel acts with one which is smaller in diameter, whatever be the form of the teeth, the latter is usually called a *pinion.* Wheels having the teeth formed on their circumferences so as to project from thence in the direction of the radii are called *spur-wheels:* but when the teeth are perpendicular to the plane of the wheel, the latter is called a *crown* or *contrate wheel.* If the teeth are cut on the circumference of a wheel in a direction oblique to its plane, the wheel is said to be *bevilled;* and two wheels may have their teeth so bevilled as to revolve in planes making any angles with one another.

WHETSTONE, is a smooth flat stone used for whetting or sharpening edged instruments by friction. Whetstones, of which a peculiar kind for sharpening razors are called *Hones,* are made of various kinds of hard close-grained stone, and are moistened, when in use, with either oil or water. [GRINDSTONES; TURKEY HONE.]

WHISKEY. [DISTILLATION; RECTIFYING; SPIRIT TRADE.]

WHITE-LEAD MAFUFACTURE. This branch of industry exhibits many interesting features, both on account of the chemical relations which govern it, and the mechanical arrangements adopted.

White lead is made from common metallic

sheet lead; it is a *carbonate*, and is produced in the following way. The lead is first cast into the form of flat pieces, about 20 inches long, by 5 broad, $\frac{1}{8}$th of an inch thick, and weighing 5 lbs. In a large lofty room a pile is built up, formed in the following singular way; a layer of fine ashes is strewed over the floor: then comes a layer of tanner's spent bark, two or three feet thick; then a layer of earthen pots, about five inches in diameter, each containing a pint of strong vinegar; then a layer of the leaden plates, five or six in depth, over the open mouths of the pots; then a layer of boards; then a second layer of tan, vinegar pots, lead plates, and boards—then a third layer of tan, vinegar pots, lead plates, and boards, and so on, until the room is filled to the ceiling, a height of perhaps 20 feet. The whole is called a *stack*, which consists of as many *beds* as there are recurrences of the above series, perhaps seven or eight. A stack usually comprises about 30 tons of lead plates besides the weight of the pots, vinegar, &c. The room is then closed up, and left untouched for many weeks.

During this period a somewhat complicated chemical process goes on. The spent bark, by fermenting, gives off heat, which raises the general temperature to 180° Fahr. The vinegar, at this temperature, evaporates slowly, and gives off an acid vapour which acts upon the lead; the lead first becomes an oxide, then it becomes an acetate by combining with the acetic acid vapour, and this is transformed to a carbonate by carbonic acid arising from the tan. This action takes place in about one half of the thickness of the lead, at the two surfaces; the central part remaining unacted upon. The door is then opened, the stack taken down, and all the lead plates removed. Each piece is passed between two brass rollers, which crush and remove the earthy carbonate from the surface; the remaining metallic lead is remelted, to be used again; and the carbonate goes through further processes. The carbonate is mixed with water, brought to the state of a fine cream, evaporated, and dried: it then constitutes *white lead*, which is brought to market either in the earthy state, or ground up with oil as a paint.

There are other and more expeditious methods which have been patented within the last few years, but the above is the general method, as practised at Newcastle.

See further on this point under ZINC PAINT.

WICKLOW. This Irish county is rich in minerals. Galena green and white lead ore, and copper pyrites are found in the granitic districts. The ore is smelted in small blast-furnaces, with the aid of turf, lime, and a small portion of the purest blind-coal. In the clay slate tract are found gold, silver, copper, iron, lead, zinc, tin, tungsten, manganese, arsenic, and antimony. The discovery of native gold near Croaghan Kinshela Mountain took place about 1796, and many hundred people assembled daily to search for it in the bed and on the banks of the Ballinvalley, or Goldmine River, a stream which rises in the mountain, and joins the Daragh just above its junction with the Ovoca. Government took up the matter, and regular stream-works were established, but they were destroyed in the insurrection of 1798. They were resumed in 1801, with the addition of works for the discovery of auriferous veins; but the search was unsuccessful, and the whole of the works were abandoned.

The soil of Wicklow is very fertile in the lower tracts and along the river-courses. The crops are oats, potatoes, and some wheat. Pasturage is also much attended to. The occupations of the people are generally agricultural: manufactures being at a very low ebb.

WILLOW. The *timber* willow, the *weeping* willow, the *osier* willow, and many other kinds, render a singular variety of uses to man. The leaves, flowers, and young shoots are eaten as food by various domestic animals. The dried inner bark is mixed with oatmeal in Norway. The twigs are extensively used in Russia and Sweden as thongs and cords. The bark is used in the same countries for shoes, buckets, boxes, roof coverings, and other articles; it is also used as a tanning ingredient and when separated into fibres it is woven into cloth.

The willow timber is soft, smooth and light; it is employed in making cutting boards for tailors and shoemakers; for cork-cutters sharpening boards; for turnery; for flooring and rafters; for lining waggons and carts; for paddle-boards, water-wheels, and small vessels and boats. The smaller timber and shoots are used for ladder-poles, hop-poles, vine-props, clothes-props, rake-handles, hurdles, crates, hampers, hay-racks, hoop-barrels. In France, hats are made from strips or shavings of the white willow. Sheets of woven material called *Willow*, consist of a fabric woven with fine strips of willow wood, subsequently stiffened; they are in common use for the framework of bonnets, and of light or 'gossamer' hats. A downy substance which envelopes the willow seed is used in Germany as a wadding for ladies' dresses. The willow makes very excellent charcoal.

The best known use of the willow, however, is in making baskets. For this purpose the kind called *osiers* is chiefly selected. The principal plantations of basket-osiers in this country, and indeed in every other, are made along the banks of rivers and streams. In England the Thame and the Cam are the most celebrated in this respect; in both these rivers small islands are frequently planted entirely with osiers, and are called *osier-holts*. There are many such islands in the Thames, between Reading and London. The largest plantation of these willows is near Reading. The most extensive willow plantations in fields (instead of river banks and islands) are in the fenny districts of Cambridge and Huntingdon counties.

The application of these willows or osiers is described under BASKET MAKING.

WILNA, a government of West Russia, is somewhat rich in agricultural produce. Rye is the principal grain crop; barley, wheat, oats, buck-wheat, peas, beans, hops, flax, and hemp are likewise grown, and a considerable quantity exported. Bees are kept in great numbers, and the quality of the honey is very superior. The forests not only furnish large quantities of timber and fuel, but supply material for building every year about 3000 craft for the navigation of the Düna, Wilia, and Niemen, which never come back. Charcoal pitch, tar, potashes, and lamp-black are made. The minerals are bog-iron, saltpetre, marble, granite, sandstone, jasper, agates, and chalcedony. The manufactures are unimportant, being entirely of a domestic kind. The exports, consisting of the produce already named, are sent partly to Riga on the Düna, still more by land-carriage to Libau, and a considerable quantity by the Niemen to Prussia. The inland trade is almost exclusively in the hands of the Jews.

WILTSHIRE. There are very few mineral deposits worked in this county. In respect to commerce, the navigation of the Thames, the Kennet, and the Bristol Avon, does not commence until after those rivers have quitted the county; but the want of river-navigation is partially supplied by canals, of which three lines are connected with this county. These are the Thames and Severn canal, the Kennet and Avon Canal, and the Wilts and Berks Canal. Many of the principal towns are now accommodated with railway facilities.

In an agricultural point of view Wiltshire may be divided into two districts; a southern district comprehending all the Wiltshire Downs, with their intersecting valleys; and a northern district. The soil on the downs produces excellent short herbage, very well suited for sheep pasture. The proportion which has been converted into arable land is comparatively small, and chiefly on the borders of the valleys. In the northern district, where the top soil is thin, it is chiefly cultivated as arable land; but where it is deep and rich, there are some of the finest pastures in England, such as those about Chippenham, and thence southward to Melksham and Trowbridge, where the largest oxen may be fatted. This district is essentially a dairy country. The grass land forms the greater portion of the north-west part of Wiltshire, and the cheese made there is justly celebrated; it is mostly bought up by factors for the supply of London and other large towns.

Wiltshire is one of the most manufacturing counties in the West of England; the carpets of Wilton, and the woollen-cloths of Bradford, Trowbridge, &c. have been long celebrated, though they have been eclipsed in late years (in quantity but not in quality) by the productions of the West Riding.

WINCH AND AXLE is a machine constituting a small windlass, and consisting of a cylinder of wood which is capable of turning on its axis between two upright posts of the same material, or between the ends of a cast-iron frame. A lever at one or at each extremity of the cylinder is attached to an iron axle which passes through the cylinder, and is turned at right angles to its direction, and again turned, so as to furnish a handle parallel to the cylinder. When of a simple form it is employed to raise water from a well, earth from the shaft of a small mine, &c.; but when the cylinder or barrel is turned by the intervention of toothed wheels and pinions, in which case the machine is called a *Crab*, it is frequently employed to raise casks or heavy packages from the ground to the upper part of a building. [WHEEL AND AXLE; WINDLASS.]

WIND MEASURER. [ANEMOMETER.]

WINDLASS. The *Winch and Axle*, the *Windlass* by which on board of small ships the anchors are weighed, and even the *Capstan*, are so many different forms of the same machine. In the last two of these machines the power of men is applied at the extremities of handspokes or levers inserted at their opposite extremities in holes made in the axle or barrel to receive them. In the capstan, the axis of the barrel being vertical, the handspokes are in horizontal positions, and the men exert a continuous pressure against them while walking round.

In the machine to which the name of windlass is more particularly applied, the barrel is a horizontal cylinder. In order to turn the cylinder on its axis the men mounting on it plant their handspokes vertically in a series of holes formed at intervals for the purpose; then grasping them as high as they can reach, they pull towards themselves: when the cylinder is turned nearly a quarter round, the handspokes being almost in horizontal positions, the men throw upon them the whole weight of their bodies, and by the weight the cylinder is still further turned. After this the handspokes are drawn out and planted in other holes, which now are in vertical positios, and the like exertions of muscular force and pressure are repeated till the anchor is weighed or the weight raised. The machine permits the power of men to be applied, in one position of the handspokes, in the most advantageons manner; and in this respect it may be considered superior to the capstan.

The vertical windlass, or *capstan*, was originally a short cylindrical column turning on its axis by means of levers or bars of considerable length which passed quite through the perforations made to receive them at the top of the column; the pivot or axle upon which it turned, entered, as at present, into the floor or deck upon which the machine was placed. It appears to have been introduced into the British navy in the time of Queen Elizabeth. It is now generally made in the form of a frustum of a cone, or rather the body is cylindrical, and about it, at equal intervals, are ribs or buttresses which, projecting from the cylinder less at top than at bottom, give to the part about which the rope turns a pyramidal figure. Both the windlass and the capstan are furnished with catches, or *Paulls*, each consisting of an arm of metal turning on a pivot, and as the barrel revolves falling into notches formed in a ring of wood or metal placed round one end of the barrel.

WINDMILL. Windmills are of two kinds: in one the wind is made to act upon vanes or sails, generally four, which are disposed so as to revolve by that action in a plane which is nearly vertical; and in the other, the axis of revolution being precisely vertical, any point on the surface of a vane revolves in a horizontal plane. The former is called a *Vertical* Windmill and the latter a *Horizontal* Windmill.

The building for a Vertical Windmill is generally a wall of timber or brickwork in the form of a frustum of a cone, and terminated above by a wooden dome which is capable of revolving horizontally upon it. A ring of wood, forming the lower part of the dome, rests upon a ring of the same material at the top of the wall, and the surfaces in contact being made very smooth, the dome may easily be turned round upon the wall; and is prevented from sliding off by a rim which projects from it, and descends over the interior circumference of the lower ring. The dome in turning carries with it the windsails and their axle; and thus the windsails may be made to coincide with the direction of the wind, or the plane in which the radii of the sails turn may be made perpendicular to that direction. The revolution is sometimes accomplished by the force of a man applied to a winch near the ground; but in general the wind itself is made to turn the dome or the mill by means of a set of small vanes which are situated at the extremity of a long horizontal arm projecting from the dome in a plane passing through the vertical shaft of the mill, and on the side opposite to the great sails.

A Horizontal Windmill is a great cylindrical frame of timber, which is made to revolve about a vertical axis, and its convex surface is formed of boards attached in vertical positions to the upper and lower parts of the frame. The whole is inclosed in a fixed cylinder having the same vertical axis as the other: this consists of a screen formed by a number of boards which are disposed so that, in whatever direction the wind may blow, it may enter between them on one side only of a vertical plane passing through the axis, and thus give motion to the interior cylinder. The effective power of the Vertical Windmill is however so much greater than that of the Horizontal Windmill that the latter is now seldom constructed.

WINE MANUFACTURE. Wine is the result of the fermentation of saccharine fluids, either existing naturally in the juices of plants or artificially blended together. The roots of plants, such as the parsnip and beet; the stems of plants, such as the birch and the cocoa palm; the leaves of plants, such as the vine; the fruit of plants, such as the grape and other well-known kinds—all yield juices which may be fermented into wine. Though alcohol or spirit is present in all wines, yet many other principles exist in them also; the number of which, and the manner in which they are combined, as well as their relative proportion, give to different wines their distinctive properties.

The grape is in most countries the source whence wine is chiefly prepared, and the vintage or wine manufacture is always regarded as an important part of the national industry in the countries of central and southern Europe. It has been found that, in respect to Claret, Port, and Rhenish wines, a season which is good for one is not necessarily so for others; thus the year 1825 was very good for Claret, bad for Port, and about an average for Rhenish wines; while 1840 was middling for Claret, very fine for Port, and bad for Rhenish wines. Locality, aspect, soil, and climate all have to do with this question of quality and quantity. In respect to the modes of manufacture, a few details will be found under the names of the chief wines, and of the provinces and French departments where the most celebrated vintages are situated.

When wine contains much alcohol, it is called strong; when otherwise, *light* or *weak*. When it contains much sugar undecomposed, it is *sweet* or *luscious;* when little, *dry*. When it contains much free acid, it is *acescent;* when much carbonic acid, *sparkling* or *mousseux*. In strong wines of cheap price, spirit is added; but never in good wines, as it destroys the finer qualities.

British or *home-made* wines consist of the fermented juices of fruits, sweetened and otherwise flavoured. They are in principle analogous to real wine from grapes, but requiring much less care and attention, as no attempt is made to obtain those delicate varieties of flavour which distinguish choice wines.

WINE TRADE. The duty at present on all foreign wines is 5*s*. 6*d*. per gallon; on Cape wines, 2*s* 9*d*. The following statement shows the number of gallons imported into the United Kingdom during the year ending Jan. 5, 1850, together with the number retained for home consumption, after deducting the quantity exported subsequently to the payment of duty:—

Wines.	Imported. *Gallons.*	Retained. *Gallons.*
Cape	264,106	241,845
French	466,169	331,690
Portugal	3,004,043	2,648,242
Spanish	3,310,206	2,448,107
Madeira	165,463	71,097
Rhenish	63,380	46,405
Canary	151,239	19,868
Fayal	12,163	67
Sicilian & other sorts	533,298	444,541
Total	7,970,067	6,251,862

The stock of foreign wine in bond in London, on March 1, 1851, was as follows:—

	Pipes.
London Docks	18,346
St. Katherine's ditto	3,853
	22,199

WIRE DRAWING. Wire is a metal elongated into the form of a slender rod, generally cylindrical, but not necessarily so. In early times, metals were probably beaten out with a hammer into thin plates or leaves, which were then divided into small slips by means of scissors or some other cutting instrument, these slips being subsequently rounded by a hammer and file, so as to form threads or wires. So long as wire was formed by the hammer, the artists of Nürnberg, by whom it was fabricated, were styled 'wire smiths,' but subsequent to the introduction of the drawing process their designation was changed to 'wire drawers.' Beckmann conceives that the invention of wire drawing must be assigned to the 14th century. Previous to 1565 all English iron wire appears to have been drawn by manual strength. The first wire-mill in England was set up at Sheen, near Richmond, by a Dutchman, in 1662.

For the manufacture of iron wire the very best and toughest iron is selected. Before the process of rolling with grooved rollers had become common, the iron was prepared for use by a slow and tedious process. At the present day the preparing of iron for the wire-drawers is performed by means of rollers, which are generally 7 or 8 inches in diameter, and are sometimes made to perform 350 revolutions in a minute. A bar of steel 30 inches long and an inch square, heated to redness, is passed between the rollers, through grooves successively diminishing in size, eight times in less than a minute, and is thereby elongated to from 20 to 30 feet. For ordinary wire the rods are commonly reduced to a thickness of about one-eighth of an inch by this process; and these rods themselves are used as wire for some purposes. The kind of cast-steel wire of which the best needles and some other articles are made, is not usually submitted to the rolling process, but, after being tilted to about a quarter of an inch square, it is rounded on an anvil previous to elongation by the draw-plate.

The drawing of wire is thus managed. The draw-plate is usually formed of a stout piece of shear-steel, about six inches long and an inch and a half in diameter, but being somewhat reduced in thickness towards each end, like a cucumber, and flattened on one side. It is pierced transversely with several conical holes, the larger orifices of which open upon the flattened surface of the plate, while their smaller orifices are carefully finished to the size to which it is intended to reduce the wire drawn through them. In drawing wire by hand the draw-plate is laid against two upright pillars fixed on a bench or table, and, the extreme end of the wire to be drawn being so reduced as to enable it readily to pass through the hole, a small portion is drawn through by a lever apparatus, and attached to a cylindrical drum, mounted on a vertical axis. The workman then takes in one hand the coil of thick wire to be reduced, and in the other a lever handle attached to the drum; and while he turns the drum so as to wind the wire upon its circumference, and consequently to draw it through the plate, he imparts a kind of twist to the wire which enters the plate, by a peculiar motion of the hand in which the coil is supported.

The size of wire is commonly measured by means of a gauge, which consists of a plate of steel with a series of deep notches or slits at each edge, varying slightly from each other in width, and numbered according to the number given to wire of corresponding size.

The use of wire in manufactures has largely extended within the last few years, principally owing to the success with which a weaving process has been applied to it. The following are only some among the many applications of wire now generally adopted:—Wire netting for enclosing young plantations; strong wire netting for sheep folds, or for enclosures generally in farms; ornamental wire fences for pleasure grounds; pheasantries and hen-coops; garden bordering; plant guards; hurdles for horse and cattle pastures; fences and gates; plant trainers; arbours and arches; plant umbrellas and canopies; flower stands and stages; garden chairs; bedsteads; wire gauze blinds; sieves and riddles; Venetian blinds; bird cages; fire guards; safety lamps and lanterns; meat covers and safes. Lastly, we may mention *wire ropes*, of the use of which a few illustrations have been given under Rope Making and Suspension Bridges.

WOAD. This is a plant cultivated for the sake of the leaves, which, after being properly prepared, are used as an ingredient in dyeing blue, and as a basis for black. Three or four crops are obtained in a year. When the leaves have been gathered, they are ground in a mill to a sort of paste, which is then pressed into heaps. A blackish crust forms on the outside. After thus lying for about a fortnight the heaps are opened, the crust rubbed and mixed with the interior portions, and the whole formed into oval balls, which are pressed close and solid in wooden moulds. The balls are dried for the market. When about to be used in dyeing, the balls are broken in fragments, and allowed to ferment, by which a thick fœtid fume is given off. By steeping the leaves in water, an infusion is obtained which will impart a green dye, and this green changes to blue by exposure to the air.

WOOD. The uses of wood in the arts are illustrated in the articles Carving; Dry Rot; Ship Building; Timber; &c., and under the names of the principal timber trees.

WOOD ENGRAVING is the art of producing raised surfaces, by excision, on blocks of wood, from which impressions can be transferred by means of a coloured pigment to paper, or other suitable medium, and generally applied to pictorial representations of objects.

The art of cutting both upon metal and wood for other purposes than those which are now understood as printing, ascends to a very remote antiquity. The Egyptians indeed seem to have made a very close approximation to printing, in their wooden stamps used for impressing characters on clay or other ductile material; and printing from engraved wood blocks has been practised by the Chinese probably from the 10th century.

In Europe the first application of the art of wood-engraving took place in Germany about the beginning of the 15th century. It was probably first used for the production of playing-cards, the outlines of which were formed by impressions from wood-cuts, and the colouring filled up by hand. The first wood-cut with a date known to be in existence is of 1423; it represents St. Christopher carrying our Saviour on his shoulders across a river. The next great step was the production of block books and the adoption of moveable letters; and without entering into the disputed question of the dates of the 'Biblia Pauperum,' the 'Speculum Salvationis,' and others, they sufficiently prove the extension of its use, and many of the early books with moveable types were illustrated with pictorial wood-cuts. Maps also were engraved on wood. In an edition of Ptolemæus, printed in 1482 at Ulm, there are twenty-seven; and in a later edition, printed at Venice in 1511, the outline, with the mountains and rivers, is in wood, while the names are printed with type, and in two colours, no doubt by separate workings. In 1486 the improvement known as 'cross-hatching,' by which the bold and free effect of a pen-drawing was endeavoured to be attained, was shown in Breidenberg's 'Travels,' printed at Mentz. This invention has been usually attributed to Michael Wohlgemuth, the master of Albert Dürer. The art had now attained an excellence which induced artists of celebrity and talent to select it as the means of conveying their designs to the world. Among the most distinguished in this line was Albert Dürer, whose productions as a painter, and an engraver on copper and wood, are so numerous as to excite a doubt whether he was actually an engraver on wood himself, or whether he only put the designs on the blocks, leaving them for other hands to execute.

In the early part of the 16th century several artists of celebrity were either designers on wood or engravers. Books were also at this period profusely illustrated. The art was chiefly practised in Germany, where it was patronised by the Emperor Maximilian, for whom Burgmair produced the great work called 'The Triumphs of Maximilian.' The next great name in the annals of wood-engraving is Hans Holbein, whose 'Dance of Death' was printed at Lyon, in 1538, though Bartsch and Jackson deny that he engraved on wood, and Mr. Douse even questions his being the designer. From about 1545 to 1580 wood-engraving continued to be much used for the illustrating of books. From this period there is little to be recorded of essential importance, till the appearance of Bewick, to whom the revival of wood-engraving is chiefly to be attributed.

WOOL; WOOL TRADE. The term 'wool' is now applied almost exclusively to the fleece of the sheep. The distinction between wool and hair is more easily understood than described. Wool compared with hair is generally softer, more flexible, and more disposed to undergo the felting process, which imparts to it so much value in manufactures. Many of the wilder animals, such as the beaver, the racoon, the wild-cat, and the otter, produce both hair and wool, the hair forming the long and conspicuous outer fibres, and the shorter fibres of wool lying hidden beneath. The goats of Angora, or Ancyra, of Tibet, and of Cashmere, yield woolly fibres of great beauty, which are peculiarly suited for the weaving of shawls. For the manufacture of all kinds of woollen fabrics, except these shawls, the wool of the sheep is used. [SHEEP.]

In the time of Edward I. a duty was imposed on the exportation of British wool, and in 1337 an act was passed for prohibiting the exportation. From that time down to the reign of Charles I. the exportation of British wool was sometimes prohibited and sometimes allowed under certain restrictions and duties. From 1660 down to 1824 the exportation was strictly prohibited. In the meantime duties, sometimes more, sometimes less, were laid on the importation of foreign wool. At length, in 1824, an act was passed making the duty on importation and exportation the same, viz., 1*d.* per lb. The duty on exportation was soon afterwards removed, and in 1844 the duty on the importation of foreign wool ceased altogether.

All the finer wools used to be brought from Spain; but in 1765 the Elector of Saxony imported into his dominions a few Merino sheep, which have had a most surprising influence on the trade of wool. The Saxony Merinos, instead of degenerating, improved upon their Spanish progenitors, and the wool afforded by them has almost driven the Spanish wool out of the English market. But the most remarkable circumstance in the recent history of the wool-trade is the rapid increase in the quantity of wool imported from Australia. This is shown by comparing the quantities imported in the three following years:—

1829	1,838,642 lbs.
1839	10,128,774 „
1849	35,879,171 „

The quantity imported from various countries in 1849 was as follows:—

Australia	35,879,171 lbs.
Spain	127,559 „
Germany	12,750,011 „
Other European Countries	11,432,354 „
South America	6,014,525 „
Cape of Good Hope	5,377,495 „
East Indies	4,182,853 „
All other parts	1,004,679 „
Total	76,768,647

In 1848 the quantity of wool exported was 4,000,000 lbs.

WOOLLEN AND WORSTED MANUFACTURES. Wools are divided into two great classes—*Clothing-Wools* and *Combing-Wools*, or *Short-Wools* and *Long-Wools;* and the fabrics woven from them are termed *Woollens* or *Worsteds*, according as the one or the other is employed. Clothing wools possess in high perfection that peculiar property which enables the fibres to 'felt' or interlace one among another, and to form thereby the dense compact material of which men's garments are so largely made in this country; whereas combing-wools, though long in fibre, are deficient in the felting property, and are therefore employed for stuffs, merinos, hosiery, and a large number of fabrics which do not undergo the felting process.

Woollen Manufacture.—The sorting of the wool is the first operation. Each pack of wool contains many different qualities, according to the part of the fleece whence it was taken, and other circumstances; and much tact and discrimination are called for in the separation. The sorter has to make his selection in relation to the *fineness*, the *softness*, the *strength*, the *colour*, the *cleanness* and the *weight* of the wool; and in reference to these qualities he separates the wool into many parcels. When the proper kinds are selected, they are next *washed* or *scoured* with soap and alkali, to free them from the grease which invariably attaches to them.

If the cloth is dyed in the wool, that operation succeeds the scouring; but if dyed in the piece, many other processes intervene; and it depends a good deal on the kind of colour as to which plan is followed. Supposing the dyeing to be completed, however, the wool undergoes the process of *willying* or *willowing*, which is somewhat analogous to the *batting* or *scutching* in the cotton-manufacture; the object being to open and disentangle the locks of wool, and cleanse them from sandy and other loose impurities. The willowing machine contains a number of revolving spikes which tear asunder the fibres of the wool, and a fan which blows away the dust from them. There are frequently impurities which cannot be removed by the willy, and such are afterwards picked out by boys or women, called *Wool-Moaters*, or *Wool-Pickers*. A further opening of fibres results from the process of *scribbling;* but before this is effected, the wool undergoes that of *oiling;* it being spread out on a floor, sprinkled with olive-oil, and well beaten with staves. The *scribbling-machine* is very similar in its principle of action to the *carding-engine.* [COTTON SPINNING.]

The cardings into which the wool is brought by this operation, and which are short pieces in the form of rolls or sticks, are then spun into yarn for the use of the woollen-weaver; the process of spinning being generally effected by means of the *slubbing-billy* or *slubbing-machine*, and afterwards by the common jenny or mule-spinning machine; the slubbing-billy bringing the wool to the state of a soft weak thread, and the spinning-machine giving it the proper firmness and hardness for yarn.

The process next following that of spinning is weaving, by which the yarn is worked up into a textile fabric. [WEAVING.] Formerly woollen cloths were principally woven by hand-weavers; but the power-loom is every year superseding more and more the common loom.

As the wool has been dressed with oil before spinning, and with size before weaving, it becomes necessary to cleanse it from these impurities immediately after the weaving. This is the object of a second scouring process, in which the cloth is beaten with wooden mallets in a kind of trough or mill; soap and water being let in upon it first, and then clear water. Being then carried to the drying-room, or the tenter-ground, it is stretched out by means of hooks on rails, and allowed to dry in a smooth and extended state. It is then taken into a room and examined by *Burlers*, who pick out all irregular threads, hairs, or dirt. After this it is ready for the important process of *fulling* or *felting*, which imparts to woollen goods that peculiarity of surface whereby they are distinguished from all others. A large mass of cloth folded into many plies is put into the fulling-mill, where it is exposed to the long-continued action of two heavy wooden mallets or stocks. Superfine cloth has four fullings of three hours each, a thick solution of soap being spread between each layer of cloth every time. This process, besides felting or interlacing the fibres together, thickens the cloth remarkably, but diminishes it both in length and breadth nearly one-half.

In the fulled state the cloth presents a woolly and rough appearance, to improve which it goes through the process of *teazling* or *raising*, and *shearing* or *cutting*, the object of the first being to raise the ends of the fibres above the surface, and of the second to cut them off to a uniform level. The raising of the fibres is effected by thistle-heads, teazling-cards, or wire-brushes. Teazles are the seed-pods of the *Dipsacus Fullonum*, and are used by hand [TEAZLE]; but sometimes wire-cards are used, fixed to a machine called a *gig-mill.*

When the ends of the fibres have been thus raised to the surface, they are next sheared or cropped, a process of great beauty and singularity. Originally this process was performed by means of large hand-shears, the cloth being stretched over a stuffed table, and the workman proceeding to clip the ends of the fibres in a regular and equable manner; but the process is now more frequently conducted by a machine, which causes a revolving circular furnished with cutters to travel horizontally over the cloth, and shear it.

When the cloth has been raised and sheared (which operations are repeated two or three times for superfine cloth), it is brushed by a machine consisting of a system of brushes affixed to cylinders; the cloth being exposed at the same time to the action of the brushes and of steam. A few subsequent operations are carried on, having for their object the imparting of smoothness, gloss, &c., to the cloth, preparatory to its being placed in the hands of the dealers.

Worsted Manufacture.—All combing-wools are longer in fibre than the clothing-wools, but they are subject to the division into 'long' and 'short' combing wools; the long, varying from 6 to 12 inches in length, being used principally for coarse worsted goods, and the short, from 4 to 7 inches, being used for hosiery and some other purposes.

After the wool has been sorted, washed,

and scoured from the adherent grease. and dried in a heated room, it is carried to a machine called a *plucker*, containing a pair of spiked rollers, by the action of which the wool is cleansed, separated, and the fibres straightened, preparatory to the process of *combing*. This combing is sometimes performed by hand, by means of two instruments filled with spikes, between which the wool is drawn till the fibres assume a regular arrangement; but a very efficient machine, somewhat on the principle of the carding machine, is now frequently used for this purpose.

When the wool has been combed either by hand or machine, it is transferred to the *breaking-frame*, the object of which is to open out any fibres which may have escaped the action of the combs, and to bring the wool into the form of a roll or narrow belt. This roll is then lapped round a large bobbin or cylinder; then passed a second time through a breaking-frame; and then subjected to the action of a machine analogous in principle to the drawing-frame of the cotton manufacture; the object being to extend the length, diminish the thickness, and equalise the number of fibres of the roll or sliver. Hitherto the woolly fibres are merely slightly coherent, without having any twist; but they are now passed through a *roving-machine*, preparatory to the process of spinning. The roving and spinning are conducted much in the manner described in the article COTTON SPINNING. When spun, the worsted yarn is wound on a reel, and is then made up into hanks.

Here terminate the operations of a worsted mill. The dyeing of the yarn, and the weaving into the various kinds of textile fabrics, lead us to other departments of industry. [DYEING; WEAVING.]

Woollen Trade. Plain *broad cloth* is a specimen of plain weaving, followed by the fulling process; whereas *kerseymere* is a twilled fabric, similarly fulled. *Serges* are twills having worsted warp and coarse woollen weft. *Blankets* are made of very soft yarn, afterwards worked up into a kind of pile by milling; and many varieties of coarse cloth are of analogous structure. *Bombazeen* is a twilled mixture of worsted and silk; *Poplin* is an untwilled mixture, showing more silk than worsted at the surface. Goods called *Saxonies* and *Orleans* are made of woollen, sometimes mixed with cotton, and afterwards printed. *Stuff* is made wholly of worsted; while *Merino* is a fine woollen twill, sometimes printed. The material called *Cashmere*, if properly so named, is made of the shawl-goat wool, much in the same way as merino; but most of the fabrics so called are made of sheep's wool. *Challis* is a mixture of woollen weft with silk warp, and is generally printed. *Mousseline-de-Laine* was originally all wool, but is now frequently mixed with cotton, and generally printed. *Norwich Crape*, unlike common crape, is composed of wool and silk, something like challis, but without being printed. *Crêpe de Lyon* is formed of worsted and silk; and *Italian Net* of worsted only. These examples are only intended to indicate the sources of the varieties in woollen and worsted goods, for to enumerate all the varieties themselves would be nearly impossible. This is particularly the case in respect to Waistcoatings, where fancy weaving adds to the sources of diversity.

Mr. McCulloch made a rough estimate, a few years ago, that the value of woollen and worsted goods made in the United Kingdom averages about 23,000,000*l.* yearly; that about two-fifths of this sum are paid in wages; and that about 350,000 persons are directly employed in it. But it is admitted that the data for forming such estimates are very insufficient.

The value of all kinds of woollens, worsteds, worsted hosiery, and woollen and worsted yarn, exported from Great Britain in 1830 was estimated at 4,728,666*l.*; in 1840, at 5,327,853*l.*; and in 1849, at 8,420,342*l.*

WOOLWICH DOCKYARD. The Royal Dockyard at Woolwich much resembles those already described as existing elsewhere. [CHATHAM; PLYMOUTH; PORTSMOUTH.] The same groupings of manufacturing arrangements are to be met with in all of them, subject to certain minor differences. Woolwich is also rich in other government establishments; but they belong rather to military than to manufacturing operations, and scarcely come within the scope of this volume.

WORCESTERSHIRE. There are coal deposits of various degrees of richness in this county. The town of Dudley stands on the thicker coal-measures. In the neighbourhood of Droitwich and Stoke Prior are saliferous beds, from which a large quantity of salt is manufactured. The northern part of the county is well supplied with railways and canals. In respect to agriculture, the average produce of wheat in Worcestershire is higher than in many other counties. Potatoes are raised in great abundance for the supply of Birmingham and other large towns. Wolverley Sands have long been famous for the growth of carrots, and for raising carrot seed. Orchards are numerous, but many of the trees are old.

The northern part of the county contains many manufacturing towns. The industry of Bromsgrove, Droitwich, Dudley, and Kidderminster, is briefly noticed in separate articles. Redditch is the great seat of the needle manufacture; and Stourbridge has extensive manufactures in iron, glass, and fire-bricks.

WORMWOOD (*Artemisia absinthium*), is an indigenous perennial plant met with on waste places, but that which is required for medical use is mostly cultivated. The upper part of the stem, with the leaves and unexpanded flowers, should be collected, for these parts possess the peculiar aroma, with a strong bitter taste; while the lower part of the stem is merely aromatic, and devoid of bitterness. Wormwood possesses the properties common to aromatic bitters, but it seems to possess also some peculiar ones rendering it worthy of more attention than it receives. The bitter principle is readily absorbed, so that the flesh of animals fed upon it becomes manifestly bitter. Ale in which wormwood has been steeped (purl) is more heady than other ale.

WORSTED. [Woollen and Worsted Manufactures.]

WÜRTEMBERG is one of the most fruitful countries of Germany, and agriculture is on the whole carried on upon a good system. A manifest improvement in the breed of cattle and horses is remarked at every new cattle-show at Cannstadt, where a fête is held Sept. 26, in each year. The chief agricultural products are spelt, maize, oats, barley, rye, wheat, peas, beans, vetches, potatoes, flax, hemp, rape-seed, poppies, hops, and tobacco. Of the vineyards more than three-fifths are in the circle of the Neckar, the rest are chiefly on the Tauber and the lake of Constanz; the wines of these last districts are very different from the Neckar wines, rather resembling Rhenish. The metals and minerals are copper, lead, zinc, iron, marble, mill-stone-grit, freestone, quartz, precious stones, porcelain earth, potters'-clay, fullers' earth, chalk, salt, and a little coal. The salt works are the property of government, which has the monopoly of the salt trade; the annual produce is about 24,000 tons.

The manufactures include linen and woollen cloths, calicoes, silks, lace, hosiery, muslin, carpets, leather, paper, porcelain, earthenware, iron and steel ware, gold and silver plate, tobacco, tobacco pipes, and gunpowder; there are likewise numerous distilleries and breweries, and chemical factories. Würtemberg has a very considerable trade in its natural productions and manufactures, its horned cattle, horses, sheep, timber, wool, and printed books. The imports consist of raw cotton and cotton manufactures, silks, glass wares, wine, fruit, cheese, china, earthenware, and all kinds of colonial produce. There is likewise a very great transit trade. The inland navigation is important, especially on the Neckar, which becomes navigable at Cannstadt; above 2000 vessels are employed in it.

X

XANTHIAN MARBLES. These interesting marbles form one of the most attractive portions of the collection of antiquities in the British Museum. They consists of a large collection of sepulchral marbles of various ages, which were first made known to the European public by Mr. Fellows (now Sir Charles), who discovered them in 1838. They were all found in or near Xanthus, the ancient capital of Lycia.

Y

YARN is the general name given to the threads which are woven into the various kinds of textile fabrics, whether, cotton, silk, flax, hemp, wool, or worsted; the terms *twist*, *mule-weft*, *organzine*, *tram*, *abb*, *line*, &c., being particular names applied to particular sorts. [COTTON SPINNING; FLAX MANUFACTURE; SILK MANUFACTURE; SPINNING; WOOLLEN AND WORSTED MANUFACTURES.]

The exportation of yarn has now become very large, the perfection of English spinning-machines enabling foreign weavers to buy ready-spun yarn cheaper, in many cases, than they can spin it themselves. The quantities exported and the estimated values, in 1848, were as follows:—

Cotton Yarn ..	135,831,162 lbs.	5,927,831*l*.
Linen Yarn ..	11,722,182	493,449
Woollen Yarn .	8,429,152	776,975
	155,982,496 lbs.	7,198,255*l*.

YEAST, BARM, or FERMENT, is a substance which is deposited in an insoluble state during the fermentation of wine, beer, and vegetable juices. This substance, as is well known, is employed to produce fermentation in saccharine solutions. [BREAD; BREWING; FERMENTATION.]

YEW. The timber of the yew tree is applied to many useful purposes. In the days of archery, yew was almost exclusively employed for making bows; but various ornamental woods from South America are now substituted for it in this respect. Yew-tree wood is extensively used in cabinet making, as being hard, compact, and of a very fine close grain. It is also much used by turners for making snuff-boxes, musical instruments, &c.

YORKSHIRE. This county is rich in minerals. The lower red sandstone, or Pontefract Rock, near Pontefract, is usually a mass of yellowish sands, of the greatest excellence for the use of the metal-founder in the construction of his moulds. From beneath the magnesian deposits rise the sandstones, shales, ironstones, and coal of the West Riding of Yorkshire, and fill an enormous area in the valleys of the Aire, Calder, Went, Dearn, Dove, and Don. The whole of this large area (not less than 600 square miles) yields coal. The whole series of strata is about 4000 feet thick; and of the coal which lies in this series there are about 20 workable beds, yielding about 40 feet of coal, generally of good quality. Ironstones of excellent quality accompany the lower parts of this coal deposit. The seam of coal are worked in the west of Yorkshire as thin as 18 inches (near Halifax and Penistone), and one as thick as 8, 9, or 10 feet (Barnsley), but the average is from 3 to 6 feet. The most characteristic rock in the millstone grit of the West Riding is the quartzose conglomerate, used in making millstones.

Yorkshire is excellently supplied with canals and railways, in aid of its manufactures and commerce. The manufactures of the county are of great importance. The manufacture of woollen cloths, at Leeds, Bradford, Halifax, Wakefield, and Huddersfield, has been brought to such a degree of perfection as to compete with the woollens of the West of England, while it far exceeds them in quantity. The iron-works are very extensive. Sheffield is the great seat of the manufacture of cutlery of all kinds, as well as of tools and plated goods. Linens are extensively manufactured at Barnsley, blanketing at Dewsbury, and glass and iron at Rotherham. Hull, Whitby, and Goole, are the chief ports. Under the names of the principal towns of the West Riding, a few details will be found illustrative of the manufacturing industry of the county.

YTTRIUM, a peculiar metal discovered by Gadolin in 1794, in the state of oxide, which is named *Yttria*. It presents the aspect of small brilliant scales, having a perfect metallic lustre. After being washed and dried, it is a brilliant blackish gray powder, composed of small metallic scales. It does not oxidise either by the action of air or water, at common temperatures; but when heated to redness in the air, it takes fire, burns with much splendour, and is converted into yttria. Yttrium has not yet been applied to many useful purposes.

Z

ZEALAND, NEW. In these islands copper, manganese, and coal, have been found. The soil on the table-lands, in the valleys, and near the coasts, is generally fertile, and the surface is well wooded. The sides of the mountains are generally bare of wood, but overgrown with ferns and grasses. The New Zealand flax-plant *(Phormium tenax)*, an edible fern (*Pteris esculenta*), the sweet potato, and a variety of timber-trees, are the chief vegetable productions. Wheat, maize, and other grains and vegetables have been introduced by the colonists, and the grazing grounds afford pasture all the year round.

ZINC. This metal, in commerce frequently called *Speller*, does not occur in the native state, but is obtained from its ores, which are chiefly the sulphuret and carbonate of zinc. Zinc has a brilliant metallic lustre and a bluish white colour. It is so hard as to be filed with some difficulty, and its toughness is such as to require very considerable force to break it when the mass is considerable. The specific gravity of zinc varies from 6·86 to 7·21. It undergoes little alteration, even by the combined operation of air and moisture, at common temperatures. When heated to between the temperature of boiling water and 300° Fahr., it becomes both malleable and ductile, so that it may be rolled into sheets and drawn into wire. It fuses at 773° Fahr., and when cautiously cooled crystallises, assuming the prismatic form. Exposed to a white heat, out of the contact of air, it sublimes and is condensed unchanged.

The ores of zinc comprise the *Sulphuret*, or *Blende;* the *Oxisulphuret*, or *Voltzite;* the *Carbonate*, or *Calamine;* the *Hydrous Carbonate;* the *Sulphate;* the *Phosphate;* the *Silicate;* the *Hydrous Silicate;* the *Aluminate;* the *Oxide of Zinc and Manganese;* the *Sulphuret of Zinc and Iron.* Some of these ores are crystalline, some massive. The largest specimen ever procured, perhaps, is that which has been sent from America to the Great Exhibition, and which weighs 16,000 lbs.

The combinations of zinc with other substances are numerous, and many of them valuable. The Sulphate of Zinc constitutes *White Vitriol.* Zinc combined with copper forms *Brass;* and with iron it forms a very hard alloy. If plates of hot iron be dipped into melted zinc, they acquire the appearance of tin-plate, and the iron is prevented from rusting; the coating of zinc is sometimes applied by galvanic agency.

ZINC PAINT. An attempt is now being made to find a substitute for white lead in house-painting. White lead forms the basis of nearly all the pigments used by the house-painter; and though it is known to produce very injurious effects upon the health of those who use it, yet white lead possesses so many valuable properties, that it has outlived all the objections urged against it, and all the attempts made to supersede it. It remains to be seen whether the 'Patent White Zinc Paint' will be more successful. According to the patentees, it is free from all poisonous qualities; is unchangeable in tint by noxious gases; is so lustrous as to need no varnish; is more economical than white lead; and is easier to use. Time must test the validity of these claims. The French government is said to have adopted the White Zinc Paint in all the public works.

ZIRCO'NIUM, is a peculiar metal obtained from the earth or metallic oxide *Zirconia.* Under the burnisher it assumes the lustre of iron, and is compressed into scales resembling graphite. When heated in the air, even below redness, it takes fire; and by combining with oxygen is converted into oxide of zirconium, or Zirconia. *Zircon*, the mineral from which the earth and the metal have been named, occurs in prysmatic crystals, and consists of zirconia and silica. Zircon, like most of these new metals, has yet scarcely been brought into useful application.

LIST OF ILLUSTRATIONS.

The Wood Engravings which appear in this Work have reference chiefly to large departments, and occasionally localities, of British Industry; but they also illustrate distinct branches of those departments. For this latter reason it has been thought less desirable to attempt to place them in connection with any particular articles, than to group them together at the end of the volume. It is optional on the part of each purchaser, however, to have the engravings re-arranged by the binder in any other order.

The following table will elucidate the several pages of engravings. In the first column is given the number of the cut, as printed on the left-hand bottom corner; in the next is a brief description of the subjects; while in the third is a reference to such articles in the body of the work as receive illustration from the engravings in question.

No. of Cut.	Subjects.	Reference to Articles.
	ing the seams—sewing or covering a rope—stretching sails—driving a red-hot bolt [illegible] while building.	
29.	*Silk Manufacture.*—Specimens of Bengal, [illegible], and Italian silk—[illegible] and spinning silk—making [illegible]	[illegible]
